The inherent basis of these procedures is the Zintl−Klemm concept[19,20] and the Mooser−Pearson[21] extended $(8 - N)$ rule. Formerly applied only to classical two-center−two-electron bonds, the extended procedures comprise all varieties of bonding (multiple bonds, partial bonds, multicenter systems, radicals, and free electrons). Generally, for a compound A_mB_n, an electron transfer $A \rightarrow A^{p+}$, $B \rightarrow B^{q-}$ ($|mp| = |nq|$) to the more electronegative element B forms pseudoelements A^*, B^* that show the structural principles of the corresponding isoelectronic elements with the whole spread of homoatomic bond types. Alternatively, one can derive from the number of valence electrons e_A and e_B according to the equation $me_A + ne_B + k = 8n$ the term $k = -\sum e_{AA} + \sum e_{BB} - \sum e^*$, which accounts for the number of electrons involved in A–A and B–B bonds as well as the number of electrons e^* that are not involved in localized bonds. However, one cannot predict all structural details because k is composed of three independent terms.[5] This corresponds to the fact that the formal ions A^{p+} and B^{q-} do not need to use all remaining electrons to form covalent homonuclear bonds. Application of the $(8 - N)$ rule leads to the same result as obtained by looking at the phosphides as derivatives of phosphanes with the structural elements: (3b)P$\hat{=}$(3b)CH, (2b)PH$\hat{=}$(2b)$CH_2$$\hat{=}$(2b)S, (1b)$PH_2$$\hat{=}$(1b)$CH_3$$\hat{=}$(1b)Cl, (0b)$PH_3$$\hat{=}$(0b)$CH_4$$\hat{=}$(0b)Ne.

Table 4 Ternary and multinary metal-rich phosphides $(M/M')P_x$, all with isolated P atoms, ordered according the descending ratio $(M + M')/P$

[a]dist. = distorted type; def. = defect type; deriv. = derivative; fill. = filled up. [b]cond. = condensed. [c]These compounds have a (P_2^{n-}) dumbbell, where n and hence the P–P bond length varies with composition.

3 SYNTHESIS[1–15]

3.1 Practical Precautions

All operations with phosphorus and reactive phosphides should be done in a hood or dry box and equipment should be on hand to deal with the possibility of a phosphorus fire. Phosphides may ignite if milled mechanically under ambient conditions and even highly purified red phosphorus may contain small inclusions of white phosphorus. Therefore, all grinding should be done under an inert atmosphere. On contact with wet air or wet inert gas, phosphides may produce phosphines (odor, self ignitability). Phosphines have also been shown to be physiologically active.[3,22]

Small amounts of reactive phosphides may be transferred into a $CuSO_4$ solution in small portions under stirring, for chemical disposal. Alternatively, the material can be oxidized with a Br_2/alcohol solution. An odor-free method of oxidation with HNO_3 is the use of an autoclave.[23]

3.2 Solid-State Reactions

The most general method for the preparation of solid phosphides is from the elements; however, there are several problems to overcome in that highly electropositive metals are often air- and moisture-sensitive, so that the educts and often the products must be handled under inert conditions (glove box or Schlenk technique). A well described example for the synthesis of the air- and moisture-sensitive phosphides Na_3P_7 and Na_3P_{11} has been described.[24]

In the case of impure starting compounds (hydroxide and oxide layers are frequent impurities), corrosion problems appear leading, for example, to the formation of phosphide oxides. Such corrosion problems may be prevented by the use of inner containers made from Mo, Nb, or Ta. Silica as a crucible material is also problematic, since silicon might replace some of the phosphorus atoms, and this is hardly detectable by X rays.

The high phosphorus vapor pressure, especially in the case of the preparation of polyphosphides, makes thick-walled containers and low reaction temperatures necessary. Kinetic hindrance which occurs during the vaporization of phosphorus is reduced by adding traces of halogen or sulfur.[25] The disadvantage is the formation of by-products, such as phosphide halides or phosphide sulfides. In cases where reaction layers form on unreacted material, preventing diffusion, repeated grinding, pressing, and heating is necessary. Another method is to dissolve oxide layers by the use of fluxes.[26,27] The flux can be a metal, a halide (low-melting eutectic), or an oxide (e.g. B_2O_3). The most effective metal flux for phosphides is liquid tin. Most of the binary and ternary phosphides are stable in 2N HCl and the remaining flux can easily be removed. Nevertheless, one has to keep in mind that tin inclusion in the phosphide crystals might occur. Also, the higher homologue lead can be used as a flux agent. Since $PbCl_2$ is insoluble in cold water, the lead matrix needs to be dissolved in an oxidizing mixture of H_2O_2 and acetic acid. Crystals of metal-rich phosphides like $Ca_5Rh_{19}P_{12}$, $Yb_6Co_{30}P_{19}$, or $Eu_6Rh_{30}P_{19}$ have been grown with this technique.[28] Halide fluxes are also useful when one of the metal components has a high vapour pressure, for example, for the preparation of the series $REZn_3P_3$ or $RECd_3P_3$.[29]

To prevent strong exothermic reactions, slow heating in the temperature region of the vaporization of P (850 K $\leq T \leq$ 900 K) is recommended. The phosphorus pressure may also be reduced during synthesis via the formation of an intermediate phosphide. This phosphide then acts as a phosphorus source in the course of the reaction. For the synthesis of high-melting metal-rich phosphides, a prereaction in an arc furnace, followed by annealing with additional phosphorus in silica tubes, is possible. In some cases, metal-rich phosphides of the early transition metals can directly be prepared via arc-melting.[30] The preparation of ternary phosphides is simplified via binary compounds to reduce the reaction temperatures, the content of impurities, and the sensitivity of the educts. To prevent decomposition, high-pressure techniques are sometimes useful. This was especially useful for the preparation of the skutterudites $REFe_4P_{12}$ with the heavier rare earth elements.[31]

3.3 Thermal Decomposition, Gas-phase Reactions

Further methods of preparation are the decomposition of higher phosphides under controlled temperature and pressure, yielding compounds with lower P content. Only with highly volatile metals one also observes the gaseous metal, M(g). Under low pressure and low temperature a complete series of $[K(K_3P_7)_m(K_2P_4)_n]^+$ moieties can be formed from K(g) and P_4(g) under He gas; this method is yet to be fully exploited.[32] Chemical vapor transport reactions are suitable for the preparation and purification of phosphides, if the metals form gaseous compounds, for example, halides or oxides.[33] Even large single crystals for neutron diffraction can be obtained.[34]

Whisker growth of hexagonal β-HfP, cubic α-ZrP, and hexagonal β-TiP is possible via a mixed-metal, impurity-activated chemical vapor deposition (CVD) process from $HfCl_4/ZrCl_4/TiCl_4 + PCl_3 + H_2 + Ar$ gas mixtures at 1050 °C. Si + Pd and Si + Pt were used as mixed-metal impurity components. Such whiskers are stable in concentrated HCl.[35]

3.4 Synthesis in Solvents

Because of the solubility of alkali metals in NH_3(l), some alkali metal phosphides have been prepared from NH_3(l). Reactions in solvents, either by using compounds containing polyanions or, in the course of suitable syntheses, from compounds starting with isolated phosphorus anions or from

P_4, yield a variety of new compounds. Once in solution, higher condensed units such as P_{19}^{3-}, P_{21}^{3-}, or P_{26}^{4-} are accessible through metal–organic reactions, and they crystallize as solvates (for low coordinated phosphides stabilized in the coordination sphere of transition metals, see Scherer[36]).[37,38] The species present in solvent-free and solvated phases usually differ. An example of the conversion of polyanions into alkylated polyphosphanes is P_7^{3-} and P_7R_3.[6,39] The latter can also be prepared from Na/K alloy and P_{white} in monoglyme with $ClSiMe_3$. Conversely, P_7R_3 is converted into solvated Li_3P_7 via metalation. Besides NH_3(l), ethylenediamine, *en*, can be used for binding the alkali metal ions.

A variety of ammonia solvated alkali metal phosphides has recently been prepared in the Korber group. Examples of these peculiar compounds are $Cs_2P_4{\cdot}3NH_3$ with the 6π aromatic P_4^{2-} anion[40] and $Cs_3P_{11}{\cdot}3NH_3$.[41]

3.5 Nanoparticles

Nanocrystalline Co_2P, Ni_2P, and Cu_3P can be prepared in a mild one-step route via simple solvothermal direct reaction of the metal halides with yellow phosphorus between 350 and 410 K using ethylenediamine as solvent.[42] Using the precursors Na_3P and $CoCl_2$ with benzene as solvent, mixtures of sphere-shaped Co_2P and spindle-shaped CoP nanocrystals can be obtained in yields of about 90%.[43] Silica supported phosphide samples can be prepared by pore volume impregnation of nickel nitrate and diammonium hydrogen phosphate, followed by H_2/N_2 reduction of the dried and calcined samples.[44] Nanoscale particles of catalytically active SiO_2/Ni_2P can be obtained by reduction of nanoparticulate phosphate precursors.[45] Crystalline nanoclusters of Fe_2P, RuP, Co_2P, Rh_2P, Ni_2P, Pd_5P_2, or PtP_2 can be obtained in a silica xerogel matrix from single-source molecular precursors.[46] An overview on the nanoscale phosphide particles was given by Lukehart *et al.*[47]

3.6 Other Methods

The reduction of phosphates by carbon is a classical method, but the purity of phosphides obtained this way can be suspect. This also holds for replacement reactions, in which a redox process between a transition metal and a metal phosphide is used for the preparation of phosphides with high thermal stability. Binary main-group element and transition metal phosphides like AlP, CrP, NbP, MoP, or WP can be prepared by the reaction of the powdered metals with a melt of lithium metaphosphate $LiPO_3$.[48] Bulk samples of transition metal phosphides like Co_2P or NiMoP can be obtained via reduction of metal oxide/phosphate mixtures in a mixture of 5% H_2 in N_2. MoP, WP, Fe_2P, Ni_2P, FeP, and RuP can be synthesized by direct reduction of the transition metal phosphates in hydrogen atmosphere between 670 and 1320 K.[49]

Molecular beam methods are now widely used for the preparation of common semiconductors such as GaP and their intergrowth with other compounds. Thin films of iron phosphides of 0.5 to 25 μm thickness can be electrodeposited from sulfate solutions. Depending on the deposition conditions (time, pH, temperature), the phosphides FeP, Fe_2P, and/or Fe_3P occur.[50] The preparation of higher polyphosphides, for example, KP_{15}, as thin films demonstrates the range of still yet unexplored preparative methods.[51] This is also valid for the electrolysis of phosphates.[52] The latter techniques is mostly suited for metal-rich phosphides.[53]

4 BOND LENGTHS, BOND ANGLES, COORDINATION, VOLUMES

4.1 General Remarks

The coordination of the metal atoms and the phosphorus atoms depends strongly on the stoichiometric P/M ratio. For a compound MP_x the mean coordination number $\overline{CN}$ is a rough measure, taking into account only heteroatomic bonds: $x = \overline{CN}(M)\overline{CN}(P)$. Additional M–M and P–P bonds lead to much more complicated coordinations, often very difficult to identify. One way to analyze the coordination is to use classical polyhedra, and compare interatomic distances with tabled covalent, ionic, and metallic radii. Appropriate values for phosphorus are: $R_{cov} = 111$ pm (single bond); $R_{met} = 118$ pm (CN = 12); $R(P^{3-}) = 194$ pm (CN = 6); $R_{vdW} = 190$ pm. Weaker P–P interactions occur at larger d(P–P) distances, which can be analyzed in terms of Pauling bond order (PBO) or related procedures, for example, d(P–P) = 239 pm in cubic high-pressure phosphorus corresponds to PBO ~0.5.

4.2 P–P Bonds

The P–P bond lengths in polyphosphides may be compared with that of a single bond $d_1(P^{\pm 0}) = 222.8$ pm derived from black phosphorus.[54] The range 215–230 pm is observed, depending on the structural function and the relative charges of the P atoms (Figure 1). With strong electropositive cations the P–P distance of P_2^{4-} dumbbells $\bar{d} = 229(3)$ pm is considerably larger than $\bar{d} = 221(2)$ pm with neutral molecules. Transition metal diphosphides M^{IV} show a value $\bar{d} \sim 233(6)$ pm, but the bond lengths are tunable by the valence electron concentration (VEC). This corresponds to different tendencies for metal oxidation and reduction by charge transfer. The *cyclo*-P_n^{n-} and corresponding neutral molecules are characterized by $\bar{d} = 222(2)$ pm. The bond lengths in skutterudites (e.g. CoP_3) are much larger with $\bar{d} = 228(5)$ pm in the P_4^{4-} rings, possibly also generated by redox charge transfer. In the helical $^1_\infty(P^-)$ units $\bar{d} = 221(2)$ pm, but with significant alterations by the cation

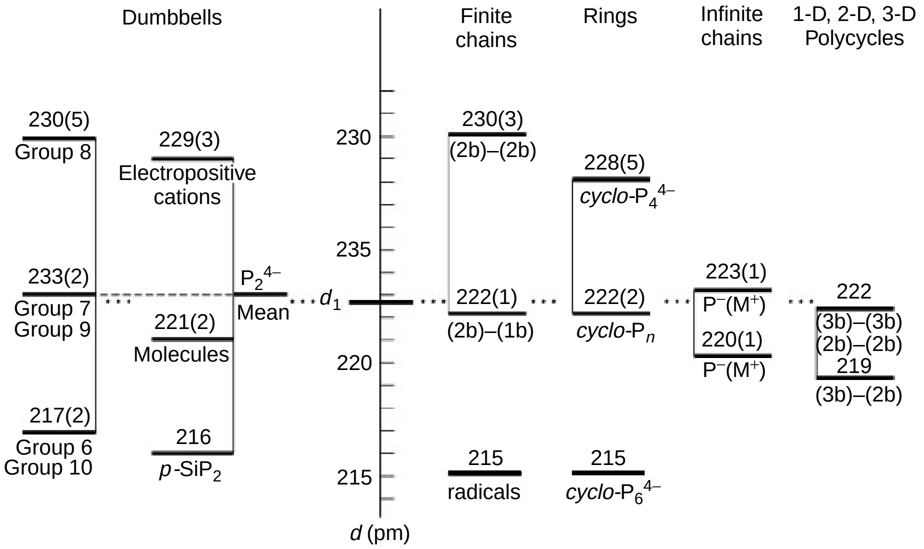

Figure 1 Bond lengths of dumbbells, finite chains, rings, infinite chains, and 1-D, 2-D, and 3-D polycycles in polyphosphides. The level of d_1(P–P) = 222.8 pm is dotted

charge: $\bar{d}(M^+) = 223(1)$ pm and $\bar{d}(M^{2+}) = 220(1)$ pm. The range is the same as for *cyclo*-$P_n{}^{n-}$. The structures of finite chains $P_n{}^{(n+2)-}$ show the differences between central and terminal bonds: (2b)–(2b) = 230(3) pm, but (2b)–(1b) = 222(1) pm. In the polycyclic 1-D, 2-D, and 3-D structures the bond lengths are strongly influenced by the P/M ratio and the different strain in the individual arrangements, for example, the (2b)–(2b) distances are most affected by the ring sizes. Furthermore, there are differences between main-group compounds and transition metal compounds. Therefore the individual values cover large ranges: 230 ≥ (3b)–(3b) ≥ 217 pm; 224 ≥ (3b)–(2b) ≥ 214 pm; and 226 ≥ (2b)–(2b) ≥ 219 pm. In general, d(3b–3b) ∼ d(2b–2b) > d(3b–2b), with mean values of about 222, 222, and 219 pm, respectively. Again, the shortening of (3b)–(3b) distances reflects bond polarity. In flexible structures such as the ${}^{2}_{\infty}(P_5{}^{3-})$ network of the rare earth pentaphosphides, (3b)–(3b) = 219 pm is shorter than (2b)–(2b) = 221 pm, as expected. However, in other structures, for example, in the ladder-like spines of the tubular type, the internal strain in the (3b)–(3b) bond results in remarkable stretching of those bonds. Temperature- and pressure-dependent structure determinations reveal very small changes of the P–P bonds.

4.3 P–P–P Bond Angles

The mean bond angles in P(black) and P(violet)[55] are 100.2° and 101.2°, respectively, and correspond to those in polyphosphide networks. In unstrained parts of these networks, the bond angles cover the narrow range 98–104°. Large deviations exist with *cyclo*-P_3 and *cyclo*-P_4 (bent bonds), as well as in transition metal phosphides which are forced by the metal coordination (60–120°).

4.4 M–P Bonds, Coordination

Coordination to metals follows the usual trends. The transition metals try to achieve octahedral coordination (with a few exceptions), but the cations of the electropositive group 1–3 elements exhibit a rich variety. The coordination polyhedra are determined by radius ratios more than by topological preferences. For polyphosphides in general, all P atoms are involved in M–P interactions according to the number of lone pairs present. The anionic (1b)P^{2-} and (2b)P^- as well as the neutral (3b)P^0 species adopt quasi-tetrahedral coordination, especially if main-group cations are involved. Only a few exceptions are known, for example Li_3P_7. With more covalent M–P bonds, the number $(m+n)$ of available lone pairs of a polyanion $P_m{}^{n-}$ is strongly related to the metal coordination number; that is, CN(M) ≤ $(m+n)$. If CN(M) > $(m+n)$, ion–ion and ion–dipole interactions dominate. The relation d[M–(2b)P] > d[M–(3b)P] is true in most cases.

Table 6 gives a survey on the range of M–P distances. The upper limits are uncertain[9] because the selected distances are only compared with atomic radii and take not into account the topology (convex polyhedra procedure). The M–P coordination in solid phosphides demonstrates both coordination and donor functions in isolated complex compounds (cf. the $(E15)_n$ complexes, stabilized in the coordination sphere of transition metals).[36] This is especially true with the polyphosphides. An extreme is $Cu_2P_3I_2$ (see Section 6.5.7), which is an adduct of CuI and elemental phosphorus (charge transfer complex). Chains of polycyclic

P_{12} units, formed by (3b)P^0, cross the CuI substructure and complete the Cu coordination by one third of the available lone pairs. Hexagonal bipyramidal units $M_2P_6^{2-}$ of the M_4P_6 phases (M = K, Rb, Cs) are $M_2[\mu\text{-}(\eta^6\text{-}P_6)]$ complexes stabilizing the unusual 2π system P_6^{4-} with short P–P bonds. In Th_2P_{11} a *cyclo*-P_6^{6-} chair acts as a twofold η^3 ligand bridging two Th atoms, forming a hexagonal scalenohedron. In the same structure, condensed skew-boat P_6 and *endo*-$P_8(C_{2v})$ rings coordinate Th atoms. The Th coordination of ThP_7 is built from a corrugated 3-D net of condensed P_6 and P_{12} rings. Trivalent rare earth metals in LnP_5 are enveloped, sandwich-like, by two *cyclo*-P_{12} with tetragonal antiprismatic eight-fold coordination. Various modifications of M–P coordination are also known with M^{2+} and M^{3+} bonded to chains and rings with multiple configurations and conformations. The donor qualities of polyphosphides can clearly be shown by comparison of the crystal structures of solvent-free and solvated compounds, showing that complete separation of cation and polyanion is only possible with the help of crown ether cryptates, or large cations, for example $(NPh_4)^+$. Examples of these structures are given in Figures 2 and 3.

4.5 Solid-State Volumes

The molecular volumes of solid phosphides can be approximated by individual increments ($V_m = \sum V_i$).**[56]** Knowledge of the structures is not necessary. Saltlike and semimetallic compounds behave differently, but there is no difference between compounds of main-group metals or transition metals. The observed relationships allow for valuable analysis with respect to structure and properties, and give very good estimates of the unit cell content (Figure 4). With saltlike phosphides the phosphorus increment, V_P, increases with increasing negative charge q(P) and decreases with increasing cation charge q(M). A suitable empirical relation is given by equation (1):

$$V_p(q(P), q(M)) = \exp(\alpha q(P) q(M) + \beta q(P) + \gamma q(M) + \delta) \quad \text{in cm}^3\,\text{mol}^{-1} \qquad (1)$$

with $\alpha = 0.046$, $\beta = -0.368$, $\gamma = -0.066$, and $\delta = 2.630$. In semimetallic phosphides, V_P(sm) is generally smaller and

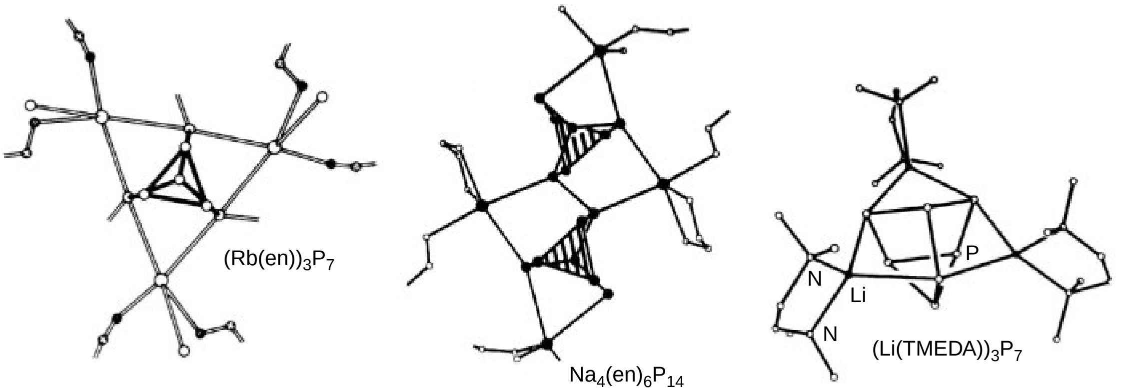

Figure 3 Some solvated polyphosphides (cf. Table 7). Note the specific positions of the alkali metal atoms with respect to the (2b)P^- atoms of the cages

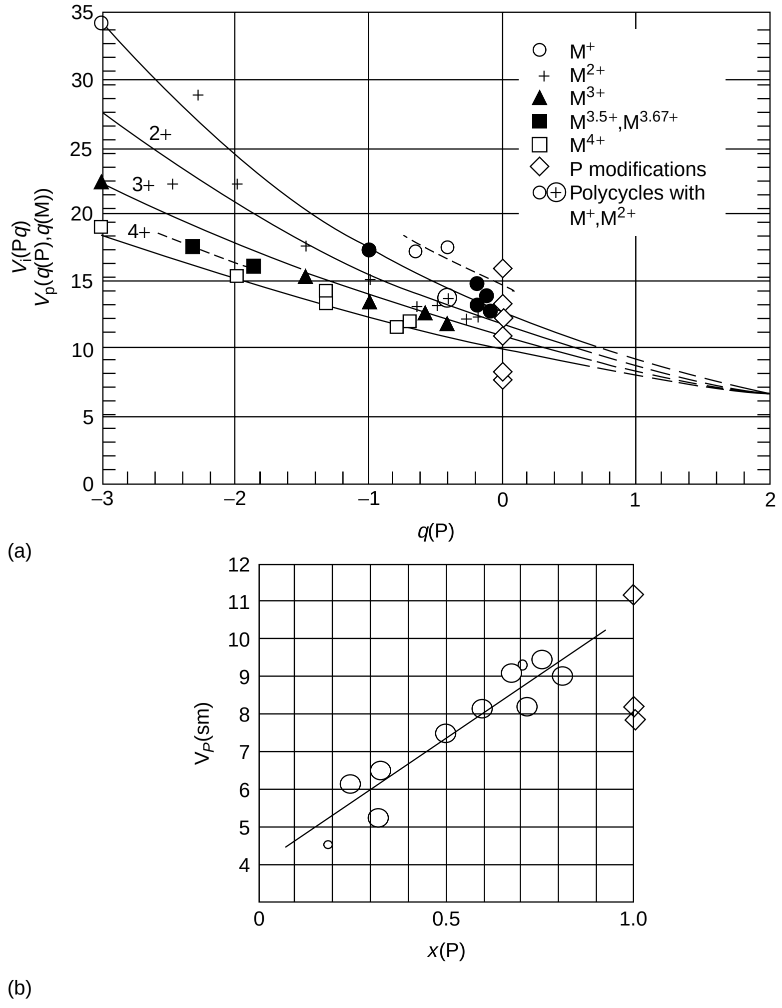

Figure 4 (a) Volume increments of phosphorus atoms (in $cm^3\ mol^{-1}$) with formal charges q(P) and q(M). The solid lines represent the functions $V_P(q(P), q(M))$ corresponding to equation (1). The broken lines connect volumes for cations with mixed valencies and extreme volumes, respectively. (b) Volume increment of P (in $cm^3\ mol^{-1}$) with molar ratio in semimetallic compounds. Mean values of sequences of compounds are given by large dots, the compounds 'Fe_4P' and Re_6P_{13} are marked by small dots. The volumes of the various P modifications are given by open squares

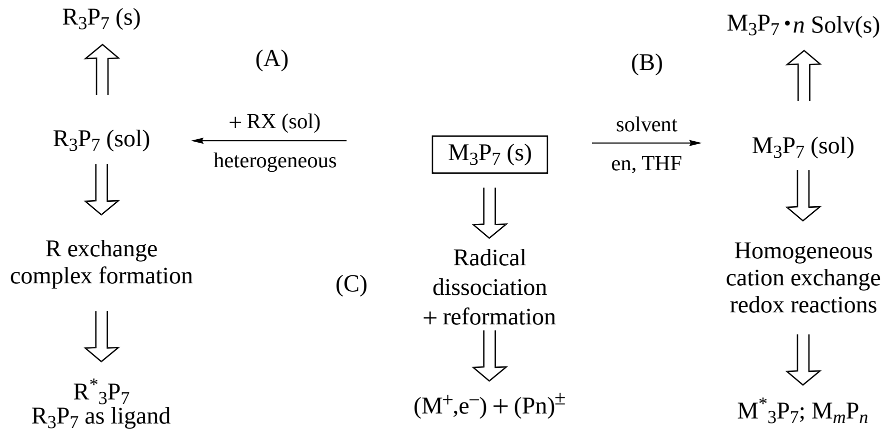
depends on the mole fraction x(P): $V_P(sm) = 7.0 \times x(P) + 4.0$ [$cm^3\ mol^{-1}$]. With electropositive metals, the observed volume V_m° is much smaller than the sum of the volumes of the elements, but the difference decreases with increasing x(P). The sum of the increments $\sum V_i$(saltlike) and $\sum V_i$(sm) span the region of V_m°, and the better fit corresponds with the physical properties. Larger deviations indicate peculiarities, for example, cluster anion formation or metals. Structural changes in homologous compounds can be analyzed and predicted according to the theorem of optimal volumes.[56]

5 CHEMICAL REACTIONS OF PHOSPHIDES

There is a broad range of chemical reactivity, for example, K_3P hydrolyzes very easily, whereas KP_{15} can only be digested by nitric acid and bromine. In general, the compounds $(E1)_3P$, $(E2)_3P_2$, and (E13)P are attacked by water, but E3P are stable (where E1 represents a group 1 metal, E2 a group 2 metal, etc.). The same is true with the transition metal phosphides in general. Only a few systematic studies exist.

The polyanions may become molecules and other derivatives as a result of chemical reaction. Suitable synthons are, for example, the solid M_3P_7 compounds which can be used in both heterogeneous and homogeneous reactions as well (Scheme 1).

A typical heterogeneous reaction transfers crystalline M_3P_7(s) into solvated molecules R_3P_7(solv). Via R–R* exchange, new compounds such as $P_7(MMe_3)_3$, $P_{11}(MMe_3)_3$, and $P_7(MPh_3)_3$ with M = Si, Ge, Sn, and Pb, and the pure P_7H_3 can be obtained (Scheme 1 path A).[57]



Scheme 1

Solutions of binary metal phosphides are accessible with polar solvents. The completely colorless solutions, obtained only with pure compounds and dry solvents, turn into deep red solutions on oxidation.[39] The state of the metal phosphides in solution is uncertain, but there is some evidence for solvated ion complexes (path B). The hydrogen phosphides $Li_2HP_7(solv)_x$ and $LiH_2P_7(solv)_x$ are formed by $[Li_3P_7(solv)_x + P_2H_4;\ Li_3P_7(solv)_x + P_7H_3]$. Na_3P_{21} is formed from P_4 and Na in solution, crystallizes as $Na_3P_{21}(THF)_{15}$, and can be transformed into $NaP_{21}R_2(solv)_x$ and then into $HP_{21}R_2$. The latter reaction steps demonstrate directly the difference in nucleophilicity of the three P^- atoms. Oxidation with P_4 in ethylenediamine leads from Na_3P_7 to $Na_4(en)_6P_{14}$ and from Cs_4P_6 to $Cs_3(en)_3P_{11}$. The latter reaction corresponds to the solid-state reaction $Na_3P_7(s) + P_4(g) \rightarrow Na_3P_{11}(s)$.

The radical decomposition (path C) of phosphides in solution with Ph_2CO yields in the case of Na_3P_7 the deep blue Ph_2CO^- and light red amorphous residues of a new, but as yet uncharacterized, form of elementary phosphorus. K_4P_6 reacts with Ph_2CO in solution under easy abstraction of only one part of potassium ($K + Ph_2CO \rightarrow K^+ + Ph_2CO^-$), yielding K_3P_7. This homolytic cleavage is completely equivalent to the thermal reaction of K_4P_6 with SiO_2 (quartz wall) at temperatures around 470 K, forming K_3P_7 and (K_2O + Si) from K(g) and SiO_2(s).[58]

From reaction in solutions, a variety of polyphosphides is obtained that are not known as solvent-free binary compounds (Table 7). Several have been characterized by ^{31}P NMR spectroscopy in solution,[38] for example, $P_{19}{}^{3-}$ and $P_{26}{}^{4-}$, which have no counterparts in binary systems. LiP_5 forms a $^3_\infty(P_5{}^-)$ polyanion in the solid state, but the corresponding anion in solution is monomeric $P_5{}^-$, an analogue of the cyclopentadienyl anion. The helical polyanions $^1_\infty(P_7{}^-)$ of LiP_7 and NaP_7 have no monomeric counterpart in the solution; here the anion is present as $R_2P_7{}^-$. Adding simply a salt (KI), trimeric $P_{21}{}^{3-}$ is formed as a finite anion in solution and it can be isolated as a solvated salt.

The effect of the solvent is demonstrated by solvent-free Li_3P_7 and solvated $(Li(TMEDA))_3P_7$; the first forms a 3-D network with ion–ion and ion–dipole Li–P interactions,[59] whereas the latter is an isolated solvated ion pair.

The reaction of white or red phosphorus or of alkali and alkaline-earth metal phosphides in liquid ammonia was extensively investigated by Korber and coworkers.[40,60–71] The simplest experiment is just the recrystallization of binary phosphides from liquid ammonia, as is realized for the ammoniates $Cs_3P_{11}\cdot 3NH_3$[66] and $Cs_3P_7\cdot 3NH_3$.[68] The reduction of red phosphorus with Ba in liquid ammonia leads to $Ba_3P_{14}\cdot 18NH_3$.[61] Here, $P_7{}^{3-}$ units are joined via P–Ba contacts to $^1_\infty[Ba_2(P_7)_2]^{2-}$ chains that are separated by $Ba(NH_3)_8{}^{2+}$ cations. The highly interesting 6π aromatic polyphosphide $P_4{}^{2-}$ is obtained via reaction of diphosphine with cesium in liquid ammonia.[40] Mixed cations like in $Ba_3P_{14}\cdot 18NH_3$[60] can be introduced through a reaction of Cs_3P_{11} with a cation exchange resin loaded with Ba^{2+}. Through a complete ion exchange, $[Li(NH_3)_4]_3P_{11}\cdot 5NH_3$ can be obtained from Cs_3P_{11}.[69]

Interesting new compounds occur if some of the alkali metal ions are exchanged by much larger substituted ammonium cations. Recently reported examples are $(NEtMe_3)Cs_2P_7\cdot 2NH_3$,[62] $(Me_4N)_2RbP_7(NH_3)$ and

$(Et_4N)Cs_2P_{11}$,[64] $(NEt_3Me)Cs_2P_7\cdot NH_3$ and $(NEt_4)Cs_2P_7\cdot 4NH_3$,[70] or $(NEt_3Me)_2CsP_{11}\cdot 5NH_3$.[71] Through proton-charged exchange resins or via in situ formation of $NaNH_2$, also some phosphorus–hydrogen species like $HP_{11}{}^{2-}$,[63] $HP_7{}^{2-}$,[65] or $[Na(NH_3)_3(P_3H_3)]^-$[67] are accessible as ammoniates.

Finally, it is worthwhile to note that most of these ammoniates are only stable at low temperatures (typically at liquid NH_3 temperature). If the compounds lose ammonia through heating or in a vacuum, decomposition sets in.

6 STRUCTURE AND BONDING[16,17]

6.1 General Remarks

Phosphide structures cover a great range of complexity, depending on composition and bonding. The polyphosphides are characteristic of the element phosphorus and offer cluster anions or polymeric networks of homoatomic-bonded P atoms as the primary structural fragments, whereas coordination by metal atoms is best described in terms of additional donor–acceptor interaction through the phosphorus electron pairs. The structures of the electron-rich phosphides with larger M/P ratios are usually described in terms of metal-atom polyhedra, centered by P atoms; these structures are not specific for phosphorus but occur also with borides, carbides, silicides, and so on. A peculiarity are phosphorus compounds with B_{12} units, similar to $B_{12}BP_2$, in which the BP_2 part of these structures is replaced by other atoms. Isomorphism is common with arsenides and sometimes occurs with antimonides.

In the following sections, only selected structures are discussed. A more complete account is given by the available textbooks and review articles.[1–15]

6.2 Monophosphides

The diversity in structure and bonding possible for phosphides is effectively demonstrated by the monophosphides. Monophosphides MP of the group 1 and 2 elements (E1, E2) are polyphosphides with ${}^1_\infty(P^-)$ chains and $P_2{}^{4-}$ dumbbells, respectively. E11 and E12 monophosphides are not known. The E3 and E13 monophosphides are the so-called ‘normal’ compounds with $3x = q(M)$ (see Section 2). With E13, they form the zinc blende structure with tetrahedral heteroatomic bonds. Ternary derivatives such as $MgGeP_2$ and $CuSi_2P_3$ have a random distribution of the M atoms, whereas $CdGeP_2$, crystallizes in the ordered chalcopyrite type with a ${}^3_\infty[GeP_{4/2}]^{2-}$ tetrahedral net (see Section 6.4). The E3 monophosphides form the NaCl structure. CeP is remarkable because of its physical properties (metal–semiconductor transition; heavy-fermion behavior). The E14 monophosphides show the ‘break’ usually observed when passing the Zintl border. Binary lead phosphides are not known; SiP and GeP are compounds with formally M^{III}, whereas SnP is an Sn^{II} compound. The nine-electron (9e) systems SiP (GeP) and SnP form topologically identical structures but with opposite atom and electron distributions.[72,73] The bonding of the four-atomic layer structure (GaS type) corresponds in the case of SiP to a molecule[72] |P≡Si–Si≡P| with Si^{3+} and P^{3-}, whereas the SnP structure is equivalent to |Sn≡P–P≡Sn| with Sn^{2+} and P^{2-}.[73] Conversely, in SnP_3, tin is oxidized to Sn^{3+} (see Section 6.4).

It is important to note that M^{IV} is the maximum oxidation state in binary phosphides (cf. Th_3P_4, Th_2P_{11}, ThP_7) and higher oxidation states are stabilized only by the formation of complexes (see Section 6.2). An exception may be UP_2 with the $PbCl_2$-type structure, but the P–P distances (269 pm) indicate an oxidation state $q(U) < 6$. Phosphorus compounds of group 15–17 elements are not covered here: PSb, PBi, and PTe do not exist, while other compounds such as PAs (Section 7) are not termed phosphides.

The group 4–10 monophosphides form similar, but clearly differentiated structure types, owing to their electron numbers. In all structures, the P atoms are trigonal prismatically coordinated by M atoms, whereas the M atoms have octahedral and/or trigonal prismatic coordination. VP (NiAs type), CrP, WP, MnP, FeP, RuP, CoP (MnP type), and NiP (NiP type) are characterized by 1-D chains of face-condensed MP_6 octahedra. This leads in the NiAs type to linear M_∞ chains, whereas in the latter two types, zig-zag chains are present, indicating gradually changing M–M interactions. In the MnP and NiP types, increasing P_2 formation occurs (P–P = 240–250 pm). TiP, ZrP, and HfP exhibit the TiAs type with pairs of face-sharing MP_6 octahedra. The M–M distances indicate M_2 pairing, corresponding to M^{III} with a d^1 configuration. NbP, TaP (NbAs type), and MoP (WC type) possess trigonal prismatic MP_6 coordination. The two structures differ in the relative orientation of the trigonal prisms but, in both, the M atom is trigonally planar surrounded by three empty centers of P_6 prisms. This facilitates the formation of three, three-center bonding states, sufficient for d^2 configurations (only NbP, HfS, and isoelectronic compounds have the NbAs structure; cf. also MoS_2 and $NaNbO_2$). Note that MoP is the only E6 monophosphide with the WC structure.

6.3 Heteroatomic Bonded Phosphides

This group consists mainly of the classical metal phosphides MP_x with $3x = q(M)$. Li_3P, Na_3P, and K_3P have the hexagonal Na_3As structure; Rb_3P and Cs_3P are not known. $K_{3-x}P$ has the cubic Li_3Bi structure[74] with a strong tendency for a lower K content down to K_2P, forming partially $P_2{}^{4-}$ dumbbells in the same structural frame. This seems to indicate that polyphosphide formation becomes more pronounced with increasing radii of the alkali metal cations. Cu_3P, however, possesses a phase with $Cu_{3-x}P$ ($0.09 \le x \le 0.26$). The structure is similar but not identical to the LaF_3 type of structure.[75] Phosphides M_3P_2 of the divalent E2 and E12 metals have the structure of Mn_2O_3 and Zn_3As_2,

respectively, or form the deficient Th_3P_4 type ($Ba_4P_{2.67}\square_{0.33}$). Ternary compounds like LiZnP, LiCdP, Li_3AlP_2, Li_5SiP_3, Li_7VP_4, and Li_9TiP_4 have CaF_2 or Li_3Bi structures with varying statistical distributions of the M atoms. Ordering is observed in some compounds, which is characteristic of the larger alkali metals. Unexpected structures are seen for RbZnP and SrAgP (and others), which are related to the AlB_2 and Ni_2In types with heterographite-like $^2_\infty[ZnP]^-$ and $^2_\infty[AgP]^{2-}$ nets in a frame of trigonal prisms, formed by Rb and Sr, respectively. Quasibinary compounds of general formula $E1(E'1)_2P$ and E1E2P are not yet known, contrary to the corresponding arsenides and antimonides. The NaCl and ZnS-type structures of E3 and E13 metals are discussed in Section 6.2.

The unique cubic Th_3P_4 structure (U_3P_4, Np_3P_4) is built from condensed ThP_8 dodecahedra (bisdisphenoids). Eu_3P_2 has the deficient Th_3P_4 structure ($Eu_4P_{2.67}\square_{0.33}$), whereas the mixed-valence compound Eu_4P_3 forms a slightly rhombohedrically distorted structure of this type.[76] The mixed valent Sn_4P_3 forms a layer structure similar to Bi_4Se_3.[77,78]

6.4 Phosphidometallates

Ternary phosphides may be also discussed as products of Lewis acid–base reactions of binary components. This is of value especially if the more acidic component is distinguished by pronounced coordination. The low coordination number (CN) of two is shown by the isolated linear $[BP_2]^{3-}$, $[BeP_2]^{4-}$, and $[HgP_2]^{4-}$ anions of Na_3BP_2, K_4BeP_2, and K_4HgP_2, respectively (Figure 5).[79–81] They are isosteric analogs of CO_2 and $[HgO_2]^{2-}$. The corresponding polymeric chain $^1_\infty[AuP]^{2-}$ with CN = 2 is present in K_2AuP.[82] Similar chains occur in the $^1_\infty[NiP_2]^{2-}$ anion of Cs_2NiP_2[83] and K_2NiP_2,[84] but with side-on bonded P_2 pairs instead of simple P bridges, and the Ni atoms have a planar rectangular NiP_4 coordination. Analogs of $CO_3{}^{2-}$ with CN = 3 are the $[SiP_3]^{5-}$ and $[InP_3]^{6-}$ anions of Cs_5SiP_3[85] and K_6InP_3.[86] In these structures, the large cations form quartets of trigonal prisms (isolated and linked to chains, respectively), the metal-rich transition metal phosphides (Figure 5). The $[Al_2P_4]^{6-}$ and $[In_2P_4]^{6-}$ anions of $Cs_6Al_2P_4$[87] and $Cs_6In_2P_4$[88] are directly comparable with $BeCl_2$ and the nonexistent $(SiO_2)_2$ dimer.

Complex anions with CN = 4 occur frequently with E13, E4, E14, E5, and E6 as central atoms. Isolated tetrahedral tetraphosphametallate anions are $[AlP_4]^{9-}$ in $Na_3Eu_3AlP_4$,[89] $[TiP_4]^{8-}$ in Sr_4TiP_4,[90] $[SiP_4]^{8-}$ in $Na_4Sr_2SiP_4$, $[PbP_4]^{8-}$ in $Na_2Eu_2PbP_4$,[91] $[NbP_4]^{7-}$ in Na_5SrNbP_4, and $[WP_4]^{6-}$ in Na_6WP_4.[92] Tetrahedral dimers $[Sn_2P_6]^{10-}$ are present in $Na_{10}Sn_2P_6$,[93] isosteric with Al_2Cl_6, and the 1-D polymers of the SiS_2 type are realized as $^1_\infty[E13P_2]^{3-}$ and $^1_\infty[E14P_2]^{2-}$, for example, in K_2NaGaP_2[94] and K_2SiP_2 (Figure 5).[95] A 3-D tetrahedral net is realized in Na_3InP_2,[96] Ag_2SiP_2,[97] and the complex structures of LnSi$_2$P$_6$ (Ln = La, Ce, Pr, Nd).[98]

An interesting compound is AuSiP[97] (Figure 5) in which the silicon and phosphorus atoms form two-dimensionally infinite puckered Si_3P_3 nets that are separated by the gold atoms, a structure similar to the Zintl phase $CaSi_2$. The monoclinic transition metal compounds TSi_3P_3 (T = Co, Rh, Ir) and TSi_4P_4 (T = Fe, Ru, Os) adopt very complicated structures.[99–101] Note that it is difficult to distinguish silicon and phosphorus on the basis of X-ray data, since these elements have similar scattering factors.

Pecularities occur with K_2GaP_2 and Ca_5P_8 in that the 1-D chain of $[GaP_2]^{2-}$ exhibits connected five-membered rings with P_2 pairs (isosteric with BS_2), and $P_8{}^{10-}$ in Ca_5P_8 is a $[S_2O_6]^{2-}$ analogue[102] (see Section 6.5.3). The unit $Ge_2P_4{}^{8-}$ in Ba_2GeP_2[103] is not fully understood; the anion looks like the 38e systems $[S_2O_4]^{2-}$ and $[N_2(CF_3)_4]$ with a single Ge–Ge bond, but is in fact a 36e system like $Cl_2C{=}CCl_2$, suggesting the possibility of a diradical.

6.5 Polyphosphides

According to their structures and physical properties, the polyphosphides are valence compounds in the classical sense. All valence electrons are in localized states and, therefore, these compounds are (or should be) insulators or semiconductors. Nevertheless, some compounds are semimetals or even metals if conduction bands are formed by sufficient overlap, but their structures often remain in accord with the picture of localized states.

To describe the polymeric and polycyclic structures, selected fragments that are related to well-known molecules or clusters are chosen. This fragmentation is arbitrary to some extent and, therefore, it is of value to look for alternative ways, which may be relevant in relating their structures to their synthesis and reactions. The helical $^1_\infty(P_7{}^-)$ chain of LiP_7 can be fractionated into, for example, sequences of polymerized $P_7{}^-$ units or may be discussed in terms of condensed $P_9{}^- = [P_{2/2}P_5 - P_{2/2}]$ units in order to demonstrate the twofold symmetry elements perpendicular to the helical axis. The $P_{16}{}^{2-}$ unit is either a polymer of $P_9 + P_7$ or a condensate of two P_9 units. In the case of polycycles with different ring sizes, the arbitrariness is reduced to the question of which ring type is seen to be the more general one, with respect to systematics or to generating the systems. The remarkable stoichiometrical variations can be rationalized by only a few simple structural subunits, which are parts of the known or hypothetical modifications of phosphorus. There exist many possibilities for polyanionic structures, such as the formation of isolated polycycles and of 1-D, 2-D, and 3-D polymers including their numerous conformational variations.

6.5.1 *Heptaphosphides*

The heptaphosphides of the cations M^{n+} ($n = 1-4$) are excellent examples to support a general discussion of the structural possibilities (Table 7, Figure 6).

The first family generates 1-D and 2-D polyanionic structures. $K_4P_{21}I(= KI\cdot 3KP_7)$ shows a structure with the

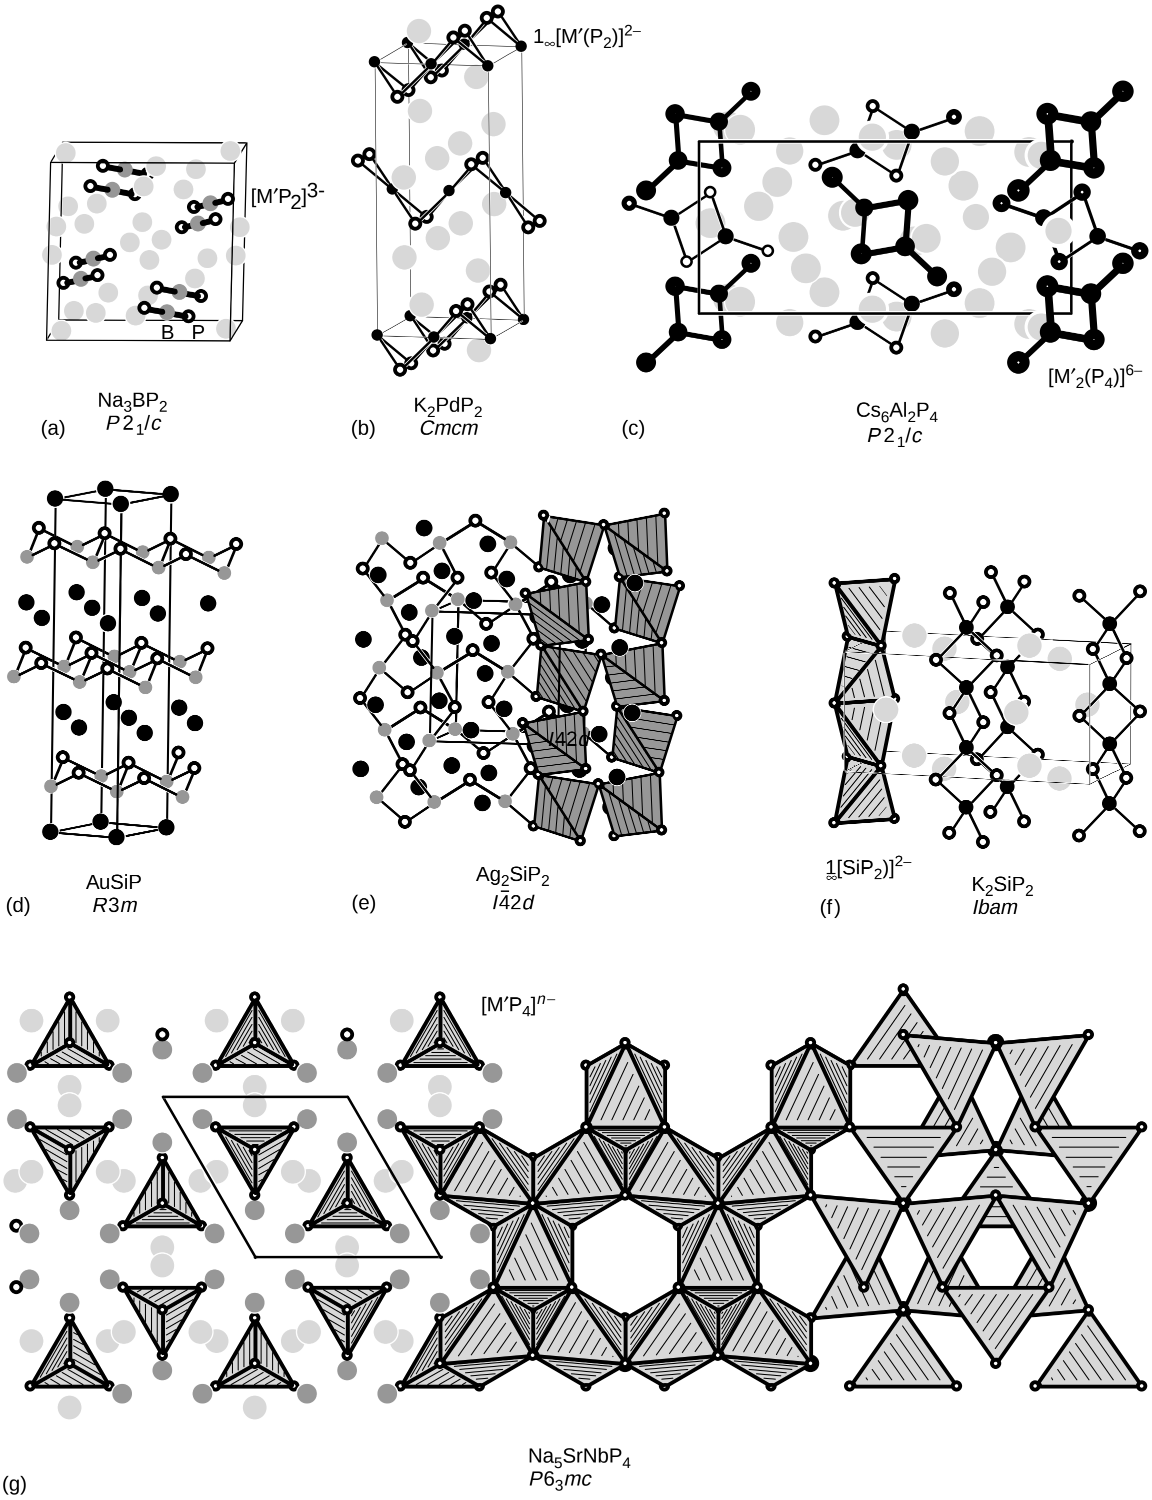

Figure 5 Examples of ternary phosphides with different coordination numbers of heteroatomic bonded metal atoms. (a) Linear unit $[BP_2]^{3-}$ ($M_3M'P_2$, Na_3BP_2 type), isosteric with CO_2; (b) $^1_\infty$ $[M'(P_2)]$ zig-zag chain with $P_2{}^{4-}$ dumbbells ($M_2M'P_2$, K_2PdAs_2 type) (P atoms, open circles; M atoms, grey circles; M′ atoms, small filled circles); (c) planar $[M'_2P_4]^{6-}$ units ($M_6M'_2P_4$, $Cs_6Al_2P_4$ type), corresponding to the unknown $(SiO_2)_2$ dimer; (d) MM′P (AuSiP type), emphasizing the two-dimensional [SiP] network; (e) $M_2M'P_2$ (Ag_2SiP_2 type), emphasizing the three-dimensional network of condensed SiP_4 tetrahedra; (f) $^1_\infty$ $[SiP_2]^{2-}$ ($M_2M'P_2$, K_2SiP_2 type), isosteric with SiS_2. The edge linked tetrahedra are shown in the left part (M atoms, grey circles; Si, black circles, and P, open circles). (g) $M_5M'M''P_4$ (Na_6ZnO_4 type) emphasizing the $[M''P_4]^{n-}$ tetrahedra (left), the octahedra around M^{II} as in the corresponding Sr and Eu compounds (center), as well as the tetrahedra around Na (right)

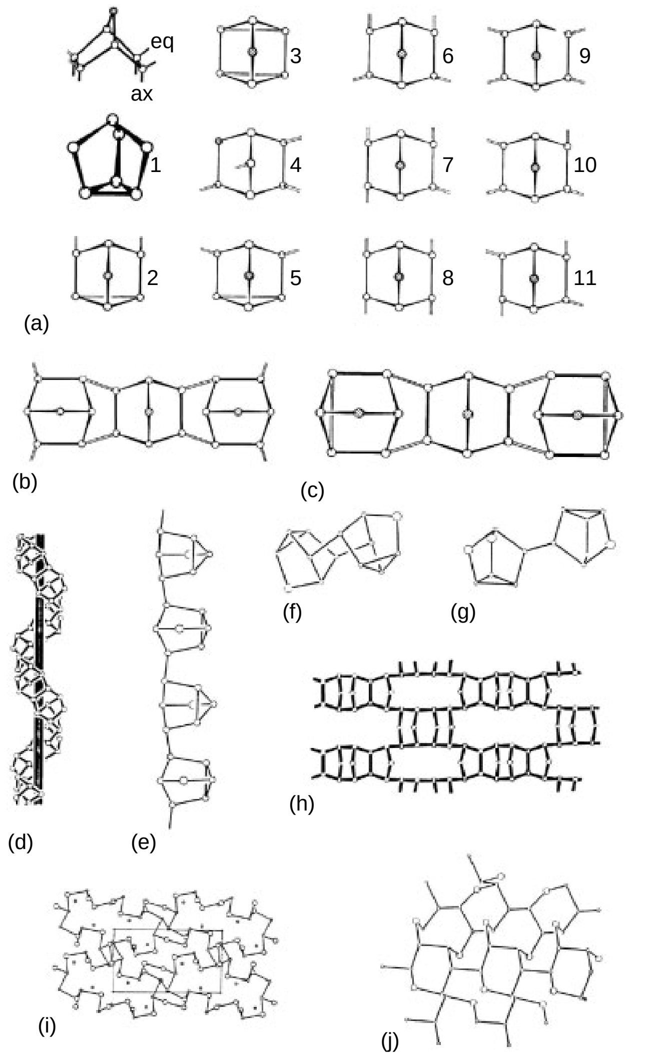

Figure 6 (a) Representatives of the heptaphosphanorbornane (top left) with axial (ax) and equatorial (eq) connectivities; (i) indicates intramolecular saturation of bonds in the descriptions below. (1) (P_7^{3-}); (2) $(ax_2i_2)P_7^-$ (end-on type of oligomeric P_{21}^{3-}); (3) $(i_4)P_7^-$ (possible monomeric structure of P_7H); (4) LiP_7 type; (5) $(eq_2i_2)P_7^-$ (CsP_7 type); (6) $(ax_2eq_2)P_7^-$ (end-on type of polymeric P_{21}^{3-}); (7) $(ax_3eq)P_7^-$ (unknown); (8) $(ax_4)P_7^-$ (unknown); (9) $(eq_4)P_7^-$ (central part of oligomeric and polymeric P_{21}^{3-} as well as of P(Hittorf)); (10) $(ax_3eq_3)P_7^-$ (unknown); (11) $(ax_2eq_2)P_7^-$ (unknown). (d) Helical unit $^{1}_{\infty}(P_7^-)$ wound around the central axis as in LiP_7 and NaP_7, built from type (4). (e) CsP_7 as $^{1}_{\infty}(P_7^-)$ chain of cages of type (5). (f) (P_{14}^{2-}), hypothetical dimer of type (2). (g) P_{14}^{4-} as found in $Na_4(en)_6P_{14}$. (h) $^{2}_{\infty}(P_7^{2-})$ network of tubular fragments in Cu_2P_7. (i) $^{3}_{\infty}(P_7^{3-})$ in LaP_7. (j) $^{2}_{\infty}(P_7^{2-})$ in EuP_7

fourfold equatorial-bonded type 9, as well as with the partially axial-bonded type 6. The formation of oligomeric P_{14}^{2-} and P_{21}^{3-}, however, can be realized in a simple way by combining type 2 with type 9. The formation of the type 5 cage leads to the CsP_7 structure type and only a small further step forms an isolated P_7^{3-} group with the structure of the well-known P_4S_3 molecule. On the other hand, type 4 units as members of the second family wind into a helical structure. LiP_7 and NaP_7 crystallize with this structure of helical tubes, whereas RbP_7 and CsP_7 have a more linear structure with connected P_7 cage units. The cavities for the cations are too small for K^+ in the helical structure but are too large in the other, and indeed the reaction of potassium and phosphorus (P:K ratio = 7:1, without iodine) leads only to mixtures of lower and higher phosphides; in the presence of iodine, $K_4P_{21}I$ is formed. From the unit cell volumes, space filling in this compound is evidently better than in both MP_7 structures. Only rubidium forms both compounds with nearly the same space filling.

A monomeric P_7^{2-} is not possible, but the dimeric P_{14}^{4-} is known from the solvated $Na_4(en)_6P_{14}$.[39] EuP_7 is a Eu^{II} compound with a polymeric P_7^{2-} structure of two-dimensional puckered layers resulting from a network of six-membered rings (chair conformation; axial and equatorial linkage).[104] For a description of P_7^{2-} in Cu_2P_7, see Section 6.5.6.

The structure of the heptaphosphides of the rare earth metals La, Ce, and Pr contains a polymeric polyanionic network $^{3}_{\infty}(P_7^{3-})$ with seven-membered and large 20-membered rings, which, nevertheless, can be related in a simple way to the P_7^{3-} cage (see Section 6.5.2).

ThP_7 is the only known compound with a P_7^{4-} substructure.[105] The 3-D network is formed by a condensed system of six-membered and 12-membered rings yielding characteristic crown-shaped cavities occupied by Th atoms.

6.5.2 Cyclic and Polycyclic Systems

The quasimolecular P_7^{3-} cage is the essential building unit of the bright yellow alkali metal phosphides M_3P_7 (formerly described erroneously as M_2P_5) and of the red alkaline earth metal phosphides Sr_3P_{14} and Ba_3P_{14}, as well as of the chloride phosphide Ba_2P_7Cl.[106] These compounds are extremely reactive, and the compounds M_3P_7 are unique in their behavior, for example, they transform to plastically crystalline modifications and they are volatile in vacuo.

The heptaheteronortricyclanes P_7^{3-} and P_7R_3 (and the related P_4S_3, As_7^{3-}, Sb_7^{3-}, etc.) differ in their topology. The bond lengths and bond angles, as well as the height of the cage, depend on their function and charges. Neutral cages are more elongated than charged ones, and the significant variations within the charged units result from progressive electron transfer in going from Li to Cs. The P_{11} cages behave similarly.

The ternary Cu_4SnP_{10} with an unusual $Sn^{II}Cu_3$ unit is the only compound with the adamantane-like P_{10}^{6-} cage.[107] This is remarkable, because in that region of composition some compounds exist. Obviously, the units P_7^{3-} and P_6^{4-} are more stable. A polymeric tubular 2-D isomer was found in $Au_7P_{10}I$.[108]

Just as the cages P_7^{3-} and P_{10}^{6-} are derivatives of the tetrahedral P_4 molecule, the P_{11}^{3-} cage, characteristic for the M_3P_{11} alkali metal phosphides,[109] is a derivative of the

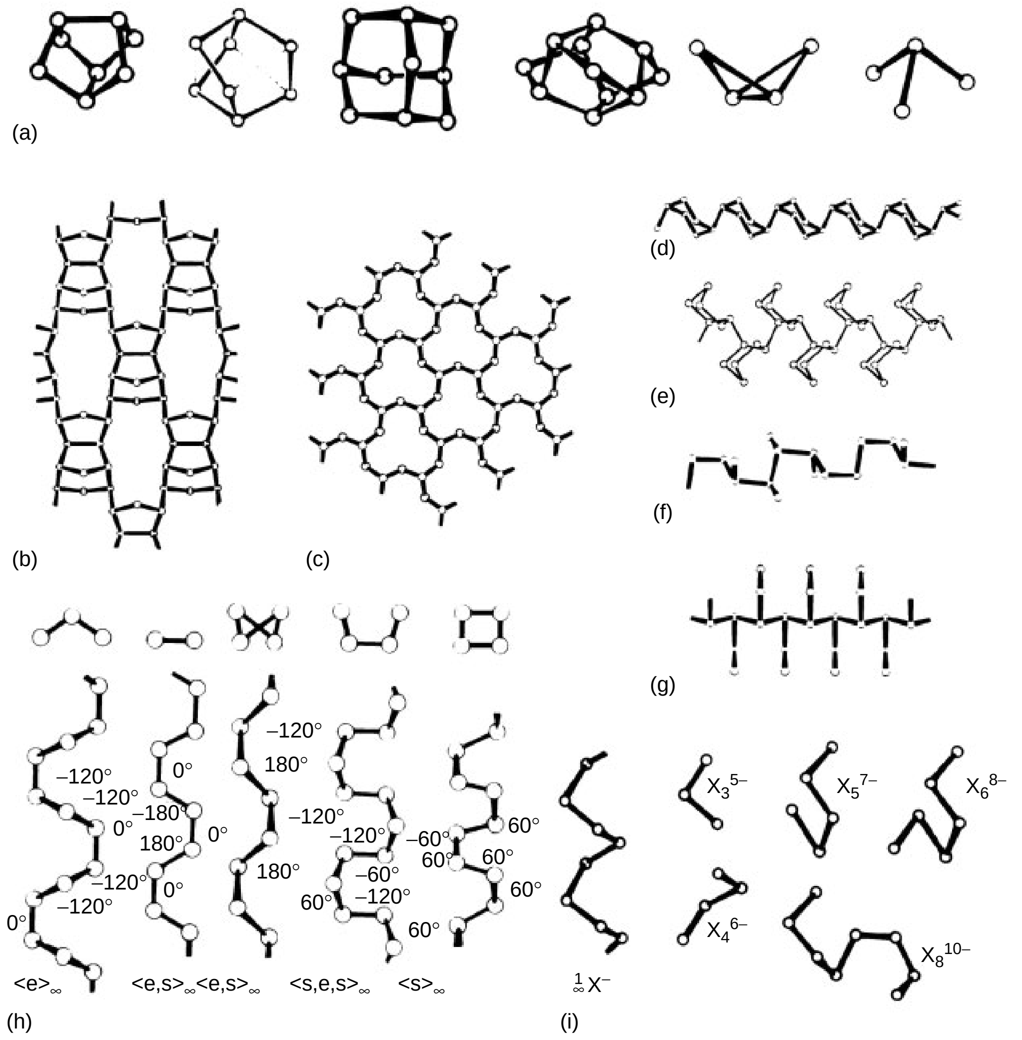

Figure 7 (a) Molecular units (left to right) $P_8{}^{4-}$, $P_8{}^{6-}$, $P_{10}{}^{6-}$, $P_{11}{}^{3-}$, $P_4{}^{2-}$, and $P_4{}^{6-}$. (b) ${}^2_\infty(P_{11}{}^{3-})$ of Ag_3P_{11}. (c) ${}^2_\infty(P_{10}{}^{6-})$ of $Au_7P_{10}I$. (d) Chain of six-membered rings (chair conformation) as found in BaP_3 and Au_2P_3. (e) Chain of six-membered rings (boat conformation, 1,2 connection) from $MoFe_2P_{12}$. (f) Branched ${}^1_\infty(P^-)$ from RuP_3. (g) Branched ${}^1_\infty(P^-)$ from ReP_3. (h) Different conformations of ${}^1_\infty(X^-)$ chains with their torsion angles and their projections along the helix axes. (i) Infinite and finite chains $X_n^{(n+2)-}$ with $n = 3, 4, 5, 6$, and 8

as yet unknown phosphacubane. This magnificently shaped chiral group is a system of six five-membered rings with D_3 symmetry. Both enantiomers are present in the crystal. On the other hand, the Ag_3P_{11} structure is built of ${}^1_\infty(P_{11}{}^{3-})$ tubular polymers.[110] In $MoNiP_8$ the chiral $P_8{}^{6-}$ polyanion is present,[111] which is a phosphacubane with three opened edges, whose bridging directly leads to $P_{11}{}^{3-}$. Some of these structures are illustrated in Figure 7. At this point, it is worthwhile to note that the neutral fragment P_8Se_3, which is isoelectronic to $P_{11}{}^{3-}$ (ufosane) occurs in the structure of $(CuI)_2P_8Se_3$.[112,113]

The M_3P_{11} phases transform into plastically crystalline modifications like the M_3P_7 phases.[4,114] In the high-temperature form (β), the phosphides match the structure of the intermetallic Li_3Bi. The Bi positions are surrounded by the cages of $P_7{}^{3-}$ and $P_{11}{}^{3-}$ with orientational disorder.

The compounds M_4P_6 of the alkali metals K, Rb, and Cs have a unique structure with planar and isometric P_6 rings.[58] The structure is a defect variant of the trigonal prismatic AlB_2 type[115] and the unusually short P–P bond distances of about 215 pm are not affected by the metal substructure. These compounds were the first examples of an unsaturated P–P bond system, although it was not possible to decide between a disordered double bond and a quasiaromatic 2π system (PBO = 1.167 from the P–P distance). An aromatic 6π polyphosphide in the form of a four-membered ring ($P_4{}^{2-}$) has been isolated in the solvated compound $Cs_2P_4{\cdot}2NH_3$ as well as in liquid ammonia.[40] The presence of the missing link in the sequence of the E_4 members has been excellently proven by X-ray (d(P–P) = 214.7 pm) diffraction, ^{31}P NMR as well as quantum-chemical calculations. The synthesis shows the application of a new preparative route, using

P_2H_4 as well as ammonia (*cf. 6.7.3*).[38] Polymers of $P_6{}^{4-}$ were found in BaP_3, Au_2P_3, and the $MoFe_2P_{12}$ phases as well.[108,115–117]

Cyclo-$P_6{}^{6-}$ has the usual chair conformation and is observed as part of the Th_2P_{11} structure.[118] The six-membered rings are inserted in a complicated 2-D phosphorus substructure and act as doubly tridentate ligands for Th. *Cyclo*-$P_6{}^{6-}$ is also present in the arsenic-like structures of SnP_3, GeP_3, and InP_3,[119–121] indicating a metal oxidation state $q(M) = +3$. The skutterudite structure type ($CoAs_3$ and derivatives, cf. Sections 8.2 and 8.7) is formed by some transition metal triphosphides (M^{3+}) and is characterized by planar *cyclo*-$P_4{}^{4-}$.[122,123]

6.5.3 Polyanionic Chains

In principle, all catenations of type $(2b)P_n{}^-$ $(1b)P_2{}^{2-}$-:2 $(0 \le n \le \infty)$ belong to the large family of chain structures with $(n+2)$ atoms. Branched chains with m nodes are characterized by $(3b)P_m^0$ $(2b)P_{n-2m}{}^-$ $(1b)P_{2+m}{}^{2-}$. The 1-D polyanion $^1_\infty(P^-)$ is characteristic of the monophosphides of the alkali metals and the diphosphides of divalent metals, but is also present in $M^{IV}P_2$ compounds: SiP_2 ($GeAs_2$ type),[124] TiP_2, ZrP_2, and HfP_2 (Co_2P type) as well as $CeSiP_3$ and GdPS contain chains and isolated P^{3-} and S^{2-}, respectively.[125,126] The M-atom coordination varies from CN 4 (e.g. Zn^{2+} tetrahedral and Pd^{2+} square planar to four $(2b)P^-$) up to CN 9 (e.g. EuP_2), corresponding to the polyanionic arrangement. There is a series of structures that provides impressive examples of configurational and conformational variability, obviously forced by external conditions such as size and coordination of the cations. Figure 7(h) demonstrates how the sequence of torsional angles labels the chains, including fourfold helices as well as chains with changing rotational direction. The cation coordination may even change the configuration of a $(P^-)_\infty$ polyanion, for example, in the RuP_3 structure, where a branched isomer $^1_\infty(P_3{}^{3-}) = {}^1_\infty[(3b)P^0(2b)P^-(1b)P^{2-}]$ is present[127] with three different states of charge according to an internal bond disproportionation. ReP_3 and Re_2P_5 behave similarly.[128,129]

With increasing charge transfer, finite $P_n{}^{(n+2)-}$ chains $(2 \le n \le 8)$ occur. These polyanions are present in compounds of M^{II}–M^{IV}. Three peculiarities should be mentioned here: (i) the coexistence of $P_4{}^{6-}$ and $P_8{}^{10-}$ in some structures and $P_3{}^{5-}$ and $P_5{}^{7-}$ in others; (ii) the existence of the pyramidal isomer $P_4{}^{6-}$ in Ni_5P_4 and in $La_6Ni_6P_{17}$;[130,131] (iii) the remarkable isomer $P_8{}^{10-}$ with the structure of a hexaphosphadiphosphate(IV) anion, present in Ca_5P_8.[102]

Important representatives of $P_2{}^{4-}$ dumbbells are the pyrites (e.g. p-PtP_2) and the marcasites (e.g. m-FeP_2) with and without M–M bonds, for example CoP_2. Dumbbells $P_2{}^{4-}$ and M–M chains characterize the structures of MoP_2 and WP_2 (see Figure (16)).[132] CoPS is given as a representative of a phosphide sulfide with either $(PS)^{3-}$ dumbbells or mixtures of $P_2{}^{4-}$ and $S_2{}^{2-}$.[133] In CuPS, a 1-D chain of twofold-connected P atoms with exo-bonded sulfur atoms occurs.[134] The polymeric $(PS)^-$ anion is isosteric with the as yet unknown phosphorus monochloride.

In the p-SiP_2 structure[135] the short P–P distance (215 pm) demonstrates a considerable amount of P → Si back-bonding according to the formulation Si^{2+} and $(P{=}P)^{2-}$. Examples are the tunable (P–P) bond lengths in the pyrite structure, as well as in the phosphides of the $MM_2'P_2$ type ($BaAl_4$/$ThCr_2Si_2$), containing a formal $P_2{}^{n-}$ dumbbell.[136] MnP and ThP_7 contain unusually large P–P bond lengths in $^1_\infty(P^{n-})$ polyanions $(2 \le n \le 3)$ with $d(P\text{–}P) = 240$ pm and bond orders PBO ~ 0.5.[105,137] $LaCo_8P_5$ and Ti_2NiP_5 should be regarded similarly.[138,139]

Many structures with $P_n{}^{(n+2)-}$ fragments belong to the large family of structures built of trigonal prisms in different orientations and sometimes combined with cubes. The frame is formed by the M atoms, with P atoms and defects centering the polyhedra. Ba_3P_4 is one example of a complete trigonal prismatic defect structure $Ba_3P_4\Box_2$, resulting in a $P_4{}^{6-}$ chain fragment. The frame of $Na_2Sr_3P_4$ is built by trigonal prisms and cubes of Sr.[140] The prisms are centered by P atoms and defects, resulting in $P_2{}^{4-}$ and the cubes are centered by Na atoms. A shear variant is Sr_5P_4, where half of the dumbbells are fragmented into P^{3-}. A fascinating structure is shown by Ba_4P_3, where Ba forms intersecting rings of P-centered trigonal prisms, empty tetrahedra, and empty tetragonal pyramids. The P_2 pairs fill the resulting channels formed by pairs of Ba_6 prisms with different orientation: $Ba_8(P^{3-})_4(P_2{}^{4-})$ (Figure 8).[141]

6.5.4 Radical Anions

Completely unexpected was the discovery of the radical anions $P_3{}^{4-}$ (19e) and $P_4{}^{5-}$ (25e) in K_4P_3 and K_5P_4 (Figure 9).[142] Both compounds are extremely sensitive to thermal and mechanical treatment. $P_3{}^{4-}$, isosteric to $O_3{}^-$, is paramagnetic with $\mu_{eff} = 1.6\mu_B$ at 300 K.

A similar polyanion radical with 19e has been found in $Ba_3P_3I_2$,[143] which can be formulated as $(BaI_2)\cdot(Ba_2P_3)$. The P–P bond distances between K_5P_4 and $Ba_3P_3I_2$ differ by 11 pm, which indicates a much more localized double bond in the Ba compound. A more symmetric $P_3{}^{4-}$ radical anion occurs in $Ba_5P_5I_3$. Here the radical anion exists beside a classical $P_4{}^{6-}$ chain with 26e. The two radicals presented here seem to show magnetic coupling, since diamagnetism is observed in the investigated temperature range. It should be pointed out that similar radical polyanions $E_4{}^{5-}$ exist with E = As and Sb.

The structures of K_4P_3 and K_5P_4 also contain filled prisms of M atoms. These polyphosphides are the binary aristotypes of a series of ternary compounds with the general formula $M_{m+2n}X_{m+n}$ where m,n give the number of slabs of CrB (m) and Ni_2In (n), respectively. For K_4P_3, $m = 2$, $n = 1$, and for K_5P_4, $m = 3$, $n = 1$.

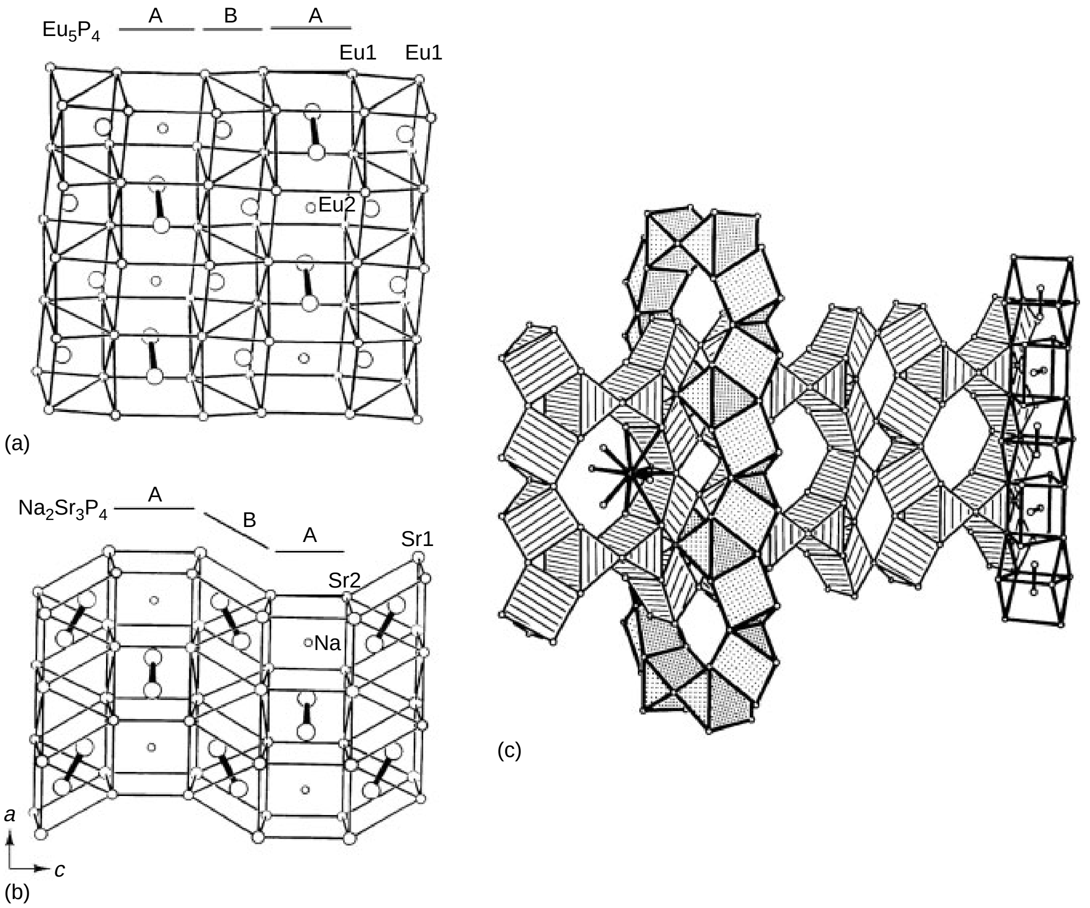

Figure 8 Examples of structures with trigonal M_6 prisms. (a) Eu_5P_4 with trigonal Eu_6 prisms centered by P atoms and defects resulting either in isolated atoms P^{3-} or dumbbells P_2^{4-}. (b) The shear variant $Na_2Sr_3P_4$ with trigonal prisms and only dumbbells. Small circles are metal atoms, large circles P atoms. (c) Ba_4P_3 types: intersecting rings of P-centered trigonal prisms, empty tetrahedra, and empty tetragonal pyramids. The two kinds of rings are striped and dotted. In the center of one ring a tenfold coordinated (bisdisphenoid) P atom is shown. The resulting channels, formed by pairs of Ba_6 prisms with different orientation, and filled with P_2 pairs, are emphasized at the right

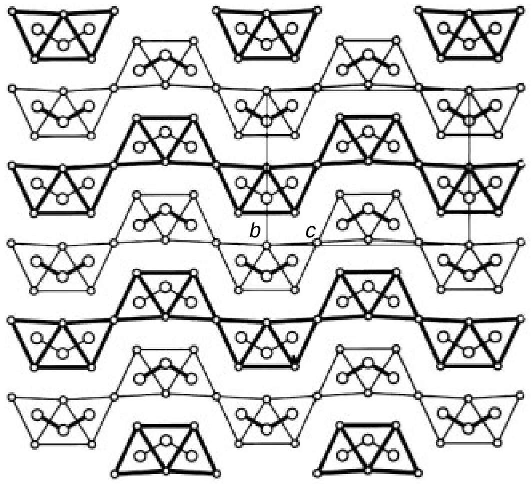
6.5.5 2-D and 3-D Nets

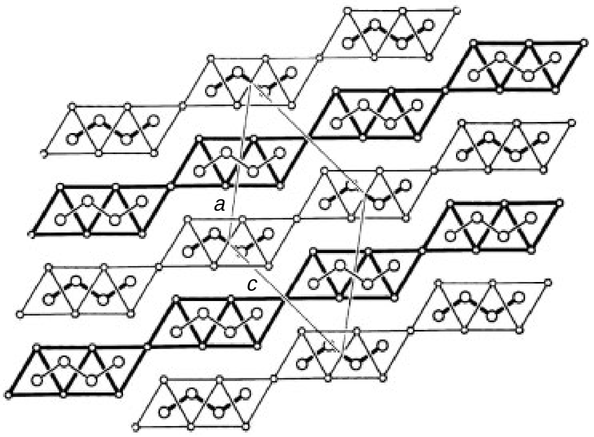
Corrugated 2-D and 3-D polyanionic nets occur if the mean charge $q(\mathrm{P})$ is in the range $0.20 \leq q \leq 0.73$. The nets are formed by condensed and connected P_n rings of different sizes and conformations ($n = 5$, 6, 7, 8, 10, 12, 14, 18, 20, 22; Figure 10). Derivatives of black phosphorus are the triphosphides MP_3 of divalent Ca, Sr, Ba, and Eu.[144,145] By removing 1/4 of the atoms in different ways, 2/3 of the phosphorus atoms remain as $(2b)P^-$. Removing only neighboring atoms the 1-D BaP_3 structure is formed, containing infinite connected six-membered rings with chair conformations and axial linkages. This polyanionic structure is comparable with that of Au_2P_3 and can be regarded as the polymeric analogue of the planar hexagonal *cyclo*-P_6^{4-}. In SrP_3, half of the P_6 rings remain complete but in CaP_3 all of them are opened and yield P_{14} rings. α-EuP_3 follows CaP_3 and not SrP_3. The ${}^3_\infty(P_5^-)$ net of LiP_5[146] is related to the pattern of black phosphorus as well as that of gray arsenic.[147] One-dimensional bands of condensed six-membered rings are connected by twofold-linked $(2b)P^-$, with these atoms occupying axial as well as equatorial positions (Figure 10).

The pentaphosphides LnP_5 of the trivalent rare earth metals form three very similar structures, with mainly identical ${}^2_\infty(P_5^{3-})$ networks. They can be derived from a structure similar to that of gray arsenic but with the six-membered rings in a boat conformation. The charge transfer disintegrates this net by removing 1/6 of the atoms and yields a 2-D net of condensed 12-membered rings. In that case, 3/5 of the remaining atoms are $(2b)P^-$. The 2-D polyanionic net is adapted, stepwise, to the decreasing size of the Ln^{3+} cations, which takes place mainly by changing the dihedral P–P angles. The structures can be interpreted as stages of a reaction path brought about by application of pressure.[1]

The unique 2-D substructure P_{11}^{8-} formed by Th_2P_{11} is more precisely described as $(P_{16}^{10-} + P_6^{6-})$.[118] Puckered P layers consist of ${}^1_\infty(P_{16})$ bands with isolated P_6 rings inserted.



K_4P_3 {$(W_3Co)B_3$} type



K_5P_4 {$(Y_4Ga)Co_4$} type

Figure 9 The known polyphosphides with radical polyanions P_3^{4-} and P_4^{5-}. Atoms connected by thin and thick lines are separated from each other by half a translation period of the projection direction. Small circles are K atoms, large circles P atoms. The unit cells are indicated by thin lines together with the labelled axes

The P_{16} bands are formed by condensed skew-boat P_6 rings and *endo*-P_8 rings. The inserted P_6 chairs are partially opened to P_3 fragments bonded to the bands and, therefore, give rise to a periodic structural modulation caused by valency and generated by a rearrangement of a single P–P bond. The Th_2P_{11} structure is an example of a frozen-in ring-opening reaction.

The tetraphosphides of divalent M^{2+} (Mg, Cd, transition metals) and the diphosphides of monovalent Cu^{+} and Ag^{+} form ${}^{2}_{\infty}(P_4^{2-})$ nets. They have condensed P_{10} rings in common, but with a rich variation in their linkages.[17,148,149] The structure of Cu_4SiP_8[150] is related to these structure types.

6.5.6 Tubular Structures

Rolling up into tubes is the special contribution of phosphorus to curved 2-D surface structures. The tubular character of the Hittorf phosphorus structure is preserved in the polyanionic linkage of the compounds with the smallest (P^{-}):(P^{0}) ratio. In $Cu_2P_3I_2$ this ratio is zero,[151] that is, this structure is formed by insertion of elemental phosphorus in CuI! The peculiar crystal chemistry of such compounds is summarized in Section 6.5.7. The tubular ${}^{1}_{\infty}(P_{12}^{0})$ substructure consists of connected P_8 cages of regular type and planar P_4 rings. Needle-shaped crystals are typical of the alkali metal compounds MP_{15}, MP_{11}, and $MP_{10.3}$.[152–154] The fivefold ${}^{1}_{\infty}(P_{15}^{-})$ tubes represent the polymerization of alternating P_7^{-} and $P_8^{\pm 0}$ units, the former a norbornane derivative of the latter, and comparable with the As_4S_4 molecule. In principle, the sequence of P_7^{-} and P_8 may be variable, but the 1:1 structure seems to be the optimized modulation in crystalline compounds. In $KP_{10.3}$ and $RbP_{10.3}$, units such as P_{35}^{-} were identified in a preliminary study (an extremely complicated twofold, noncommensurate superstructure). On the other hand, the structures of the very closely related RbP_{11} and CsP_{11} are characterized by ${}^{1}_{\infty}(P_{15}^{-})$ tubes and ${}^{1}_{\infty}(P_7^{-})$ chains of type 5. The repetition lengths of P_{15}^{-} and P_7^{-} chains correspond as $\tau(P_{15}^{-}) = 2\tau(P_7^{-})$. Therefore, a whole series of compounds with twin-slab structures may exist in a very narrow compositional range, differing slightly in energy but, of course, having very different kinetics. Linear fivefold tubes are also characteristic for ternary phases like $HgPbP_{14}$ and for the chalcogenides $P_{14}S$ and $P_{14}Se$, respectively.[155–158] Lead and sulfur act as heteroatoms in the frame. The above mentioned alternation of P_7^{-} and $P_8^{\pm 0}$ subunits is a necessary condition to form strain-reduced tubular structures. Thus no ${}^{1}_{\infty}(P_5^{-})$ structures exist in crystalline compounds. In LiP_5,[146] a strain-free 3-D structure with P_6 chairs is formed. Another possibility is realized with TlP_5 and BaP_{10},[159,160] where the curvature of ${}^{1}_{\infty}(P_5^{-})$ tubes is compensated for by the formation of an upside down polymerization of those tubes and results in a corrugated complex 2-D structure of alternating parallel and antiparallel oriented fivefold tubes that are partially opened at the roofs (Figure 11; Table 8).

The winding of these tubes into spirals results in the structures of LiP_7 and NaP_7.[161] The fourfold ${}^{1}_{\infty}(P_7^{-})$ helix is a very rigid building unit and not suited for the larger alkali metals. This unit is especially interesting with respect to its dimensionality. It represents, on one hand, a more complicated 1-D chain, where the chain links are connected via two bonds in both directions, typical for the tubelike chains. On the other hand, by looking at the tubes as rolled-up surfaces, the phosphorus substructure of LiP_7 is a rolled-up 2-D structure that results in different curvature and strain in the central and peripheral regions. The structures of $K_4P_{21}I$, Ag_3P_{11}, and Cu_2P_7 (with polymers of P_7^{-}, P_{11}^{3-} and P_7^{2-}) are characterized by 2-D arrangements of connected short tubelike parts, whose connection result in larger P_n rings, appropriate as cavities for the other atoms.[110,149,162]

There is one very impressive feature in all tubular chains and in structures with shorter or longer parts of these, that is, the wavelike development along the chain direction.

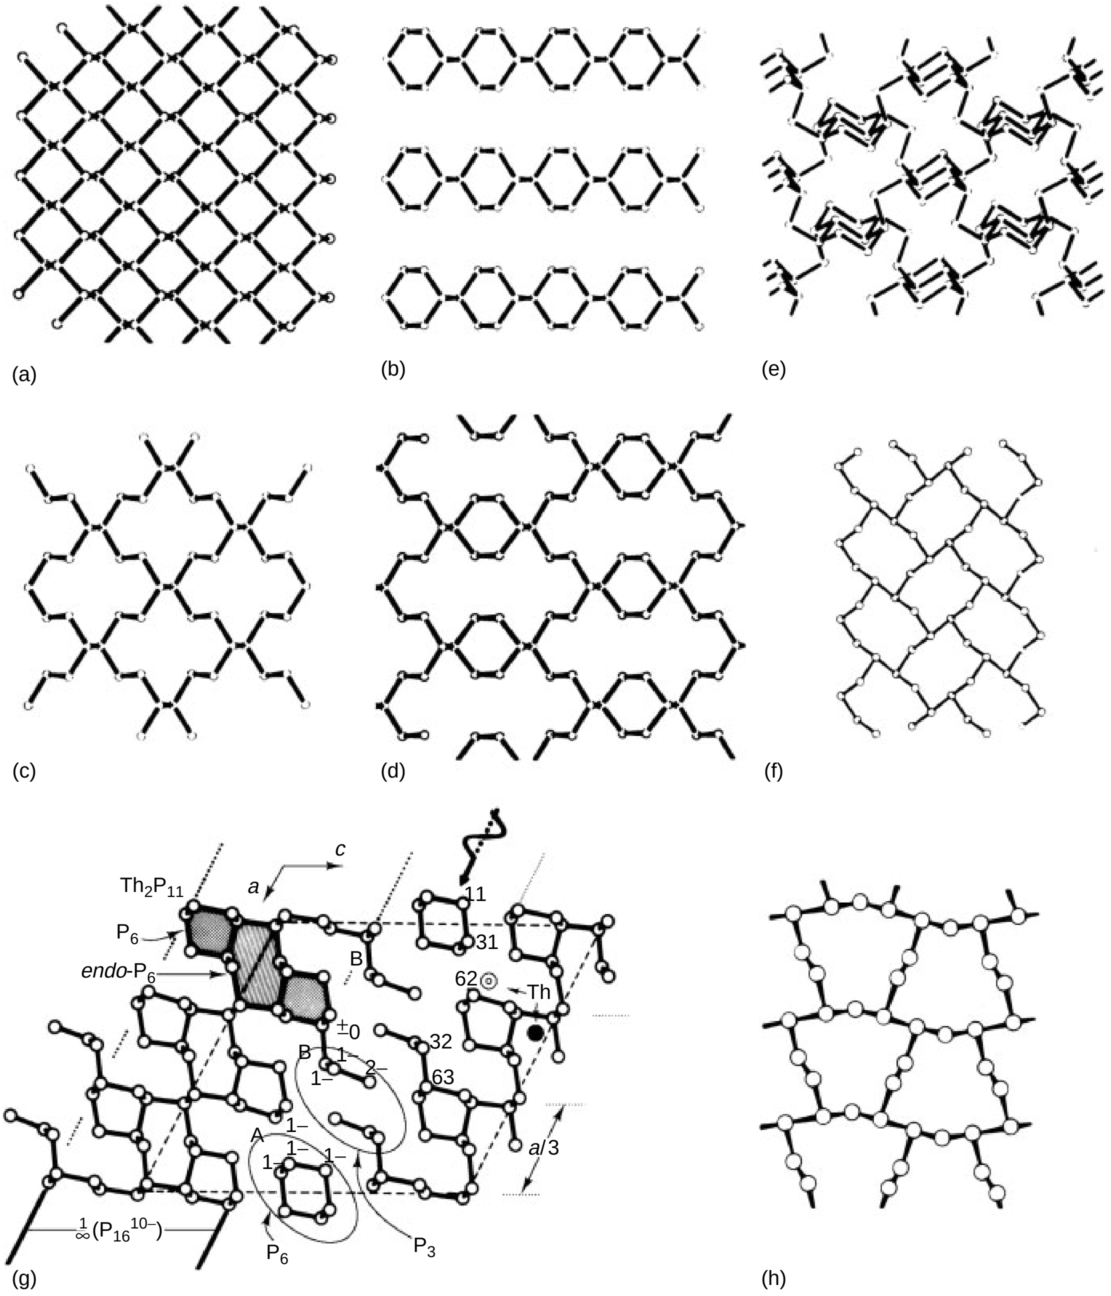


Figure 10 (a) Black phosphorus; its derivatives (b) BaP_3; (c) CaP_3 and α-EuP_3; (d) β-SrP_3 and β-EuP_3. (e) Shows the ${}^{3}_{\infty}(P_5{}^{-})$ network of LiP_5 and (f) the condensed P_{10} rings of MgP_4 (similar network exists in CuP_2). (g) Shows the substructure ${}^{1}_{\infty}(P_{16}{}^{10-})$ of Th_2P_{11} with inserted $P_6{}^{6-}$ rings. The arrow gives the direction of modulation while A and B (each circled) denote the two stages of modulation. (h) The ${}^{2}_{\infty}(P_5{}^{3-})$ unit of LnP_5

6.5.7 Phosphorus Frameworks in Matrices

Although some of these compounds belong indeed to the phosphide halides (see Section 6.7.2), they are discussed separately here, owing to their interesting structural features. The monovalent copper halides CuBr and CuI act as solvents for a large variety of polymeric and oligomeric main-group molecules. The first compound of this structural family was $Cu_2P_3I_2$, that is, $(CuI)_8P_{12}$.[151] Also, the compounds $(CuI)_3P_{12}$ and $(CuI)_2P_{14}$ with phosphorus strands similar to Hittorf's phosphorus have been reported.[163] All of these structures can be considered as neutral phosphorus substructures that are embedded in a copper halide matrix. Some of the neutral phosphorus fragments are presented in Figure 12. As an example for the packing of the 1-D phosphorus units in the copper halide matrix, the structure of $(CuI)_2P_{14}$[164] is

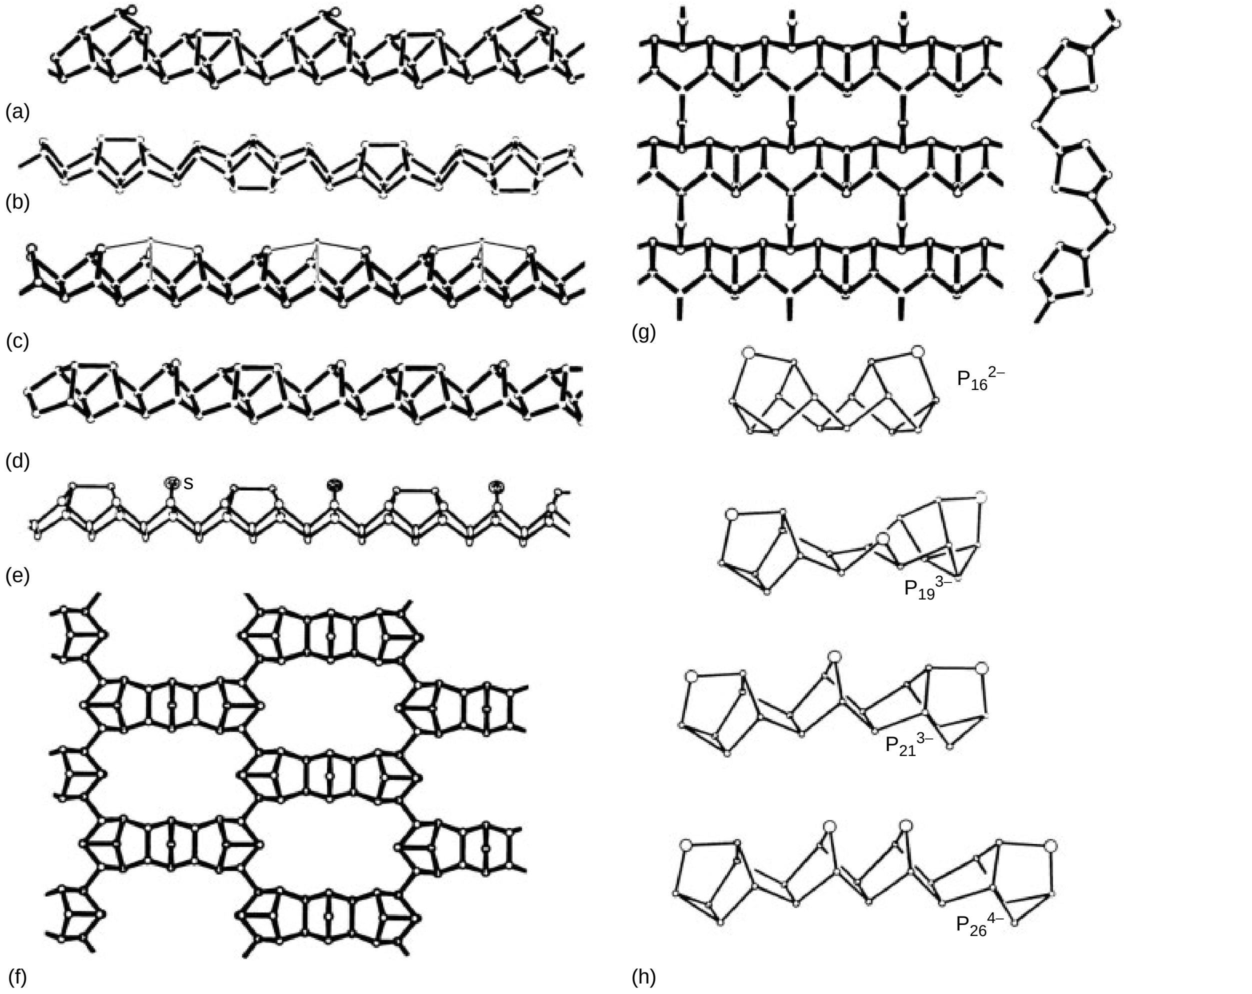

Figure 11 (a) Tubular unit in P (Hittorf); (b) $Cu_2P_3I_2$: ${}^{1}_{\infty}(P_{12}{}^{\pm 0})$ polymer generated by glide plane operation from P_{12} units; note the fragments P_8 (cf. Figure 7a) and P_4 rings; (c) framework ${}^{1}_{\infty}(P_{14}M^{II})$ as in the structure of $HgPbP_{14}$ type (M^{II} indicated by small spheres); (d) ${}^{1}_{\infty}(P_{15}{}^{-})$ from MP_{15}; (e) ${}^{1}_{\infty}(P_{14}S)$ (isoelectronic with $P_{15}{}^{-}$); (f) ${}^{2}_{\infty}(P_{21}{}^{3-})$ framework from $K_4P_{21}I$; (g) 2-D arrangement of linked pentagonal tubes as found in BaP_{10} and TlP_5 (seen perpendicular and parallel to the puckered layer); (h) structures of polyanions from solutions (cf. Table 8)

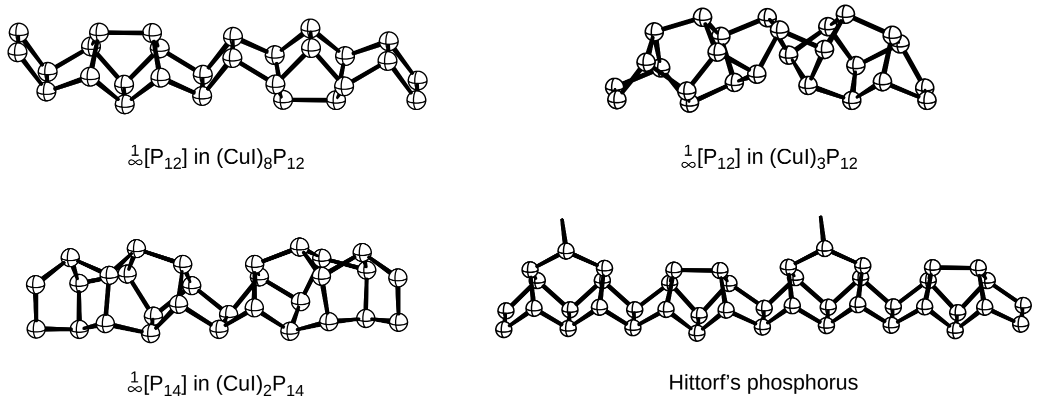

Figure 12 Phosphorus units in the structures of $(CuI)_8P_{12}$, $(CuI)_3P_{12}$, and $(CuI)_2P_{14}$ as compared to Hittorf's phosphorus

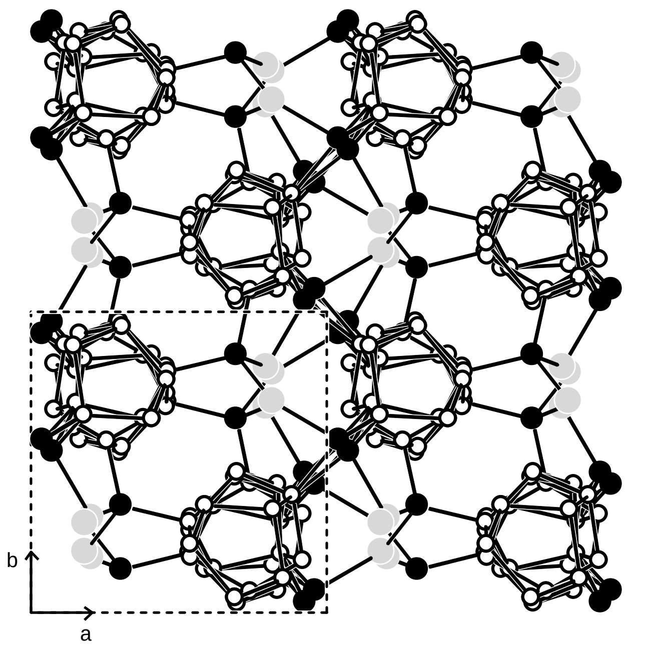

Figure 13 View of the $(CuI)_2P_{14}$ unit cell along the [001] direction. Copper, iodine, and phosphorus atoms are drawn as black filled, grey, and small open circles, respectively. The phosphorus substructure and some relevant Cu–I and Cu–P bonds are emphasized

shown in Figure 13. Besides the neutral substructures, also some fragments with 1-D phosphorus anionic units exist, like ${}^1_\infty[P_{15}{}^{1-}]$ in $(CuI)_2CuP_{15}$[165] or ${}^1_\infty[P_{20}{}^{2-}]$ in $(CuBr)_{10}Cu_2P_{20}$.[166] All tubular phosphorus modifications (see Section 6.5.6) can be considered as to be constituted from five and six-membered rings, however, one can easily recognize well-known building units, for example, the P_8 realgar analogue, the norbornane analogue as well as four-membered rings. It is thus not astonishing that these compounds form. We note, that some of these tubular units observed in the copper phosphide halides have been theoretically predicted by Häser to be more stable than other isomeric forms.[167] This structural concept has also been extended to molecules like P_4Se_4 in $(CuI)P_4Se_4$[168] or $(CuI)_3P_4Se_4$.[169]

The CuI containing compounds have been investigated with respect to a potential copper ionic conductivity.[170,171] First hints for a copper mobility were obtained by Möller and Jeitschko through the ion exchange reaction in aqueous $AgNO_3$ solution: $Cu_2P_3I_2 + 4Ag^+ \rightarrow Ag_2P_3I_2 + 2Ag\downarrow + 2Cu^{2+}$.[151] During the reaction, elemental silver is deposited and the reaction solution becomes blue owing to solvated Cu^{2+}. Conductivity data (impedance spectroscopy) show predominantly ionic conductivity for $(CuI)_8P_{12}$ and $(CuI)_3P_{12}$ with activation energies of 0.45 and 0.59 eV. In contrast, $Cu_3P_{15}I_2$ has a predominantly electronic conductivity with a higher activation energy of about 0.72 eV.[171] A remarkable feature in $Cu_6P_{10}Br_5$ as well as in $Cu_3P_{15}I_2$ is the occurence of neighbouring copper cations (3x and 2x) along the spine of the tubular units, leading to some hints of enhanced ion mobility along the needle axis (tube axis).

The only compounds in the system carbon–phosphorus which have been considered up to a distinct level are compounds with a substitutional replacement in C_{60} like $C_{59}P$ or $C_{69}P$,[172] endohedral $P@C_{60}$,[173] and a crystallization product between neutral C_{60} and neutral P_4, that is, $(P_4)_2C_{60}$.[174]

6.5.8 *Isomerism*

In solid-state structures of polyphosphides, one observes all limiting cases of formal charge distribution within different isomeric polyanionic networks, for example,

$$(P_3)^{3-} : CoP_3\{[(2b)P^-]_3\} \hat{=} {}^1_\infty\{[(3b)P^0][(2b)P^-][(1b)P^{2-}]\}RuP_3 \quad (2)$$

$$(P_4)^{6-} : Sr_3P_4\{[(2b)P^-]_2[(1b)P^{2-}]_2\} \hat{=} \{[(3b)P^0][(1b)P^{2-}]_3\}Ni_5P_4 \quad (3)$$

Here, both 'isomers' are homogeneous with respect to their partial structures. Heterogeneous mixtures are

$$P_3{}^{7-} : CeSiP_3\{[2(0b)P^{3-}] + {}^1_\infty[P^-]\} \hat{=} \{[(0b)P^{3-} + P_2{}^{4-}]\}AlSiP_3 \quad (4)$$

$$P_4{}^{6-} : \alpha\text{-}CeP_2\{[2P_4{}^{6-}]\} \hat{=} \{[P_3{}^{5-} + P_5{}^{7-}]\}\beta\text{-}CeP_2 \quad (5)$$

Further examples are the two SiP_2 modifications with $P_2{}^{4-}$ dumbbells on one side and $\{^1_\infty(P^-) + P^{3-}\}$ on the other. The pair MoP_2/TiP_2 with $q(M) = 4$ behaves analogously, but with additional Mo–Mo interactions in MoP_2.

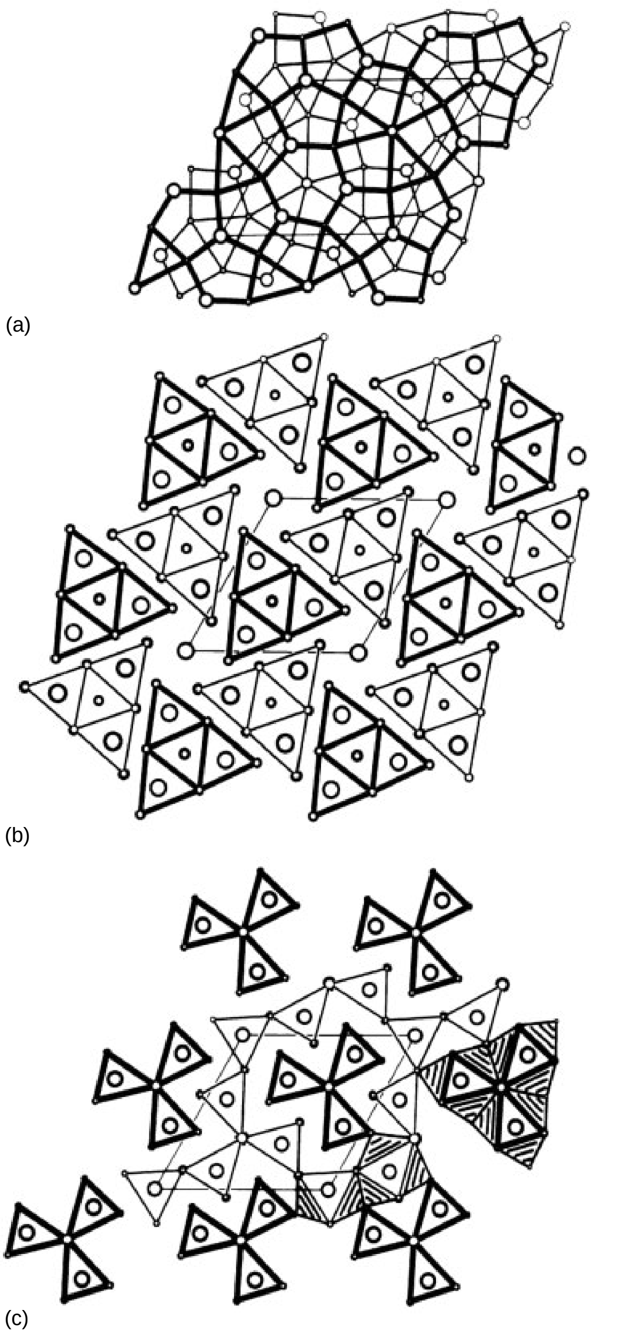
The phosphide sulfides GdPS, CoPS, and NbPS ($q(M) = 3$) contain $\{^1_\infty(P^-) + S^{2-}\}$, $\{(P_2{}^{4-} + S_2{}^{2-})$ or $(PS^{3-})\}$, and $\{(P_2{}^{4-} + S_2{}^{2-}) + Nb_2$ pairs$\}$.

6.6 Metal-rich Transition Metal Phosphides

The metal-rich varieties of the transition metal phosphides have many structures and properties in common with the so-called refractory hard metals. In these compounds, MP_x, the M–M interactions become increasingly important with decreasing x. This is indicated by the M–M distances which are in the region of metallic and also of covalent diameters ($2R_{met}$ and $2R_{cov}$, respectively). The difference with closed-shell cations is clearly demonstrated by comparison of the isotypic pair Na_2O/Rh_2P with the ratio $d(M–M)/d(M–X) = 1.155$. The transparent insulator Na_2O has $d(Na–Na) = 278\,pm < 2R_{cov} = 314\,ppm$ $\langle 372\,pm = 2R_{met}$; the closed-shell cations Na^+ have no electrons for Na–Na bonds and, therefore, the close M–M approach has no effect. On the other hand, the opaque 'hard' metal Rh_2P has $d(Rh–Rh) = 275\,pm \sim 2R_{met} = 270\,pm > 2R_{cov} = 250\,pm$; obviously, the Rh–Rh approach at d(Rh–Rh) is sufficient for M–M interactions because of the open-shell configuration of the Rh cations. Sometimes it may be difficult to state that M–M bonding exists without knowledge of the electronic band structure, however, excellent proof is provided by the occurrence of distinct clusters (M_2 pair, M_3 triangle, empty M_6 cluster).

The structures of the metal-rich transition metal phosphides are primarily governed by the M-atom arrangement, whose octahedral and trigonal prismatic holes are partially centered by isolated P atoms. Trigonal prismatic (tp) sixfold coordination dominates, and is frequently extended up to ninefold coordination by additional atoms above the rectangular prism faces (mono-, di-, tricapped). Depending on how it is described a structure can emphasize quite different patterns of repeating units; this is demonstrated for $Zr_2Fe_{12}P_7$ in Figure 14.[175]

1. Metallurgists act like egalitarians in describing structures as stackings of nets where all atoms become simple nodes, classified with Schläfli symbols. Owing to this, all differentiation between the atoms is lost. The $Zr_2Fe_{12}P_7$ structure is formed by two different nets at two different heights, that is, the net $\{5^3 + (456)_3 + (4356)_3 + (343434) + (345^2)_3\} \hat{=} ZrFe_6P_4$ (drawn bold in Figure 14(a)) and the net $\{(343434) + (3464)_3 + (4^26)_3 + (3434^2)_3 \hat{=} ZrFe_6P_3$ (drawn thin in Figure 14a).
2. Dividing structures into suitable units can serve to rationalize a series of structures by one formula. The resulting vacant sites may be filled by additional atoms



(a)
(b)
(c)

Figure 14 Three different representations of the $Zr_2Fe_{12}P_7$ structure type projected along the c axis. Atoms connected by thin and thick lines are separated from each other by half a translation period. Smallest circles are Fe atoms, medium circles Zr atoms, large circles P atoms. (a) Two different nets in two different heights. For the Schläfli symbols, see text. (b) Large trigonal prismatic building blocks AB_6C_3 from four trigonal B_6 prisms (with overemphasized schematic separation of blocks in different heights). Note that the three outer B_6 prisms of the blocks are base centered. The vacant sites between the blocks are filled with the P atoms. (c) Trigonal prism strands $^1_\infty[ZrFe_6P_3]$ and an open network of trigonal prisms $^3_\infty[ZrFe_6P_4]$. The threefold capping of the trigonal prisms is emphasized at the upper right. This leads to a complete 3-D structure with CN 9 for the P atoms

(Figure 14b). Here $Zr_2Fe_{12}P_7$ is a member of the family with the generalized formula $A_nB_{(n+1)(n+2)}C_{n(n+m)+1}$ with $n,\ m = 1$. Hereby blocks of prisms of composition $AB_6C_3 \hat{=} ZrFe_6P_3$ are evident. The vacant site is filled by a P atom: $2\ ZrFe_6P_3 + P \hat{=} Zr_2Fe_{12}P_7$. This purely geometrical description is extremely helpful in differentiating the huge family of metal-rich phosphides.

3. The more individual the chemical description, the better the structure is identified in terms of different bonding or interaction. The appropriate fundamental units in the present structures are, therefore, the P-centered trigonal prisms, sometimes extended by their trigonal prismatic caps. In this way, the $Zr_2Fe_{12}P_7$ structure is separated into two interpenetrating patterns of trigonal prisms, that is, a tristar ${}^1_\infty[(PFe_{4/2}Zr_{2/6})] \hat{=} P_3Fe_6Zr$ and an infinite net with ${}^1_\infty[PFe_{6/4}(PZr_{2/6}Fe_{2/2}Fe_{2/4})_3] \hat{=} P_4Fe_6Zr$. The interaction of these subunits to a complete 3-D structure is performed by threefold capping of the trigonal prisms (Figure 14c).

6.6.1 M_3P and Related Structures

The Fe_3P type, Ti_3P type, and α-V_3S type are a group of similar structures, characterized by a frame of M atoms whose patterns are related to the stella quadrangula pattern as derived from the tetraederstern motif; this is very common in intermetallic phases.[13,121] The M-atom frame may also be seen as intersecting thin slabs of a face-centered cubic metal. The channels are filled by 1-D columns of slightly distorted M_4P_4 heterocubane units, showing a clear separation of M_2 regions and MP regions, respectively. The P atoms have CN 9 and CN 8. The $Ni_{12}P_5$ structure is related to the above cited types, but with a different pattern of the M-atom frame. This now corresponds to a simple cubic arrangement whose cubic holes are alternating, centered by P atoms (CsCl type), as in the Ni_8P unit. Again the channels are filled by Ni_4P_4 columns, resulting in $Ni_{12}P_5$. The latter P atoms are 10-fold coordinate (Figure 15).

A second group of M_3P phases has the cementite Fe_3C structure (Table 3) built from distorted trigonal prisms and octahedra of M atoms, the former centered by P as well as M. The complete structure can be derived from a hexagonal close-packed M structure by twinning. The $Pd_{4.8}P$ structure is a modified Fe_3C type.

6.6.2 M_2P and Related Structures

The M_2P phases form mainly four structure types: Co_2P, Fe_2P, Ta_2P, and Rh_2P. The Co_2P type is a branch[176] of the widely occurring $PbCl_2$ structure with chains of twofold-linked tricapped trigonal prisms centered by P atoms (Figure 16). Ternary representatives are ZrFeP, TiFeP, and so on. Some modifications may occur in the direction of the related Co_2Si type with dicapped trigonal prisms.

The Fe_2P type demonstrates another variety of tricapped prism linkage, that is, a disproportionation into isolated and threefold linked units. Completely different is the Ta_2P structure[177] (Figure 16), where condensed M_6X_8 clusters and strings of condensed M_4 tetrahedra can be recognized: ${}^1_\infty[Ta_6Ta_{4/2}P_{12/2}] + {}^1_\infty[Ta_4] = Ta_{12}P_6$. Again the P atoms are trigonal prismatically coordinated. Nb_7P_4 is closely related, forming simple 1-D cluster chains with single Nb atoms completing the P coordination to trigonal prisms: ${}^1_\infty[Nb_4Nb_{2/2}P_{8/2}] + 2Nb = Nb_7P_4$. Another related arrangement is adopted by Nb_8P_5.[178]

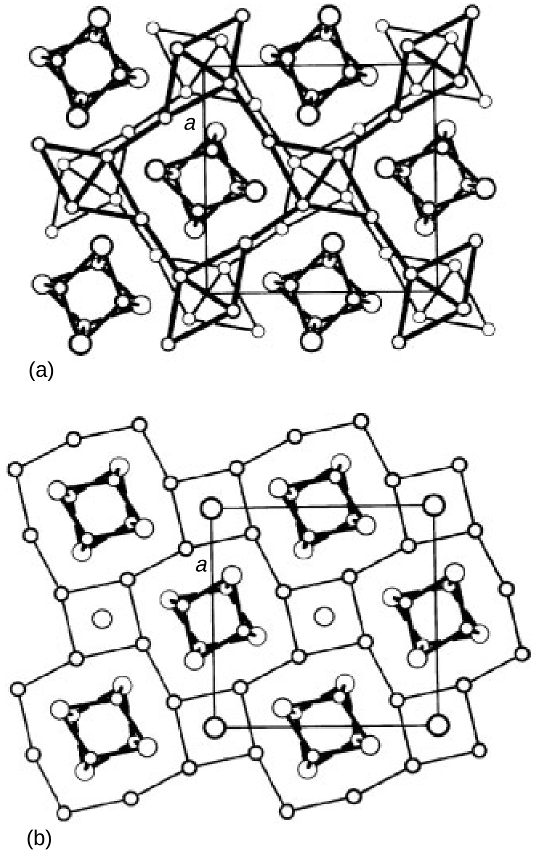


Figure 15 (a) Ni_3P type with emphasized 1-D heterocubanes Ni_4P_4 and tetraederstern network. (b) $Ni_{12}P_5$ type with heterocubanes Ni_4P_4 and connected PNi_8 cubes. Small circles are Ni atoms, large circles P atoms

A huge series of ternary phosphides $M_mM_nP_x$ exists with $m + n \sim 2x$ having structures with (mainly) tricapped trigonal prisms around phosphorus, for example, Co_2P and Fe_2P. Depending upon the M/M′ ratio in the range $1 > M/M' > 0.125$ ($ZrRuP$–$LaCo_8P_5$), patterns of fascinating shapes occur, which can be regarded as higher homologues of the Co_2P chains and Fe_2P stars.

The field of transition metal-rich phosphides in the ternary systems R–T–P (R = Zr, Hf, rare earth metal, actinoid metal) has intensively been investigated in the last 10 years by the groups of Franzen and Kleinke, Guérin, Jeitschko, Kuz'ma, and Mewis. From a geometrical point of view, the main building motifs of these structures are mono-, di-, or tricapped

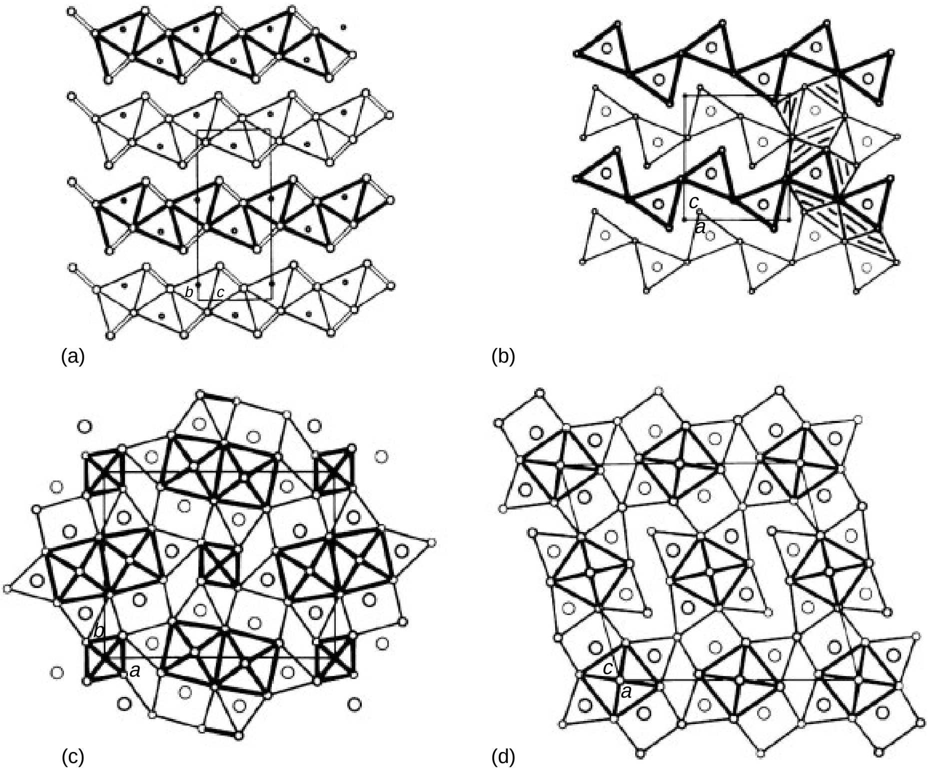

Figure 16 Top: AB_2 structure types with emphasized trigonal prisms. Thin and thick lines connect atoms that are separated from each other by half a translation period of the projection direction. Small circles are metal atoms, large circles phosphorus atoms: (a) MoP_2, the $P_2{}^{4-}$ dumbbell is indicated by an open thick bond; (b) Co_2P ($PbCl_2$) with layers of trigonal prisms. Some empty half octahedra have been indicated in the right. Below: phosphides with condensed and isolated metal octahedra: (c) Ta_2P with condensed M_6 octahedra, in which note the 1-D chain of $Ta_{4/2}$ between the octahedra: (d) Nb_7P_4 with emphasized octahedra; small circles are metal atoms, large circles P atoms. Note that in (c) and (d) the P atoms are in positions corresponding to X in M_6X_8 clusters

trigonal prisms around the phosphorus atoms. This crystal chemistry is to some extent similar to silicide chemistry.[179] The different patterns of the connectedness of the trigonal prisms was summarized in a recent review by Kuz'ma and Chykhrij.[14] A survey on the phase diagrams and the typical coordination polyhedra was given by Chykhrij.[15] Many of these metal-rich phosphides belong to structural families with distinct building rules.[179–181]

M′–M′ bonding plays an important role in most of these compounds, owing to the large transition metal content. Thus, one observes a large variety of M′–M′ bonds in the various structure types of transition metal-rich phosphides. As examples, we present the cobalt and iron substructures of the $Yb_6Co_{30}P_{19}$[182] and $La_2Fe_{25}P_{12}$[183] structures (Figure 17). The pronounced M′ networks leave larger channels where the rare earth or actinoid metal atoms are located. Overviews on other M′ substructures have been reported.[184–186] In these drawings, only M′–M′ distances shorter than 280 pm are shown.

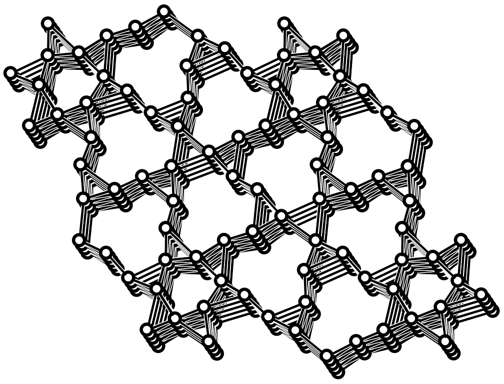
6.6.3 *Phosphide Structures with* $x > 0.5$

Ti_5P_3 (Mn_5Si_3 type)[187] is a member of the face-condensed octahedral M_6X_8 clusters: ${}^1_\infty(Ti_{6/2}P_{6/2})$. The packing of the cluster columns forms large channels which are filled by 1-D linear Ti chains with short Ti–Ti distances (254 pm). The structure ${}^1_\infty[Ti_2(Ti_3P_3)]$ is directly comparable with that of (□K)(Mo_3Se_3). The empty M_6 octahedra may be filled for electronic reasons by C and N (a well-known feature of cluster compounds), yielding the Nowotny phases (e.g. V_5P_3N).

Other real cluster compounds are $Ag_6Ge_{10}P_{12}$ and $Ag_6Sn_4Ge_6P_{12}$ with the units $\{[Ag_6Ge^{II}_4]P_{12}\}$ and $\{[Ag_6Sn^{II}_4]P_{12}\}$ connected by Ge^{IV} to a 3-D structure.[188] The cluster units are $Rh_6(\mu_3\text{-}CO)_4(CO)_{12}$ analogs with $Ag_6{}^{4+}$ octahedra which are fourfold μ_3-capped by Ge^{II} and Sn^{II}, and bonded to 12 P atoms as exo ligands. These systems act as thermally activated threefold two-level systems (Figure 18).[189]

Transition metal clusters can also occur in compounds with a much higher phosphorus content. A recent example is the structure of Ag_3SnP_7,[190] which contains isolated tetrahedral Ag_3Sn clusters and ${}^1_\infty[P_7]$ chains (Figure 12). Similar distorted tetrahedral Cu_3Sn clusters occur also in the Cu_4SnP_{10} structure described in Section 6.5.2.[107]

Hf_3P_2 has the Sb_2S_3 structure with a 3-D net of connected groups of six condensed Hf_6 *tp*'s, four of which are P centered and monocapped.[191] Rh_4P_3 forms parallel zig-zag slabs of *tp*'s with different orientation, alternately centered by the P



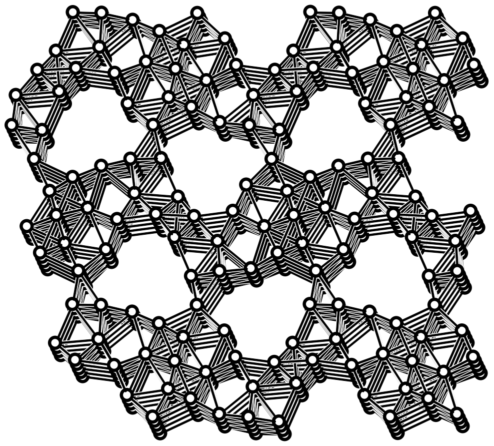


Figure 17 Transition metal substructures in $Yb_6Co_{30}P_{19}$ and $La_2Fe_{25}P_{12}$. All Co–Co and Fe–Fe distances equal or smaller than 280 pm are drawn

atoms.[192] Mo_4P_3 is related but with larger NiAs-type segments. In both structures, phosphorus has CN 7 and 6. The Re_3P_4 structure is a deficient variant of NiAs (□Re_3As_4) and is also related to cluster compounds.[193] Triplets of face-condensed P_6 octahedra are centered by Re atoms forming linear Re_3 groups. The octahedra are further connected via common edges.

Many more complex structures of metal-rich phosphides can be formally cut into 2-D slabs of different size and can thus be considered as intergrowth structures.[194,195] These slabs are parts of quite different arrangements but have common areas which fit together. The structures of the small slabs derive from simple binary or ternary types like AlB_2, Cu_3Au, $CeMg_2Si_2$, SrPtSb, $CaAl_2Si_2$, $ThCr_2Si_2$, or $CaBe_2Ge_2$. As examples, the structures of $Ca_5Pd_6P_6$, $Ca_4Pd_5P_5$,[196] $Ca_3Cu_2Zn_2P_4$, $Ca_4Cu_3Zn_2P_5$,[197] $Sr_2Pd_3P_3$,[198] and $Eu_2Pt_7AlP_3$[199] are presented in Figure 19. Such intergrowth structures are also formed in the families of pnictide oxides and arsenides.[200] Even more complex intergrowth structures of Cu_3P, $LaLi_3P_2$, and $PrLi_2P_2$ related

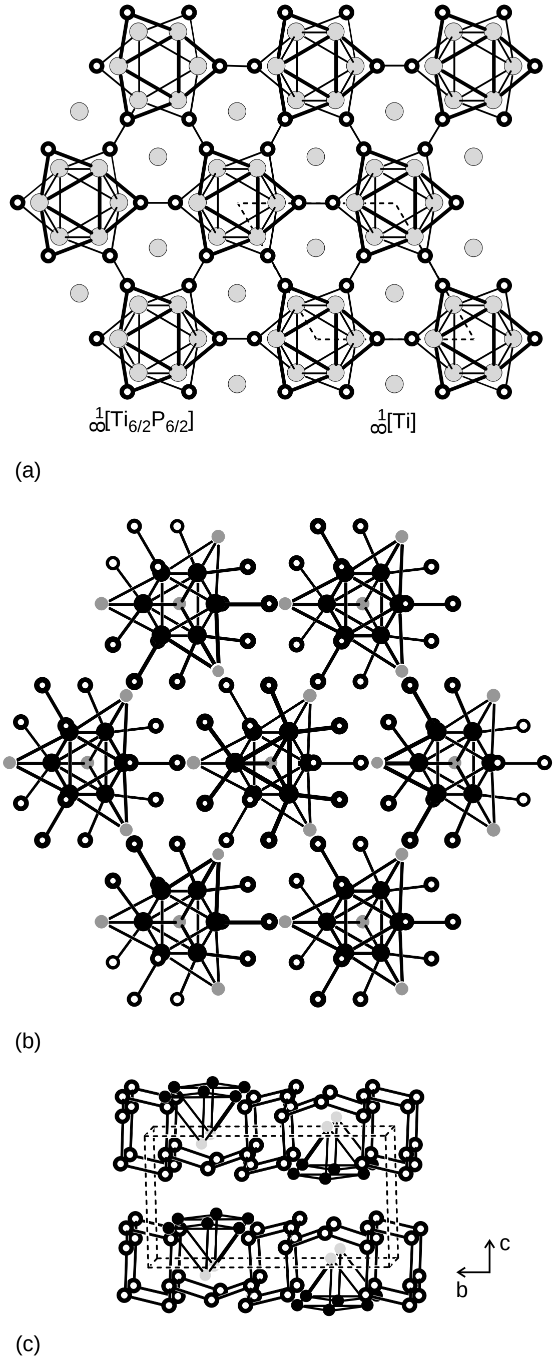

Figure 18 (a) M_5P_3 (Mn_5Si_3 type) structure of Ti_5P_3 with emphasized $_{\infty}^{1}[Ti_{6/2}P_{6/2}]$ octahedral chain and $_{\infty}^{1}[Ti]$ metal-atom piles. The chain $Ti_{6/2}P_{2/2}$ corresponds to face-condensed M_6X_8 clusters (2X are omitted). Small circles are Ti atoms, large circles P atoms. (b) $M_6M'_4M''_6P_2$ structure showing $[Ag_6M^{II}_4]P_{12}$ cluster in $Ag_6Ge_{10}P_{12}$, view along the cubic [111] direction. Small circles are Ge^{II} atoms, medium circles Ag atoms, large circles P atoms. The Ge^{IV} atoms as well as the unit cell edges have been omitted for clarity. The Ge^{IV} atoms are in tetrahedral holes formed by the P atoms of neighboring clusters; (c) view of the Ag_3SnP_7 structure approximately along the [100] direction (Ag, black filled circles, Sn, grey circles, P, open circles). The tetrahedral Ag_3Sn cluster and the $[P_7]$ network are emphasized

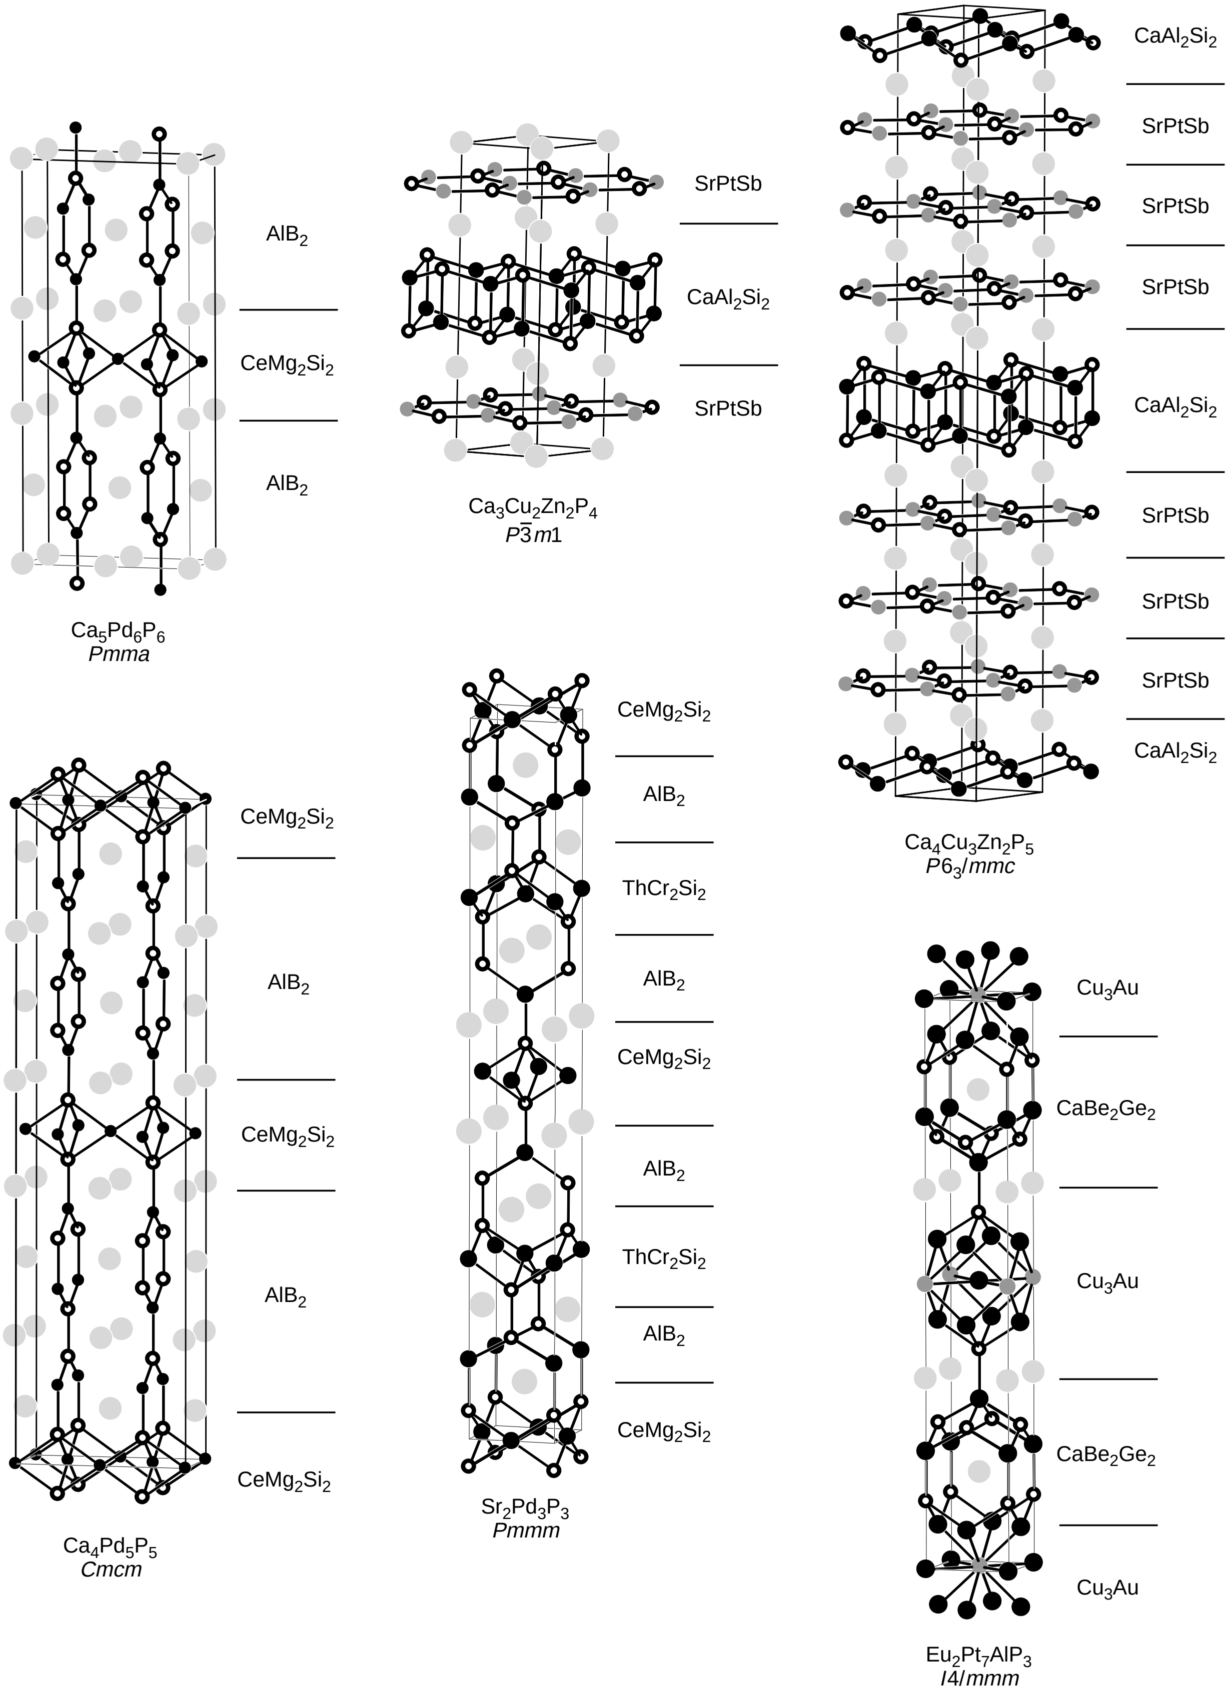

Figure 19 Some examples of slab structures (longest crystallographic axes in upright position)

slabs occur for the rhombohedral structures of $Yb_3Cu_{8-x}P_6$ and $Y_3Cu_{8-x}P_8$[201,202] with values of up to 60 Å for the c axis. Also, the $Ho_2Cu_{6-x}P_{5-y}$ structure belongs to this family.

In this context, it should be emphasized that the phosphides of the $BaAl_4/ThCr_2Si_2$ type show various P–P distances which change their length with size and electron configuration of the M atoms. Compounds like $CaCu_{1.75}P_2$ (225 pm P–P distance) or $CaNi_2P_2$ (230 pm) have P_2 pairs with a P–P single bond, while the bond order (see Sections 4.1 and 4.2) in $CaCo_2P_2$ (245 pm) is around 0.5.[203] Other phosphides have much longer P–P distances (up to 384 pm in $BaFe_2P_2$[203]) and consequently have no P–P bonds. The influence of the electron count on M–P and P–P bonding in such phosphides has theoretically been investigated by Hoffmann and Zheng.[204–206] So far, more than 600 compounds crystallize with the $BaAl_4/ThCr_2Si_2$ type. Just and Paufler have listed the c/a ratios of all of these compounds and they analyzed the dependence of the z parameter of the X atoms from the c/a ratio.[207] In a recent work, it was clearly demonstrated that there are definitely two branches for this family of compounds: the $BaZn_2P_2$ branch with isolated phosphorus atoms and the $BaAl_4/ThCr_2Si_2$ branch where Al–Al and Si–Si bonds (or X–X bonds in general) occur.[208,209] The simple formula $d_{X\text{–}X} = (0.16 + 0.04(c/a))\cdot c$ allows a fast estimation of the X–X distance. Changes of the P–P distance under high pressure also influence the oxidation state of the transition metal (see Section 8.6).

6.7 Phosphide Oxides, Halides, and Hydrogenphosphides

The first proof for an oxygen incorporation in pnictides was found with Eu, not for a phosphide, but for an antimonide.[5,210] Later on, more systematic studies of the quasibinary systems M_3Pn_2–MX_2 and M_3Pn_2–MO (M = Ca, Sr, Ba, Eu; X = O, Cl, Br, I; Pn = P, As, Sb) by Hadenfeldt and coworkers[211–213] led to a series of new compounds. Further on, phosphide oxides have been obtained during phase investigations of the binary alkaline-earth metal–phosphorus systems.[214] Most likely oxygen was gettered in the samples through oxydic or hydroxidic surface impurities of the alkaline-earth metals. In recent years, also a huge number of quaternary phosphide oxides with ZrCuSiAs and related structures[215] and a variety of phosphide halides with peculiar crystal structures have been reported.[216,217] The main difference of these solid-state compounds to phosphorus halides and phosphates is the absence of P–O and P–X bonds.

6.7.1 Phosphide Oxides

The first hints for phosphide oxides have been observed by Maass in 1970.[218,219] He obtained products assumed to be the phosphides Sr_2P and Ba_2P during phase analytical investigations in the systems Sr–P and Ba–P, but he already suspected that these phases might indeed be phosphide oxides. Detailed X-ray investigations by Hadenfeldt and coworkers revealed the correct compositions AE_4P_2O (AE = Ca, Sr, Ba).[211,213] These phosphide oxides crystallize with a tetragonal K_2NiF_4 or orthorhombic La_2CuO_4 type structure (Figure 20) with an octahedral OM_6 coordination of the oxygen atoms. According to the Zintl-Klemm electron transfer, the cations M^{2+} and the anions P^{3-} and O^{2-} are present, and thus these phosphide oxides are expected to be insulators or semiconductors that correspond, for example, with the greenish yellow color of Ca_4P_2O.

Besides the ternary phosphide oxides, a huge number of quaternary transition metal-containing phases has been reported. The $Ba_2Mn_3P_2O_2$ structure[220] (Figure 20) has octahedrally coordinated oxygen atoms (4Ba + 2Mn). The Mn2 and phosphorus atoms form a tetrahedral network that resembles the RET_2P_2 phosphides with $BaZn_2P_2$ structure (see Section 6.6.3). The manganese atoms in these pnictide oxides show magnetic ordering at comparatively high Néel temperatures.[214] Octahedral oxygen coordination also occurs in the phosphide oxides $Na_3Sr_7(P_3)_3O$, $Na_3Eu_7(P_3)_3O$,[221] $Th_4Fe_{17}P_{10}O_{1-x}$,[222] and $Ba_{11}KP_7O_2$.[223] The $Na_3Sr_7(P_3)_3O$ structure contains bent P_3^{5-} units while isolated P^{3-} and dimeric P_2^{4-} anions occur in $Ba_{11}KP_7O_2$. All phosphorus atoms in $Th_4Fe_{17}P_{10}O_{1-x}$ are isolated with trigonal prismatic coordination.

All of the remaining transition metal-containing phosphide oxides have oxygen atoms in a tetrahedral coordination of rare earth or actinoid atoms. So far 35 isotypic phosphide oxides with ZrCuSiAs type structure (Figure 20) have been reported, that are ThCuPO,[224] UCuPO,[225] and the rare earth series REMnPO,[226] REFePO, RECoPO,[227] REZnPO,[228] and RERuPO[227] with the early rare earth metals. According to the isolated phosphorus atoms we can formulate, for example, $RE^{3+}Fe^{2+}P^{3-}O^{2-}$. Several crystals of these phosphide oxides have a golden tint while powders are dark grey. Certainly, chemical bonding in RETPO is not purely heteroatomic and one can at least assume some weak T–T bonding.[226,227] Besides the simple ZrCuSiAs type, the tetragonal structures $U_2Cu_2P_3O$,[229] $Th_2Ni_{3-x}P_3O$,[224] and $La_3Cu_4P_4O_2$[215,230] have been reported. These structures have a much longer tetragonal axis and they may be considered as intergrowth structures of simple slabs that derive from the $HfCuSi_2$, $CaBe_2Ge_2$, and $BaZn_2P_2$ type structures (for details see Ref. 224 and 230). Only the phosphorus atoms in $Th_2Ni_{3-x}P_3O$ and $La_3Cu_4P_4O_2$ form pairs. The only exception in the series of phosphide oxide structures (all other structures presented in Figure 20 are tetragonal) is the rhombohedral NdZnPO type.[228] Also, this structure is built up from NdO layers with tetrahedrally coordinated oxygen and from ZnP layers (Figure 20). According to the transparent crystals and the formal oxidation states $Nd^{3+}Zn^{2+}P^{3-}O^{2-}$, one expects semiconducting behavior.

6.7.2 Phosphide Halides

The occurrence of ternary compounds containing phosphorus besides halogen is a small but still increasing field of

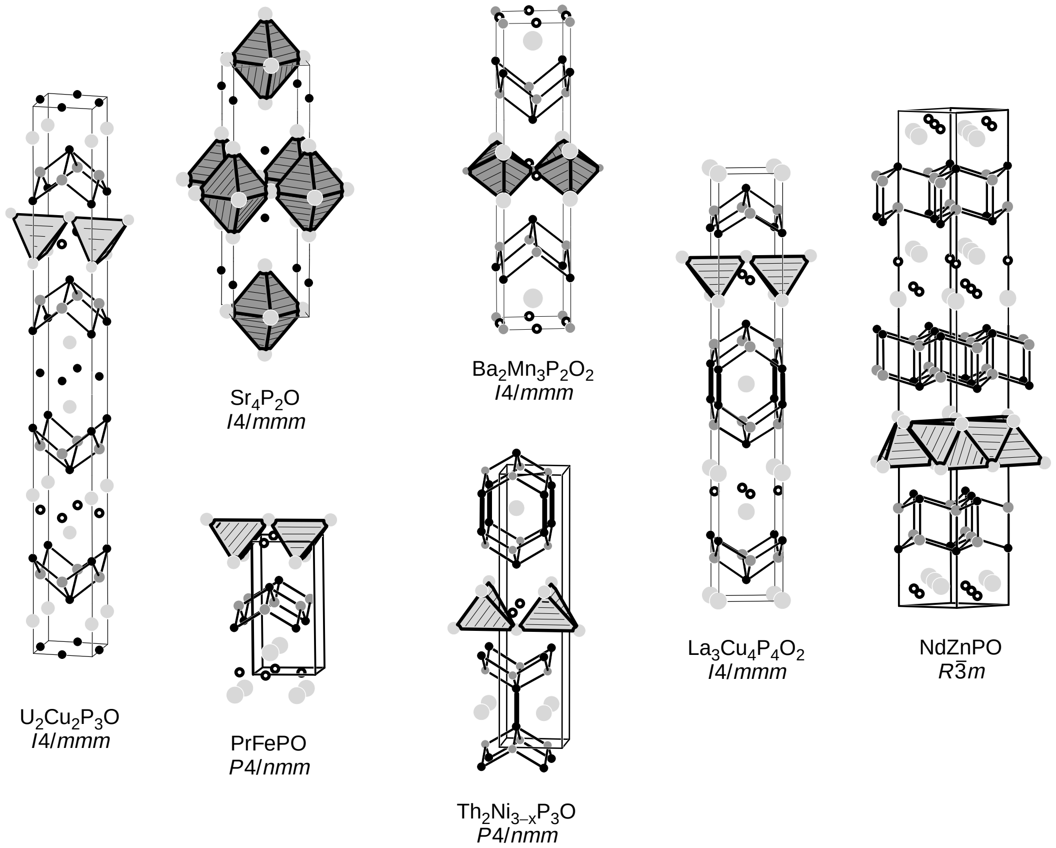

Figure 20 Crystal structures of various ternary and quaternary phosphide oxides of the alkaline earth, rare earth, and actinoid metals. Alkaline earth (rare earth, actinoid), transition metal, phosphorus, and oxygen atoms are drawn as large light grey, medium grey, filled, and open circles, respectively. Some relevant coordination polyhedra around the oxygen atoms and the transition metal–phosphorus bonds are emphasized

interest (see Table 9). In all compounds, one observes a clear charge separation, that is, the phosphide halides are pure salts. Some of the copper halides, containing phosphorus frameworks, have already been discussed (cf. Section 6.5.7). Those with radicalic polyanions are summarized in Section 6.5.4. The first phosphide halides have been detected when halogen was added to the reaction mixtures in order to overcome the kinetic hindrance of phosphorus to go into the gas phase.

The crystal chemistry of the phosphide oxides discussed above is closely related to the structural slabs of the well-known $BaZn_2P_2$ type (isolated P^{3-}) /$BaAl_4$ type (P_2 pairs) and related compounds. This is different for the phosphide halide structures. Some relevant structures of the phosphide halides are presented in Figure 21 and a list is given in Table 9. These structures contain isolated phosphorus atoms, P_2 pairs, or one-dimensional spirals like in the structure of elemental selenium.

The Eu_2PBr and Eu_2PI structures[231] belong to the $NaFeO_2$ type space group $R\bar{3}m$, as do Ca_2PBr, Sr_2PBr, and Ba_2PBr.[232] Both phosphorus and halogen atoms have a distorted octahedral europium coordination, and these octahedra are condensed via common edges. These phosphide halides are simple salts according to $(2\,Eu^{2+})\,P^{3-}Br^{-}$. Antiferromagnetic ordering of the europium magnetic moments has been observed for Eu_2PBr and Eu_2PI.[233] The phosphorus atoms are isolated in the structures of Cd_3PCl_3[234] and $(Hg_2P)_2HgBr_4$.[235] Each phosphorus atom is tetrahedrally coordinated by cadmium forming linear chains of edge-sharing tetrahedra in $Cd_3PCl_3 \equiv (3Cd^{2+})\,P^{3-}\,(3Cl^{-})$. These chains are embedded in the packing of the chlorine atoms. The most remarkable structure occurs for $(Hg_2P)_2HgBr_4$ which is the phosphorus analogue of the Millon's base salts. The $[Hg_2P]^+$ cation has the same topology as the $[Hg_2N]^+$ cation.

P_2 pairs occur in the structures of Cd_2PCl_2[236] and $Hg_7P_4Br_6$.[237] The monoclinic structure of Cd_2PCl_2 has some similarities to the well-known K_2NiF_4 type. The P_2 pairs (P–P 218 pm) are located in slightly elongated, distorted octahedra of cadmium atoms. These octahedra have the same topology as the NiF_6 octahedra in K_2NiF_4. The layers of the corner-sharing P_2Cd_6 octahedra are separated by the chloride anions. According to the P–P single bond distance of 218 pm, an adequate formula is $(4Cd^{2+})\,P_2{}^{4-}\,(4Cl^{-})$. The structural characteristics of $Hg_7P_4Br_6$ are similar, but the condensation of the distorted P_2Hg_6 octahedra is different. Assuming a P–P single bond (220 pm), the formula is $(7Hg^{2+})\,(2P_2{}^{4-})\,(6Br^{-})$.

Hg_2P_3Cl and Hg_2P_3Br[238] contain one-dimensional infinite chains of phosphorus atoms at P–P distances of 219 and 220 pm, in agreement with P–P single bonds, leading to the formula $(2Hg^{2+})$ $(3P^-)$ Br^-. The related cadmium compounds Cd_2P_3X (X = Cl, Br, I)[239] have been studied with respect to their semiconducting behavior with band gaps of 0.6, 0.7, and 0.2 eV for Cl, Br, and I, respectively. The most phosphorus-rich phosphide halides are Ba_2P_7Cl and $M_4P_{21}I$ (M = K, Rb) with isolated $P_7{}^{3-}$ anions and 2-D layers of condensed fragments of Hittorf's phosphorus (Figures 6 and 11). For details, see Section 6.5.

Also, some phosphide halides with the clathrate-I structure have been reported (see Table 9).[240–249] Clathrates are a fascinating group of compounds, because they exist not only as noble gas hydrates $(E18)_8(H_2O)_{46}$, but also with M^{13}, M^{14}, and M^{15} as framework elements. All clathrates with M, M′, P and X (X = Cl, Br, I) belong to the *clathrate*-I type. The framework consists of Y_{20} dodecahedral and Y_{24} tetrakaidodecahedral cages (Y = skeleton atoms M, M′, P). The anions are located in these cages according to size and charge. The cationic Y_{46} skeleton requires $46 \times 4e = 184$ *electrons* and all Y atoms are $(4b)Y$. In Table 9 (lower part), the compounds with P as a part of the skeleton are given. If 184 electrons are available from less than 46 atoms, some defects (□) are present. The clathrates containing (In, Zn, Sn, P, Cu, □) have the skeleton (184e) and in total an ionic charge of 8+. They also belong to the *clathrate*-I type. The phosphide $Ba_8[Cu_{16}P_{30}]$,[249] has been included here, even though there is no halogen present (cf. Table 5), but is a *clathrate*-I type, too. It forms a fourfold superstructure of the cubic subcell and consists of an anionic framework with a charge of 16− under the assumption that 8 Ba^{2+} atoms are present. All copper atoms are exclusively coordinated by phosphorus atoms. However, from the 30 P atoms, 150e are delivered for the skeleton bonding. Therefore, the copper atoms should provide $184e - 150e - 16e = 18e$ with 16 Cu atoms. With a skeleton requiring (184e), 2 Cu atoms should have the charge 2+. As this compound was proven to be a semiconductor with a band gap of 0.7 eV, a valence compound is very likely. This could be reached, for example, by the substitution of Cu by P, leading to $Ba_8[(Cu_{15.5}P_{0.5})P_{30}]$. Besides this open question, the structure consists of a finite polyanionic chain $(P_{18}{}^{20-})$ and a finite branched polyanion $(P_{12}{}^{14-})$ (dodecaphospha-4,5-diethyloctane). Considering a weak P–P bond in this polyanion

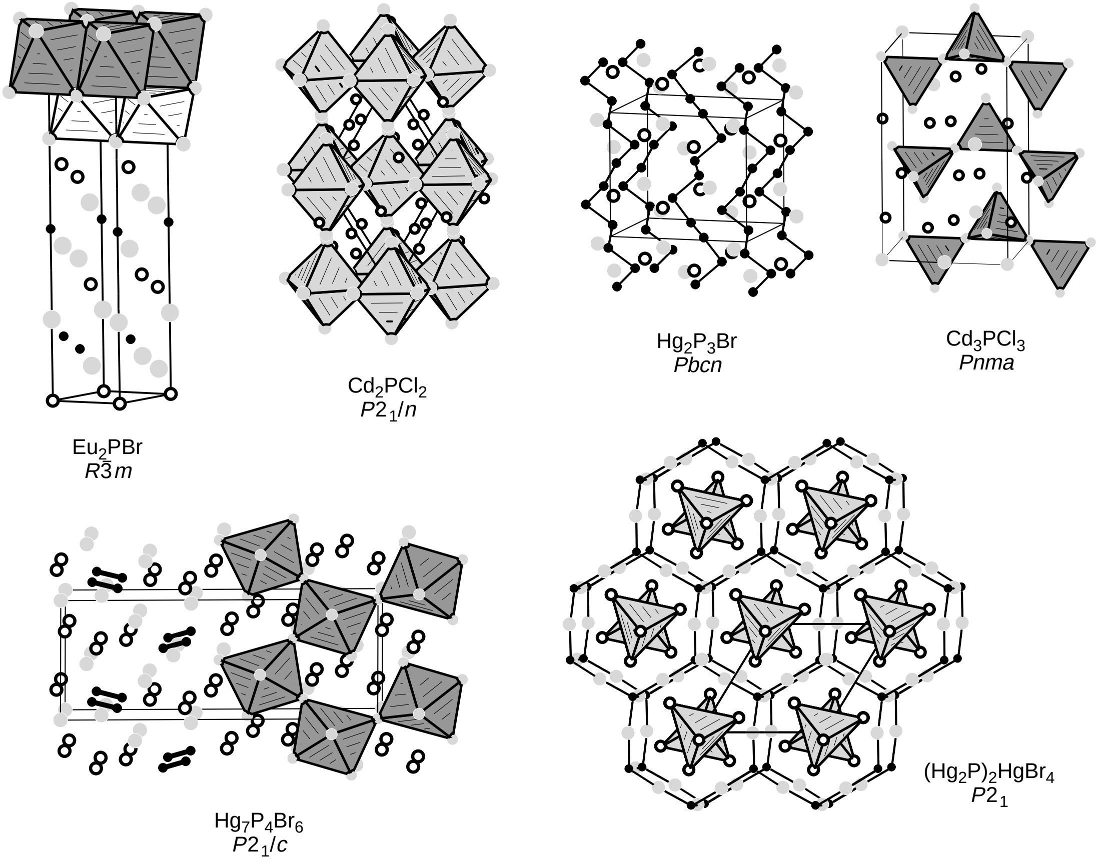

Figure 21 Crystal structures of various ternary phosphide halides. Europium (cadmium, mercury), phosphorus, and halogen atoms are drawn as large light grey, filled, and open circles, respectively. Some relevant coordination polyhedra around the phosphorus atoms and the P–P bonds are shown. The $HgBr_4$ tetrahedra in the $(Hg_2P)_2HgBr_4$ structure fill the channels of the three-dimensional $[Hg_2P]$ network

with a $PBO = 0.5$, the charge is augmented even to $P_{12}{}^{15-}$. However, the discrepancies between composition, properties, and structure still need to be clarified.

6.7.3 Hydrogenphosphides

There are only few well defined examples of compounds being composed from a metal, phosphorus, and hydrogen. However, with the occurrence of new compounds it often was stated, that undiscovered hydrogen takes part in the formation of a compound. We will here not refer to the compounds, for example, monophosphane(3), diphosphane(4) and the higher phosphanes, as this has been reviewed by Baudler in a very comprehensive paper.[38] Despite the fact that the phosphines form numerous compounds, the compound LiP_5H_4 should be mentioned because the metalation of P_2H_4, especially with Li, gives access to a lot of other phosphanes.[250] The reaction of P_2H_4 in liq. NH_3 is a new route to polyphosphides and hydrogen phosphides.[251]

The alkali metals form the complete series of APH_2 compounds ($A = \text{Li} \rightarrow \text{Cs}$) via preparation in liquid ammonia. These compounds can be described as derivatives from phosphine named as alkali metal phosphanide(2), or as alkali metal dihydrogen phosphide.[252,253] They show interesting phase transitions caused by rotation of the PH_2 moiety. However, owing to their extreme sensitivity against moisture and oxygen, these compounds have not been investigated further.

With $A = \text{Rb}$[254] and Cs,[255] compounds of the type $A_2[PH]$ can be prepared containing an isolated hydrogenphosphide anion $[PH]^{2-}$, which could also be named for example, as dicesiumphosphanide(1), when starting from phosphane(3). The orientation of the PH unit could not be determined by X-ray analysis, but its existence has been proven by solid-state ^{1}H-NMR. The metal phosphide Ti_3P forms hydrides or deuterides up to a maximum content of 2.6 H (D). The exact crystal structure depends on the H (D) content and the temperature.[256] We note, that exact reliable studies of compounds M/P/H are very rare.

7 PHOSPHORUS–ARSENIC SUBSTITUTION

The only binary P/As compounds are the $(P_{1-x}As_x)_4$ molecules,[257] the limited mixed crystal series $P_{1-x}As_x$

of black phosphorus and gray arsenic,[258] and $P_{20}As$, a derivative of $P_{Hittorf}$, where As occupies special positions.[259] Arsenic can substitute phosphorus positions also in the neutral one-dimensional phosphorus chains of $Cu_2P_3I_2$ with a maximum substitution $Cu_2P_{1.8}As_{1.2}I_2$.[260] The mixed pnictogen modifications demonstrates an increased stability relative to $Cu_2P_3I_2$.

In metal phosphides, the substitution of P with As is much more common. A series of pyrite representatives $M^{IV}PAs$ are known (not given in the tables) with either statistically distributed $P_2{}^{4-}$ and $As_2{}^{4-}$ units, or statistically orientated $(PAs)^{4-}$ dumbbells. The molecule-like $P_7{}^{3-}$ anion, as well as the defect variants of the black phosphorus structure (EuP_3 etc.), shows complete miscibility. The whole series of valence tautomeric systems $(P_{1-x}As_x)_7{}^{3-}$ was proven to exist in ethylenediamine solutions of $Rb_3(P_{1-x}As_x)_7$ mixed crystals.[261] Mixed crystals in the whole range also exist with EuP_3, EuP_2, and EuP. A statistical distribution of P and As is found in the three different polyanionic substructures $^2_\infty(P_{1-x}As_x)_3{}^{2-}$, $^1_\infty(P_{1-x}As_x)_2$, and $(P_{1-x}As_x)_2{}^{2-}$. In $Eu(P_{1-x}As_x)_3$, a weak preference of As for the $(2b)P^-$ positions occurs, which form the most flexible part of the polymeric structure. During thermal decomposition the P:As ratio is changed systematically and in accordance with an enrichment of As in the solid with a smaller P:Eu ratio. With $Eu(P_{1-x}As_x)_2$, a structural phase transition takes place from the EuP_2 to the $EuAs_2$ type, which mainly differs in the conformation of the chains $^1_\infty(P^-)$.[262]

EuP belongs to the NaCl structure with Eu^{3+} and P^{3-}, but EuAs forms the Na_2O_2 structure with Eu^{2+} and $As_2{}^{4-}$. The polyanionic EuAs structure is stable in $EuP_{1-x}As_x$ mixed crystals within $0.05 \le x \le 1.00$.[263] The relationships are quite different in the strained helical polyanionic structures of LiP_7 and NaP_7, where the As atoms demonstrate a pronounced preference for the peripheral atomic positions of the $^1_\infty(P_{1-x}As_x)_7{}^{3-}$ helix. This distribution seems to be affected by structural strain more than by differences in polarity.[264]

Phosphorus–arsenic substitution can help to stabilize peculiar compounds that do not exist as binary phases. So far, a binary arsenide W_5As_4 has not been reported. Nevertheless, $W_5As_{2.5}P_{1.5}$[265] can be synthesized. It adopts the tetragonal Ti_5Te_4 type, as Mo_5As_4 does. Most likely radii criteria are responsible for the stability range of this pnictide which contains one-dimensional chains of vertex-shared W_6 clusters.

The $BaAl_4$ related phosphide $SrNi_2P_2$ has been investigated with respect to P/As substitution $SrNi_2P_{2-x}As_x$ up to $x = 1.25$.[266] The arsenic substitution has a drastic effect on the first-order phase transition of the $I4/mmm$ HT modification (at room temperature) to the *Immm* LT modification (around 100 K), where the unit cell is tripled. The LT modification displays a modulation of shorter (246 pm) and longer (326 pm) P/As–P/As distances.

8 PHYSICAL PROPERTIES AND APPLICATIONS

For the determination of reliable physical data, the use of well defined and sufficiently sized single crystals is a necessary prerequisite (see Section 3). Even small amounts of impurity phases can irreversibly affect the property measurements.

8.1 Colors and Band Gaps

Metal phosphides cover the full range of colors from colorless to black, sometimes with metallic luster. The corresponding band gaps E_g are given for some compounds in Figure 22. General trends can be seen: (a) the band gap E_g is dependent on the polyanionic partial structure and increases with increasing P/M for comparable connectivities of P substructures; (b) E_g decreases with increasing charge q(M) in comparable anionic structures; (c) within the same group, E_g decreases with the heavier cation; (d) transition metals seem to lower E_g; (e) with decreasing mean charge q(P) (cf. family 4), one obtains a 'diluted' structure, and therefore larger E_g; (f) the interconnection of building units leads to a decrease of the gap; (g) tubular and infinite chain structures are related to the Hittorf violet P value (families 2 and 3); (h) the large spread of E_g values with isolated P^{3-} ions demonstrates the influence of cation charge P/M ratios, and electronegativity differences of P and M. It is not possible to derive the optical and electrical properties from the M/P ratio alone (metal rich, nonmetal rich); a detailed knowledge of the structures is necessary. Although semiconducting and even semimetallic behavior can be expected with compounds having distinct M–P, P–P, and M–M bonds, which can be derived from their structure and band structure calculations, these properties are not well understood (this is especially true for metallic compounds).

8.2 Superconductivity

Some phosphides are also superconducting (Table 10). Two interesting examples are the filled skutterudite $LaFe_4P_{12}$ as well as the ternary Fe_2P analogue ZrRuP with $T_c = 13$ K. The ternary transition metal phosphides MoNiP (ZrNiAl type) and MoRuP (TiNiSi type) were prepared under high-pressure (4 GPa) high-temperature (1870 °C) conditions. Both phosphides show a transition to the superconducting state around 15.5 K. These are the so far highest T_c's for metal phosphides.[267] The superconducting properties seem to arise from the Mo 4d electrons,[268] as the variety of Mo containing compounds indicates (Table 10). The $ZrFe_4Si_2$ type phosphides $ZrNi_4P_2$, $ZrRu_4P_2$, and $HfRu_4P_2$ have been prepared under high-temperature, high-pressure conditions. While no superconductivity could be detected for the nickel compounds down to 2 K, superconducting transitions are found at 11 K and 9.5 K for $ZrRu_4P_2$, and $HfRu_4P_2$, respectively. The upper critical field H_{c2} for $ZrRu_4P_2$ of 12.2 T at 0 K is remarkable.[269] The two superconducting modifications of ZrRuP have been

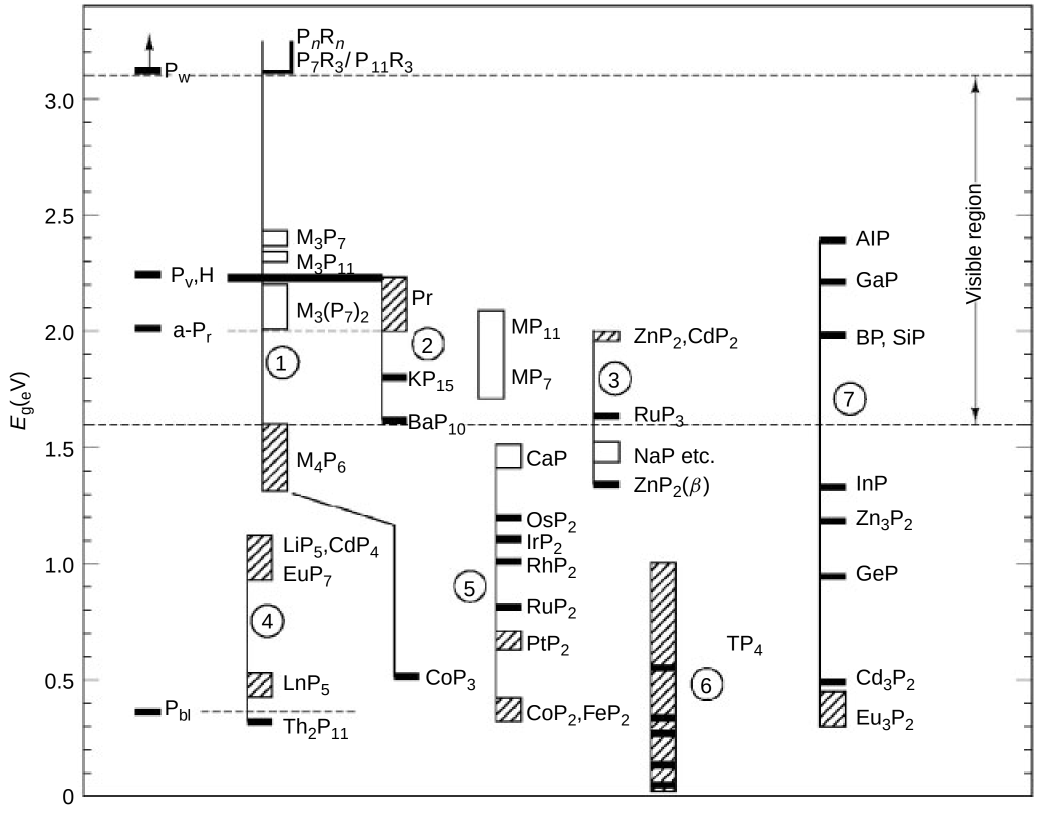

Figure 22 Ordering of E_g values according to structural relationships. Values estimated only from structure and color are represented by open rectangles. The structural correlations are (1) cycles and polycycles, (2) tubular and related structures, (3) infinite chain, (4) nets related to black phosphorus, (5) dumbbells, (6) nets with transition metals, and (7) isolated P^{3-}. Metallic phosphides are not given

Table 10 Superconducting materials

Phase	T_c (K)	Phase	T_c (K)
P_{met}	5.8[271]	Pd_7P_3[b]	0.70[272]
$(P_{1-x}As_x)_{met}$	≤10[273]	TiRuP	1.2[274]
$(GaP)_{met}$	9.3[275]	$ZrRuP_{ortho}$	3.76[270,276,277]
SnP	2.8–4.0[278]	$ZrRuP_{hex}$	13.0[270,276,277]
$ZrP_{0.95}$	≈4.6[279]	$ZrRu_4P_2$	11.0[269]
ZrP_2	(4.5)[274]	HfRuP	10.8[274]
TaP_2	0.4[269,280]	$HfRu_4P_2$	9.5[269]
$V_3(Si_{1-x}P_x)$	14.8–16.6[281]	TaRhP	4.7[277]
Mo_3P	~7[282]	MoNiP	15.5[267,268]
Mo_4P_3	2.5[283]	MoRuP	15.5[267,268]
Mo_5P_8	5.8[282]	WNiP	~5[267]
Mo_4P_3	3.0[282]	WRuP	~5[267]
W_3P	2.76[282,284]	$LaFe_4P_{12}$	4.08[285]
Rh_2P	1.3[272]	$LaRu_4P_{12}$	7.20[285]
Rh_4P_3	1.22[283]	$LaRu_2P_2$	4.1[136]
Pd_7P_3[a]	1.00[272]		

[a]High-temperature form. [b]Low-temperature form.

reinvestigated by synchrotron X-ray diffraction. The hexagonal ZrNiAl modification becomes superconducting at 13 K while orthorhombic TiNiSi type *o*-ZrRuP has a T_c of approximately 4 K.[270] Details of the pressure-induced phase transitions have been reported. The superconductivity of GaP under pressure, as well as that of SnP, is also noteworthy (Sn ?). A famous example is the cubic high-pressure modification P_{cub} ($T_c = 5.8$ K). T_c increases up to 10 K upon substitution with As.

8.3 Thermochemistry

Real information about the thermodynamic stability of solid phosphides is very rare.

The bright yellow higher alkali metal compounds M_3P_7 sublime congruently and dissociatively into their elements, $M_3P_7(s) = 3M(g) + \frac{7}{4}P_4(g)$ (cf. NH_4Cl), whereas Li_3P_7 decomposes to lower phosphides under similar conditions.[286] The large entropy contribution to the stability of these compounds makes them unique among alkali metal phosphides. The M_3P_7(s) compounds are stable with respect to both phosphorus-rich and metal-rich compounds in the corresponding system. The metal-richest alkali metal phosphides decompose stepwise by evaporation of metal up to the M_3P_7 formation. The phosphorus-richest alkali metal polyphosphides, MP_{15}(s), decompose under vacuum conditions in one step directly to the corresponding M_3P_7(s) phases. This is surprising, since there are many phases

known between MP_{15} and M_3P_7. However, some experimental details indicate the intermediate formation of the other phases. The relative stability of the intermediate phases is strongly influenced by the unique behavior of the M_3P_7 phases, whose stability changes rapidly with pressure and temperatures. With respect to red phosphorus, the evaporation of P_4 from MP_{15} is strongly activated.

The heptaphosphides LnP_7 (La to Pr) decompose at about 600 K, forming the corresponding pentaphosphides.[287] At about 750 K, further decomposition starts, yielding the diphosphides. All other pentaphosphides LnP_5 (Nd to Lu) decompose directly to the monophosphides. The mean enthalpy for vaporizing one P_4(g) is about 150 kJ mol^{-1} for LnP_7, about 200 kJ mol^{-1} for LnP_5, and 170 kJ mol^{-1} for YbP_5 (α, β). Although, in general, the P_4(g) equilibrium pressure at a given temperature increases with decreasing cation radius, some irregularities obviously are affected by the electron configuration of Ln^{3+} as well as by the different stabilities of the decomposition products.

The binary system Eu/P is an example of phases with a negligible metal partial pressure.[145] The polyphosphides vaporize incongruently according to the reaction $a\mathrm{EuP}_m(\mathrm{s}) \rightarrow a\mathrm{EuP}_n(\mathrm{s}) + \mathrm{P}_4(\mathrm{g})$, where $a(m-n) = 4$. The stability regions of the europium polyphosphides are known from vapor pressure measurements demonstrating the large stability of β-EuP_3 and low stability of EuP_2. EuP_2 is only stable above 750 K and below that temperature β-EuP_3 decomposes directly to Eu_3P_4. From the stability regions one can derive appropriate methods of synthesis. It is interesting that the phosphorus-richest phases possess the largest atomic excess enthalpy. The entropy of formation per mole of P_4(g) during the vaporization reaction, ΔS (600 K), increases slowly from Eu_3P_4 to EuP_2, α-EuP_3, and violet Hittorf's phosphorus (131, 144, 162, and 175 J K^{-1} mol^{-1}), but is much larger for β-EuP_3 and EuP_7 (212 and 215 J K^{-1} mol^{-1}). This effect seems to be related to the phosphorus partial structures: there are, on one hand, short $P_4{}^{6-}$ chains, 1-D chains $^1_\infty(\mathrm{P}^-)$, twistable 2-D nets $^2_\infty(\mathrm{P_3}^{2-})$, and a strained network of connected tubes, but, on the other hand, 2-D polyanions with strain-free P_6 and P_8 rings.

From the heat capacities of LiP_{15} and KP_{15}, it was derived that the soft vibrational modes at low temperature are only affected by interaction between the metal cation and the six nearest neighbors.[288] Therefore, the covalently bonded $P_{15}{}^-$ tubes and the ionic interaction between the cation and the polyanion produce two distinctly separate sets of vibrational excitations (see below). At low temperatures, interchain vibrations occur, partially transmitted through the cations. At higher temperatures, intrachain vibrations, propagated through the covalently bonded tubes, are the dominant vibrational modes.

The thermal properties of the huge number of ternary or even quaternary phosphides have only scarcely been investigated. However, these data are important for planning the syntheses of new compounds. For example, the ternary skutterudite type phosphides do not melt congruently.

8.4 Magnetic Properties

The magnetic properties and Mössbauer spectra allow the characterization of the electronic state of transition metal and rare earth cations, which is necessary to prove the above mentioned electron transfer.[8,289] The polyphosphides allow the consecutive separation of magnetic cations to study electronic interactions and magnetic ordering phenomena. Magnetic phase transitions have been studied with rare earth monophosphides and others. All europium polyphosphides are Eu^{II} compounds, but in EuPtP the valence increases with decreasing temperature.[290] The pentaphosphides LnP_5 are Ln^{III} compounds. Deviations from the Curie–Weiss law are caused by: (i) transitions to magnetically ordered phases at low temperature (Sm, Gd, Dy, and Tb); (ii) crystal field splitting of the degenerate ground states (Ce, Nd, and Tm); and (iii) contributions of van Vleck's TIP (Sm and Pr). TbP_5 and DyP_5 order ferromagnetically within cation layers and antiferromagnetically, coupled via P atoms, between adjacent layers. The crystal field splitting, as well as the susceptibilities, can be simulated by assuming only two different interaction parameters, corresponding to (2b)P^- and (3b)P^0, respectively. With the mixed crystals $M(P_{1-x}As_x)_3$ (M = Ca, Sr, Ba, Eu; $0 \le x \le 1$), the longitudinal Hall effect has been observed for the first time. The unexpected large anomalies in magnetoresistance are caused by the coexistence of the galvanomagnetic properties of group 15 elements and the magnetic properties of europium cations. Multiple magnetic phase transitions occur in the (T,B) phase diagrams, which are changed by pressure and x(As), and exhibit a rich variety of phenomena (paramagnetic, incommensurate ordered antiferromagnetic, spin-flop phases).[145]

The ternary phosphides show an extremely large variety of magnetic phenomena. With the diamagnetic rare earth elements scandium, yttrium, lanthanum, and lutetium, the rare earth–transition metal–phosphides are mostly Pauli paramagnets. The small susceptibility contribution arises from the conduction electrons of these metallic compounds. This is also the case for related phosphides with titanium, zirconium, or hafnium as the electropositive component. In some peculiar cases, the transition metal atoms carry the magnetic moments. Interesting examples are the 125 K ferromagnet $LaCo_2P_2$[291] or the 113 K antiferromagnet $CaCo_2P_2$.[292] In the calcium compound, the cobalt magnetic moments order ferromagnetically in the basal plane, but these planes order antiferromagnetically along the c axis, corresponding to a propagation vector $\mathbf{k} = (0, 0, 1)$. Also, some of the $RE_2Co_{12}P_7$ phosphides show magnetic moments on the cobalt atoms.[293] A highly interesting phosphide in this context is $EuCo_2P_2$, where a transition from the 4f Eu local moment to 3d Co itinerant magnetism occurs under an applied pressure of 3.1 GPa.[294]

The families of equiatomic phosphides CeTP, EuTP, and YbTP have thoroughly been investigated with respect to valence changes or mixed-valency. All these data are

reviewed in recent articles.[14,295–297] Also, the families of RET_2P_2 and $RE_2T_{12}P_7$ phosphides have intensively been studied with respect to their magnetic properties by Jeitschko and coworkers. Most data are summarized in the review by Kuz'ma.[14] Crystal growth of the RET_2P_2 and $RE_2T_{12}P_7$ phosphides from a tin flux offers the possibility to measure the susceptibilities || and ⊥ to the crystallographic *c* axis. Numerous magnetic structures of the RET_2P_2 and $RE_2T_{12}P_7$ phosphides have been determined from neutron diffraction data. Figure 23 gives an overview of the different magnetic cobalt substructures in MCo_2P_2 (M = Ca, Sr, Ce, Pr, Eu).[292]

Various cerium and uranium-based phosphides have been studied with respect to the magnetic ordering phenomena. A remarkable compound is Ce_2AuP_3 that orders ferromagnetically with a relatively high Curie temperature of 31 K. Some of the uranium phosphides have comparatively high magnetic ordering temperatures that approximately scale with the structure type and the uranium content (Figure 24).[298]

8.5 Vibrational Spectra and Optical Applications

Raman and IR spectra of polyphosphides clearly show the separation of internal and external modes (Figure 25). The external modes are strongly pressure and temperature dependent, whereas the internal cluster modes are nearly unaffected. In the plastically crystalline phases of M_3P_7 and M_3P_{11} the external modes disappear completely.[299] The internal modes are still present in the melt, demonstrating molecule-like behavior as well as the high thermal stability of those polycyclic anions. With solid Rb_4P_6 and Cs_4P_6, the vibrational behavior of P_6^{4-} is like that of benzene! The vibrations of the 1-D tubular polymers P_{15}^- in KP_{15}, and the corresponding ones in Hittorf's phosphorus, are separated in a very similar way.[300] They can be assigned to the structural fragments P_7, P_8, and P_9. Vibrational spectra of amorphous red phosphorus prove the presence of similar tubes with P_8 and P_9, as well as of P_7 cages of the nortricyclane type.

In 2-D corrugated polyanionic nets (α-EuP_3), the separation of vibrations is still present. The high-frequency modes are mainly associated with vibrations within the layer, whereas the low-frequency modes are dominated by M–P vibrations.

High-quality single crystals of $ZnGeP_2$ can be synthesized from the binary zinc and germanium phosphides. $ZnGeP_2$ is used for infrared laser radiation frequency conversion.[301] Binary indium phosphide InP is an important material for optoelectronic and electronic devices as well.[302] In this context, the interactions of various transition metals with InP have thoroughly been investigated in order to check for potential high-temperature contacts to InP.

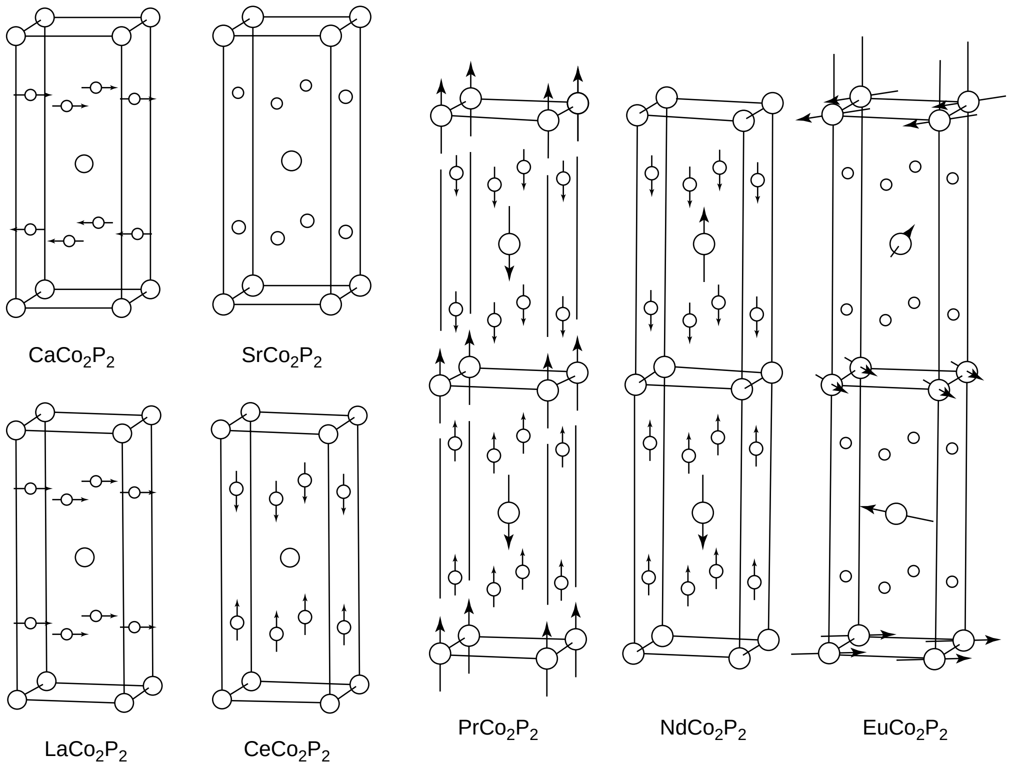

Figure 23 Magnetic structures of the phosphides ACo_2P_2 (A = Ca, Sr, La, Ce, Pr, Nd, Eu). The cobalt atoms (small circles) with their ordered magnetic moments are shown together with the A atoms (large circles), which are in the positions (0 0 0) and (1/2 1/2 1/2) of the body-centered nuclear cell (from Reehuis *et al.*[292])

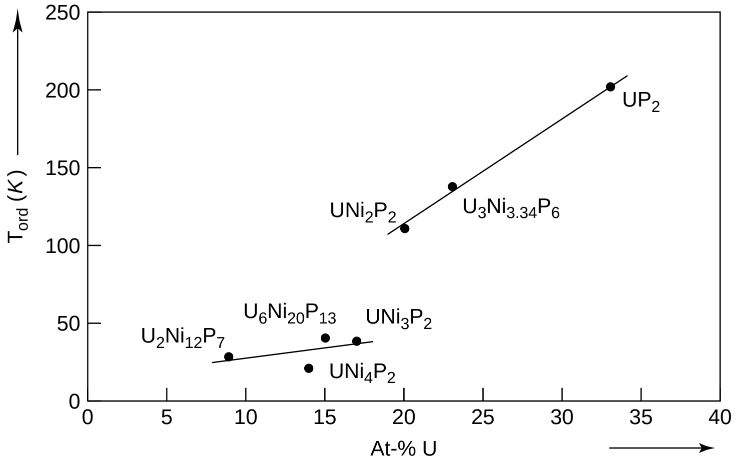

Figure 24 Magnetic ordering temperatures of uranium nickel phosphides with crystal structures belonging to two different structural families (from Ebel *et al.*[298])

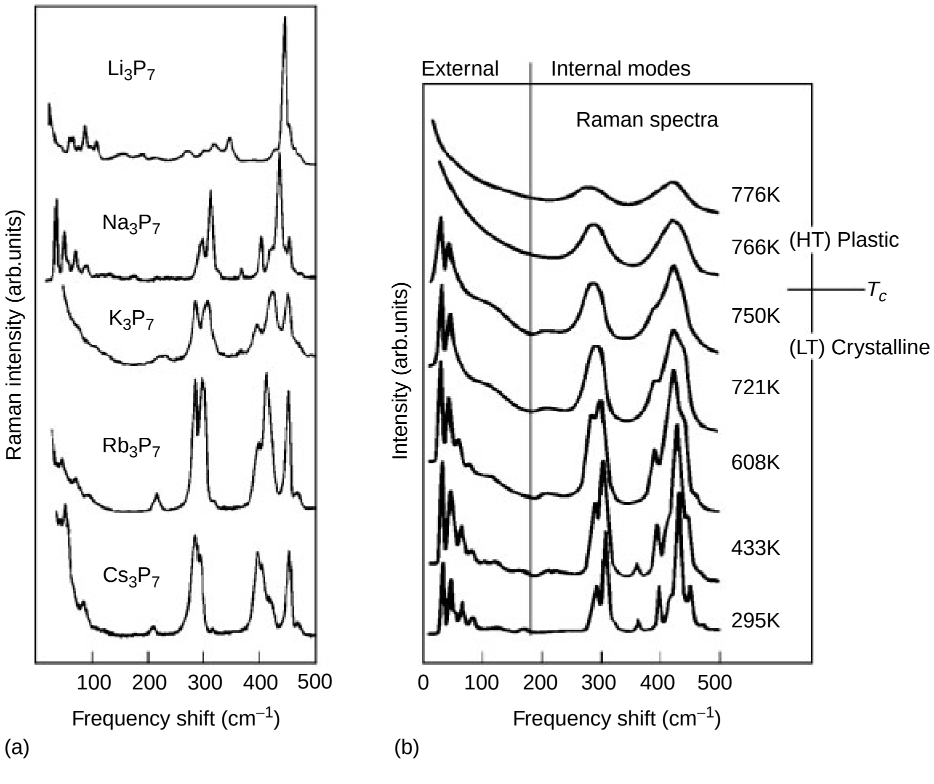

Figure 25 (a) Raman spectra of solid M_3P_7 (M = Li, Na, K, Rb, Cs) and (b) temperature-dependent Raman spectra of Na_3P_7, indicating the first-order phase transition at T_c from the low-temperature (LT) crystalline α-phase to the high-temperature (HT) plastically crystalline β-phase. Note the disappearing of the sharp external lattice modes just above T_c

8.6 Phase Transitions with Temperature and Pressure

Phase transitions with temperature and pressure have mostly been studied with simple (binary) compounds.[303,304] There is a complete lack of systematic studies. Some phase transitions with temperature have been discussed.[114,145,299,305] Pressure-induced phase transitions, for example, of SiP, GeP, ZnP_2, and europium phosphides, have been reported.[124,306] Eu_4P_3 undergoes a phase transition from the rhombohedral phase ($Eu_4P_3 \equiv Eu_3^{II}Eu^{III}P_3$) into Eu_4P_3 with Th_3P_4 type structure at 8(1) GPa, where the average oxidation state of Eu is still noninteger.[307] α-Co_2P (*oP*12, Co_2Si type)

undergoes a reconstructive phase transformation at 1428 K into β-Co_2P (*hP*9, Fe_2P type) before it melts at 1659 K. Among this big class of compounds, β-Co_2P is the only known high-temperature phase. Furthermore, it shows the highest axial ratio c/a and the smallest distortion of the *hcp* structure.[308]

The monophosphides REP (RE = La, Ce, Pr, Nd, Sm, Gd, Tb, Tm, Yb) crystallize in the NaCl-type structure at ambient pressure. All of them undergo phase transitions, some into a tetragonally distorted CsCl related structure (La, Pr, Nd) and the others into a more complicated unknown high-pressure phase (Sm, Gd, Tb, Tm, Yb) at pressures from 35 to 51 GPa, respectively.[309] It might be that a disproportionation occurs, similar to that in Eu_2As_2.[310]

The Mo phosphides have not only been investigated because of their interesting superconducting properties (see Section 8.2) but also because of their potential catalytic activity for hydroprocessing of crude oil (see Section 8.8). The high-temperature powder diffraction of MoP_2 indicates decomposition into unknown products above 839 K. The high-pressure experiment indicates that no phase transition occurs up to 6.8 GPa. Even the pressure dependance of the bulk modulus shows no anomaly for this compound, indicating that MoP_2 cannot be regarded as a layered compound.[311]

Some of the tetragonal RET_2P_2 phosphides have been investigated under high-pressure conditions. To give an example, $SrRh_2P_2$ shows an extremely anisotropic compressibility, with a much stronger decrease of the c lattice parameter.[312] This leads to a decrease of the P–P distance from 328 pm at ambient pressure to 231 pm at 6.8 GPa, thus strongly influencing the chemical bonding from isolated P^{3-} ions to $P_2{}^{4-}$ pairs.[313] It is fundamental to note that upon oxidation of phosphorus ($P^{3-} \rightarrow P^{2-} + e^-$), the rhodium atoms are reduced. Other RET_2P_2 phosphides show continuous decrease of the lattice parameters.

The cluster compounds $[Ag_6M^{II}_4P_{12}]Ge_6$ with M^{II} = Ge, Sn show at low temperatures a valence fluctuation of the inner core $Ag_6{}^{4+}$, which can be seen in the elastic behavior[314] and vibrational anharmonicity[315] as well as in the measurements of the specific heat.[316] The valence fluctuations generate a pronounced Schottky anomaly, which can be emphasized more clearly by the comparison and therefore possible normalisation of cluster compounds.

8.7 Thermoelectrics – Skutterudites

Although the first filled skutterudites were already synthesized in the late 1970s by Jeitschko and coworkers,[317] this class of phosphides has found renewed interest in recent years with respect to the outstanding thermoelectric properties. However, the thermoelectric properties of the filled skutterudites with the higher homologues arsenic and antimony are superior to the phosphides. Most of the research on filled lanthanide skutterudites has recently been reviewed by Uher,[318] Nolas *et al.*[319] and Sales.[320] Besides the thermoelectric properties, filled skutterudites have attracted considerable interest because of their rich variety of electronic and magnetic ground states, such as heavy-fermion mediated superconductivity, ferro- or antiferromagnetism, hybridization gaps (Kondo insulator behavior), non-Fermi-liquid behavior and quantum critical points, quadrupolar ordering, and field-induced heavy-fermion states.[321] The binary cobalt skutterudite CoP_3 can take up lithium with a reversible capacity of 400 mAh/g at an average potential of 0.9 V versus Li/Li^+.[322]

8.8 Catalysis

Various catalytically active transition metal phosphides, for example, Co_2P, Ni_2P, MoP, WP, CoMoP, or NiMoP, can be prepared from metal oxide/phosphate or nitrate/ammonium metatungstate precursors by reduction in a hydrogen flow.[323,324] The product selectivities of these phosphides resemble those of classical sulfidic catalysts. Typical application areas are reactions such as the hydrodenitrogenation of o–propylaniline at 3 MPa and 643 K. The cobalt phosphide Co_2P has been tested as a hydrodesulfurization (HDS) catalyst[325] for fuel purification. The phosphide is prepared on a silica matrix. In technical HDS catalysts, it is assumed that transition metal phosphides form as reactive species on the catalysts surface. Amorphous Ni_2P can be used in heterogeneous catalysis.[326] Fine powders can be obtained by reaction of aqueous nickel chloride with sodium hypophosphite using highly diluted sodium borohydride to initiate the reduction.

The semiconducting polyphosphide RuP_3 has shown to possess a photoelectric reactivity, which is traced back to the presence of Ru pairs with metal–metal bonds. This working hypothesis of the presence of two adjacent metal centers as a prerequisite for catalytic properties has shown to be very powerful.[327]

8.9 Precipitation hardening

The ternary phosphide FeTiP (mineral name florenskyite), recently discovered in the Kaidun meterorite,[328] is responsible for precipitation hardening in certain interstitial-free ferritic steels.[329] FeTiP (Fe_2P type structure) is a very stable compound. Chemical bonding is governed by strong metal–phosphorus interactions. Similar ternary phosphides occur also as precipitations in Pd–Ni–Cu–P glassy alloys modified by addition of Cr, Mo, Fe, or Ta.[330] The phosphides NiCrP, MoNiP, FeNiP, and (Pd, Ta)NiP with Fe_2P type structure strongly influence the microstructure and the mechanical properties of the glassy alloys. Binary iron phosphides are also the source for PH_3 generation on wet commercial ferrosilicon alloys.[331]

1 INTRODUCTION

1.1 Discovery and Development

Phosphorus, atomic number 15, was first isolated by the alchemist Henning Brandt in 1669, during the course of attempts to discover the ubiquitous philosopher's stone. Brandt's method involved the putrefaction of urine followed by concentration and distillation of a red oil, which was then recombined with part of the residue. Subsequent redistillation yielded phosphorus, which was collected in water. That he had succeeded in generating something out of the ordinary was evidenced not only by the fact that the new material glowed in the dark but that it also burned when exposed to air. The rather poignant fact that during WWII bombing raids, the latter property resulted in the destruction of the very place, Hamburg, where Brandt discovered the element, has not been lost on commentators. Brandt's method yielded only 1% of the available phosphorus. Improvements soon followed, however, from the work of a range of chemists – some famous (e.g. Robert Boyle, whose process was revealed posthumously to the Royal Society in 1694) and some largely forgotten (e.g. Boyle's assistant Ambrose Godfrey who, by the time of his death in 1741, had amassed considerable wealth from production of the element). Boyle also demonstrated that small amounts of air have to be present in order to see the element glow (now known to result from transient oxides[1]) and named the element as 'aerial noctiluca'; in due course the name phosphorus (from Greek, meaning lightbearer) was generally accepted.

Around 30 years after Godfrey's death, Gahn and Scheele deduced the presence of phosphate in bone and showed that treatment of bone ash with sulfuric acid, followed by heating of the resulting phosphoric acid with charcoal resulted in elemental phosphorus. The process was refined in France by Pelletier and then Coignet, ensuring that French exports of the element to Britain rose to 4.5 tons per annum in the 1840s. Within a few decades, however, the British firm Albright & Wilson had an annual production about 100 times greater than this and by the turn of the century had taken things a stage further with the introduction of an electric furnace process that allowed direct conversion of naturally occurring phosphate to phosphorus via heating with sand and carbon. This is effectively the technique used today, and the demand for phosphoric acid (and to a lesser extent other materials such as PCl_3) lead to worldwide production greater than 1 million tons in the mid-1970s, though a decrease in demand for phosphate from the detergent industry and the development of methods for direct conversion of mineral phosphate to high purity phosphoric acid has meant that annual production of the element now runs at about half a million tons. For details of the history of phosphorus and the development of its industrial chemistry, the interested reader is directed to recent, highly readable 'biography' of the element.[2] Many other works provide very fine introductions to the chemistry of the element.[3–5]

Since its production became routine, the chemistry of phosphorus has grown more and more, with a 'cutting edge' that has brought together both the apparently complex (for example the structure of allotropes, such as Hittorf's violet) and the ostensibly simple (such as a double-bonded bismuthene of the type RP=BiR′). That the former was first prepared in 1865, whereas the latter is a breakthrough only recently achieved,[6] serves to highlight the complex nature of the element and its compounds. If the three prime motives behind the work on phosphorus in the last century were to be brought together, they would seem to make strange bedfellows. The incentives driving the production of toxic pesticides and nerve gases, of polyphosphate sequestering agents for detergents, and finally of substituted phosphane ligands for industrially pertinent catalytic systems, would seem to share little apart from mere cupidity. But for all that, there is a subtle and important chemistry that links all of these and there have been innumerable academic and technological advances that have stemmed from them.

1.2 Atomic Properties of Phosphorus

As noted below, phosphorus exists in a number of allotropic forms but all, of course, share atomic properties. Phosphorus

exists as only one stable isotope, ^{31}P, which has a mass of 30.97376. In addition, about 16 radioactive isotopes are known,[7] of which ^{32}P is by far most important. The fact that it is a pure β-emitter of a half-life of 14.28 days ($E_{max} = 1.710\,MeV$) and that phosphorus is so important within biological systems (thus allowing ^{32}P labelled materials to be used in tracer studies) has ensured demand for this isotope. Fortunately, this demand can be readily met via the large scale generation of the material through the neutron irradiation of $^{32}S(n,p)$ or $^{31}P(n,\gamma)$ targets.

The fact that ^{31}P is 100% abundant in nature and that it is a spin 1/2 system makes it potentially ideal for nmr work, and with the advent – and ready availability – of modern FT spectrometers, ^{31}P nmr spectroscopy has become very much 'routine'. While its inherent sensitivity to the NMR effect is lessened by a magnetogyric ratio of $10.84 \times 10^{7}\,rad\,s^{-1}\,T^{-1}$ (thus making it less sensitive than ^{1}H and ^{19}F for example), the technique is still readily applicable to small-scale work.

In the ground state, phosphorus has the electronic configuration $[Ne]3s^2 3p_x 3p_y 3p_z$ with three unpaired electrons; this, together with the availability of low-lying vacant 3d orbitals accounts for the predominance of the oxidation states III and V in phosphorus chemistry.

2 UTILIZATION OF PHOSPHORUS

There are two quite different aspects to be taken into account when assessing the utilization of the element. One is to think of the many ways in which nature cycles phosphorus through the environment – broadly speaking this is out of our control, though as will be noted, there is ample opportunity for pollution concerns involving this element. The other is to think of ways in which we can utilize the element industrially or in the laboratory. This section will provide a brief introduction to both areas.

2.1 Natural Phosphorus Distribution and Cycles

Phosphorus is the 11th most abundant element in the Earth's crust (occurring to the extent of about 1120 ppm), though it is important to realize that, unlike its close neighbor in the periodic table, sulfur, it is never found in an elemental form. The predominant mineral form in which phosphorus is found is the orthophosphate family, and of the many hundred examples known, the apatites ($3Ca_3(PO_4)_2{\cdot}CaX_2[Ca_{10}(PO_4)_6X_2]$) are most common and most significant industrially.[8] The total mass of such material to which we have access is estimated to be equivalent to somewhere in the region of 9×10^{9} tons of phosphorus. Utilization of this has increased sequentially over the last 100 years; thus in 1900 about 3 million tons were mined. By 1928, this had risen to $>$10 million tons per annum for the first time; the 100 million tons per annum barrier was broken in 1972 and world production peaked at 166 million tons in 1988. The figure for 2000 was 133 million tons, equivalent to about 18 million tons of elemental phosphorus, though only a fraction of the material mined is now actually converted to the element.[9]

In considering how phosphorus cycles through the environment, we have to bear in mind one important point – unlike many other Main Group elements that play a major role in environmental (and hence biological) processes, phosphorus will not naturally form significant amounts of any volatile compound. Thus, phosphate cycles very slowly; the primary inorganic phosphate cycle (Figure 1), which consists of three steps, starts with the leaching of phosphate from the land by weathering. This material will be carried by rivers down to the oceans, after which the precipitation of apatite phosphate into the sea occurs. In the final step, the marine deposits are subjected to a geological process that ultimately brings the phosphate material back to dry land. Of course, this kind of geological process requires a passage of immense time to progress – many millions of years – and the presence of life on earth augments this cycle with its own organic perambulations.

Oceanic plants and algae take up phosphate and they either die or are consumed. The phosphate is then released again into the environment by decay or excretion. Of course, this cycle links to the inorganic cycle through the replenishment of phosphate (food) in the seas via river leaching; the precipitation mentioned earlier is augmented by the organic debris that generates sediments. Although the net transfer of phosphorus is in the direction of the primary cycle, there are movements in the opposite direction: from water to land by fish-eating creatures such as seabirds and humans, and from sediment to solution by decay and hydrolysis processes.

As alluded to earlier, phosphorus has a major role play in life. There are two fundamentally important aspects to this role. First, phosphorus (in the form of inorganic, primarily calcium, phosphates) is the major structural material in vertebrate bone. Second, phosphate esters provide linkages in biologically important systems. The major energy storage and transfer mechanisms in all living systems involve the synthesis and breakdown of phosphate ester linkages such as those present in adenosine diphosphate (ADP) and adenosine triphosphate (ATP); whereas the storage and transfer of coded genetic information involve Nucleic Acids (DNA, RNA) that are diesters of phosphoric acid.

2.2 Utilization of Phosphorus in the Laboratory/Industry

As we will see, worldwide production of elemental phosphorus continues on a massive scale. This reflects the fact that many processes rely on its conversion to industrially relevant materials. One of the most significant of these processes is the conversion to phosphoric acid, which then finds use in a wide range of applications. This technique of

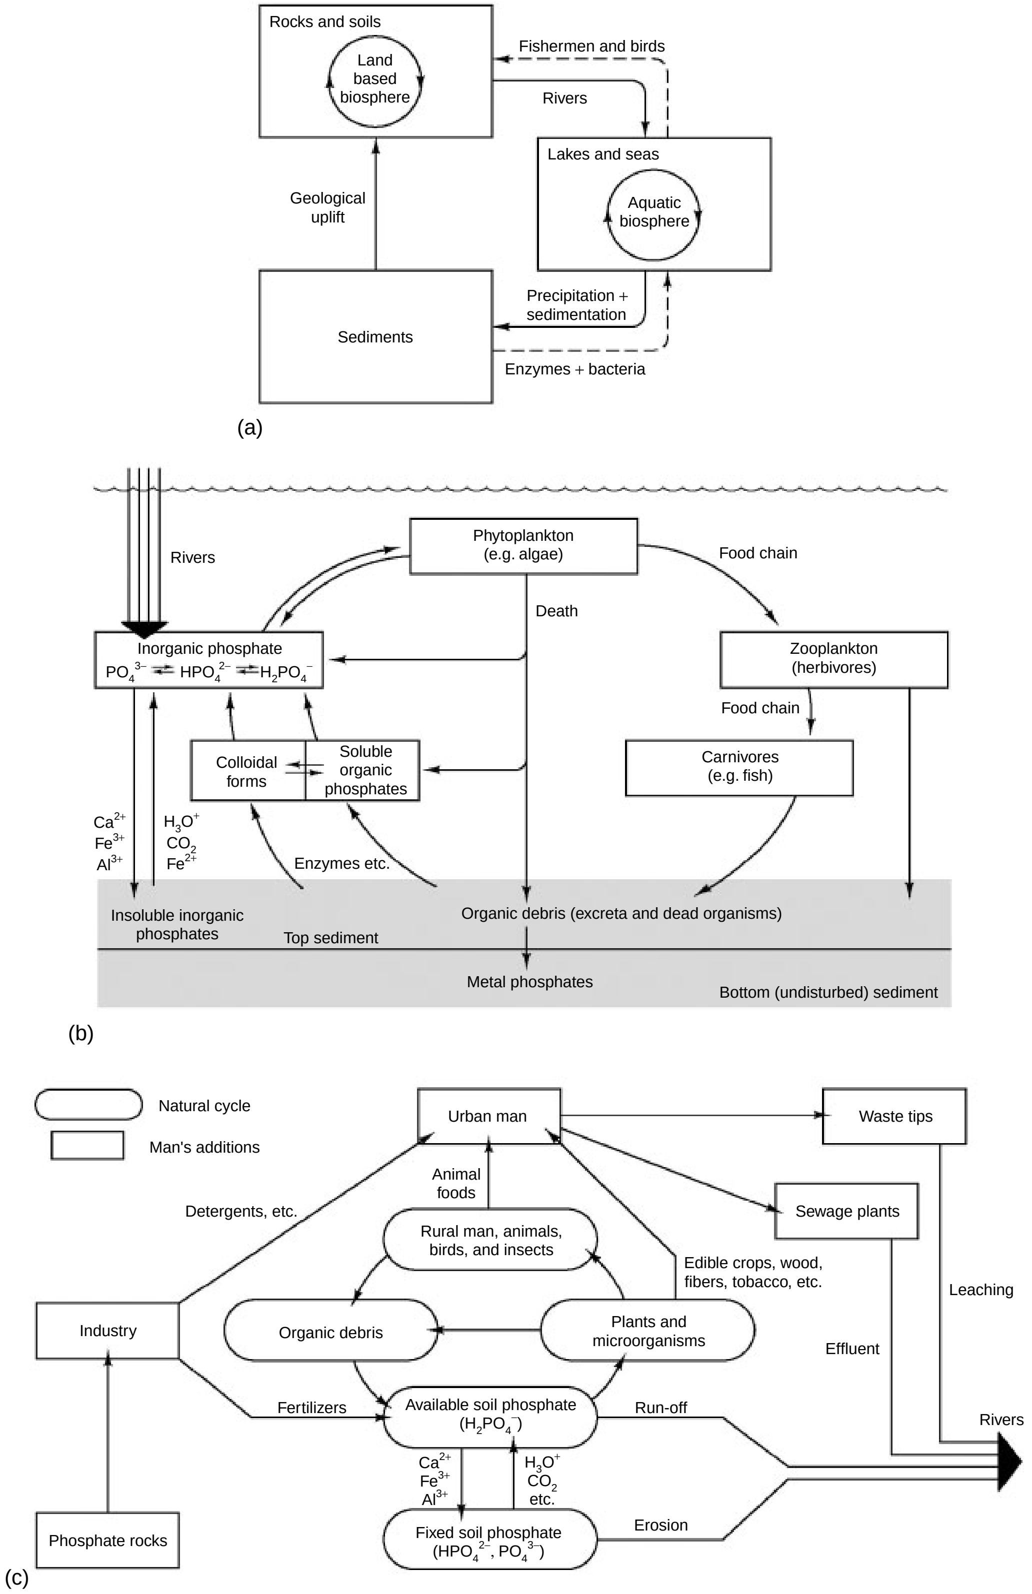

Figure 1 (a) The primary and secondary cycles; (b) the water-based phosphate cycle; (c) the land-based phosphate cycle.[8] (Reproduced by permission of The Royal Society of Chemistry)

production of the acid is known as the ‘thermal’ process, and involves burning of the phosphorus to produce phosphorous pentoxide (P_4O_{10}), which is then hydrated. In reality, however, >90% of the phosphoric acid production comes in the form of high volume, low cost, low purity material that results from the ‘wet’ process (see Section 7.2). Large amounts of the element are also converted to P_4S_{10}, PCl_3, and $POCl_3$ – again, further details of such processes and the uses of the products are presented later in the relevant sections. The standard process of conversion of naturally occurring phosphates to phosphorus generates the ‘white’ allotrope; this in turn can be converted to the ‘red’ form, which has a different reactivity pattern and finds much use – again, details of this are provided later.

In terms of research work in laboratories investigating phosphorus chemistry, the element itself is often the starting material of choice. Here again the different reactivities of the white and red allotropes come into play – in such circumstances the ease of handling of the less reactive, far less toxic red form may be a consideration, though many of the reactions we will see below utilize the white form via appropriate use of anaerobic handling techniques. Many phosphorus compounds that act as important starting materials for further work are readily available. The kinds of reactions that may allow one to convert some of these materials to further compounds hinge upon the reactivity of the bonds between phosphorus and other elements. Examples of reactivity of such bonds will be seen in later sections. Perhaps the most common involves a nucleophilic attack upon the P–Cl bond and concomitant substitution – in this way many examples of substituted phosphanes can be generated. There are of course plenty of other examples of reactive bonds, ranging from P–H to the P=S double bond in some phosphorus sulfides (which are readily desulfurized with sulfur scavengers such as PPh_3).

By way of assessment of the relative bond strengths, the following correlations have been drawn up[3] (see also Table 1).

- P–H bonds are weaker than N–H or C–H and are comparable in strength with Si–H or S–H.

Table 1 Some examples of bond distances and strengths in phosphorus compounds

P–X	Single-bond lengths (pm)	P–X bond enthalpies (kJ mol^{-1})
P–H	142	328 (PH_3)
P–F	153	490 (PF_3)
P–Cl	200	319 (PCl_3)
P–Br	214	264 (PBr_3)
P–I	247	184 (PI_3)
P–B	197	–
P–C	184	264 (PMe_3)
P–N	177	ca. 290
P–P	222	209 (P_4)
P–O	162	407 (P_4O_6)
P–S	209	–

- P–halogen bonds are roughly as strong as C–halogen and stronger than N–halogen.
- P–O bonds are stronger than N–O or C–O.
- P–C bonds are at least as strong as C–C, but may be a little weaker than N–C.
- P–P bonds are somewhat weaker than C–C, but stronger than N–N or As–As, and comparable with Si–Si or S–S.
- P–N bonds are fairly strong and comparable with P–P; they are stronger than N–N but a little weaker than P–C.
- P=O bonds are stronger than P=S and much stronger than P–O, but somewhat weaker than C–O or N–O.
- P=P bonds are considerably weaker than N=N or C=C.
- P≡P bonds are weaker than N≡N, P≡N, or C≡C, but stronger than As≡As.
- P≡N is probably the strongest bond formed by phosphorus.

Upon undertaking chemistry of phosphorus systems, the question of characterization of reaction products comes to the fore. In addition to X-ray crystallography, which has been absolutely invaluable in many situations, ^{31}P nmr and infrared spectroscopy are routinely applied to phosphorus systems. Figure 2 and Figure 3 provide some indicative chemical shifts (on the basis of the standard phosphorus reference, namely 85% aqueous phosphoric acid) and stretching frequencies that result from these techniques.

3 ALLOTROPES OF PHOSPHORUS AND THEIR PRODUCTION

Phosphorus exists in many allotropic modifications of various complexity (see Figure 4); a 2002 review perhaps sums up the situation best by referring to phosphorus as being available in a ‘bewildering variety of physical states’.[10] In terms of materials that may be used in standard laboratory conditions, these may be assigned to three different ‘families’ – ‘white’, ‘red’ (or ‘violet’), and ‘black’ phosphorus, and we will look at their structures in due course. Before doing so, it is worth noting that the simplest possible scenario, monatomic P, is known to exist but only becomes the predominant species in phosphorus vapor at temperatures in the order of 3000 K (at atmospheric pressure). Below such temperatures, diatomic P_2 (P–P distance 187 pm) predominates and is, of course, analogous to the simplest form of phosphorus’ lighter congener N_2. The fact that P_2 is not stable at RT provides a good example of the changes in relative bond strengths upon descending a group from the first main row to the second. Put simply, while the N≡N triple bond is *more* than three times the strength of an N–N single, the P≡P bond strength is *less* than thrice that of the single bond. P_2 is in fact in equilibrium with P_4; thus dissociation of P_4 into $2P_2$ reaches 50% at ≈2100 K and dissociation of P_2 into 2P reaches 50% at ≈2800 °C. There is

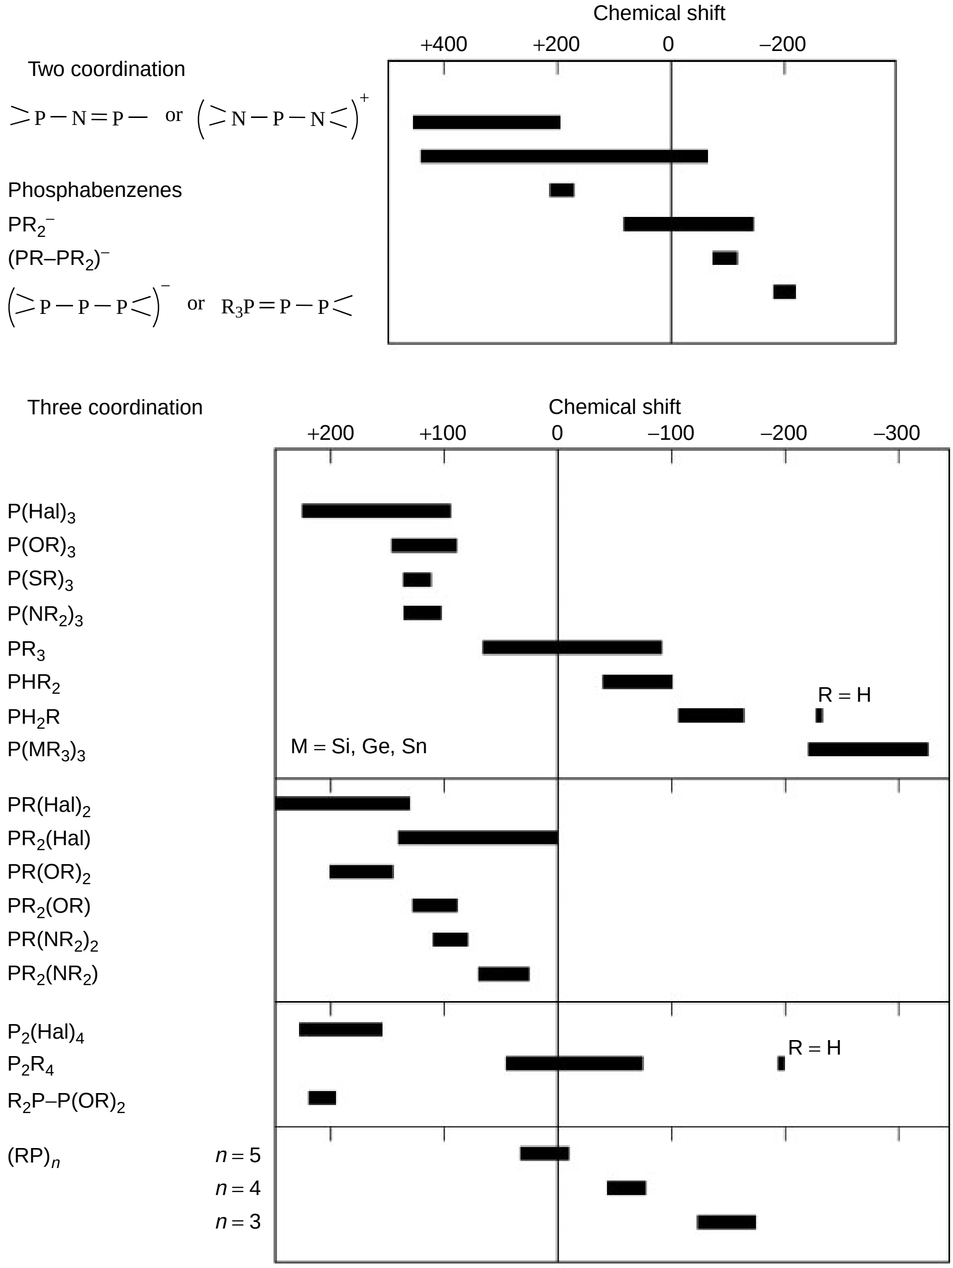

Figure 2 The chemical shift ranges for phosphorus in various coordination numbers

evidence of the formation of other species such as P_3, P_6, P_8, as well.

3.1 White Phosphorus

As noted earlier, for many years after its discovery the only source of phosphorus was urine and all the original work on production of the element involved production of the allotrope known as white phosphorus (after its white – or yellowish – waxy appearance) (Table 2). The efficient preparation of this allotrope by heating phosphate rock with sand and coke was first patented by A. Muller in 1861 and two rival groups – J. B. Readman and T. Parker/A. E. Robinson – both filed patents for the use of electric furnaces to accomplish this task in 1888.[2] This remains effectively the current method for phosphorus production well over a century later. Thus a typical modern phosphorus furnace produces about 4 tons of white phosphorus per hour via the action of massive carbon electrodes upon multitonne mixtures of phosphate rock, silica, and coke, at a reaction temperature in the region of 1400 to 1500 °C. The phosphorus vapor is driven off and then condensed by water, producing an approximately

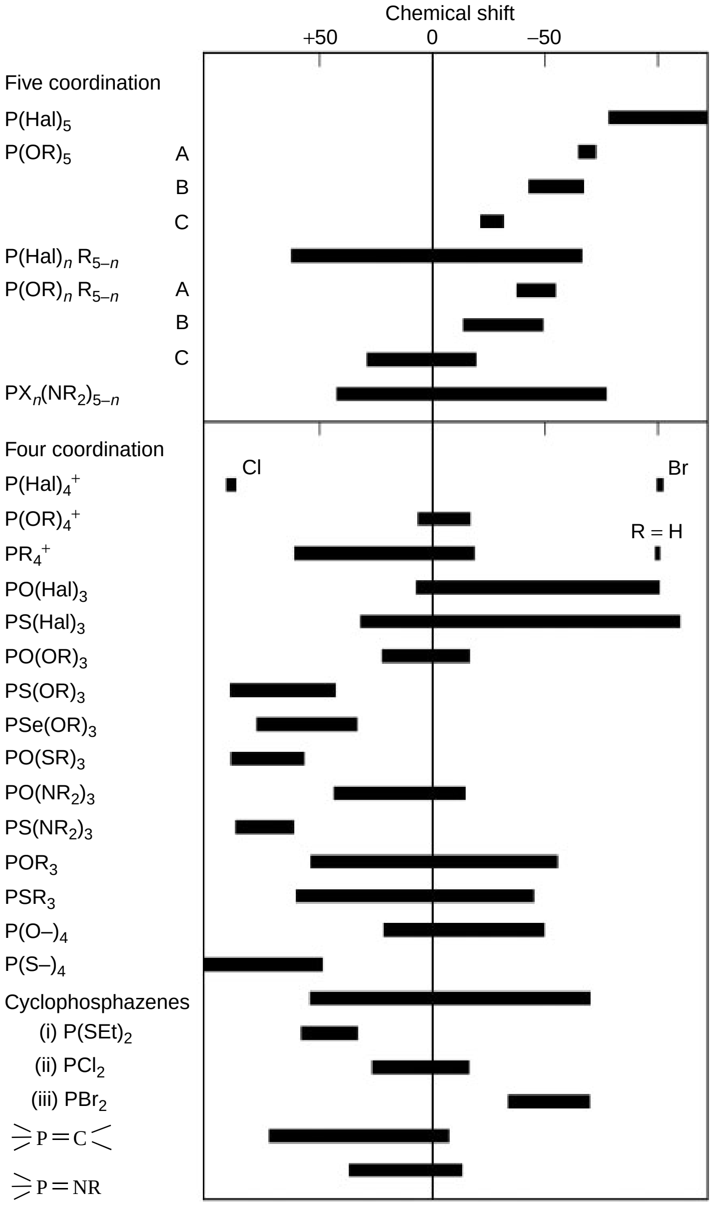

Figure 2 cont'd

90% yield of elemental phosphorus based on the phosphorus content in the raw material.

The white phosphorus produced in the above manner is the most common form of the element. It forms a waxy solid that is insoluble in water – in fact, storage under water proves one of the safest means of containing the material as it ignites in air with a self-ignition temperature of 34 °C (an aqueous copper sulfate solution is commonly used to deactivate spillage of the solid material). It is soluble, to varying degrees, in a range of solvents; in CS_2 for example, dissolution of about 880 g phosphorus per 100 g CS_2 can be achieved. It is worth noting that the element in its white form is extremely toxic. Upon ingestion, doses as low as 100 mg can prove fatal via liver failure, while prolonged intake of smaller amounts of the material can also have dire consequences. Thus, the rather comical sounding phrase 'phossy jaw' belies the agonies endured by sufferers of this industrial disease, prevalent among match workers in the late 1800s and early 1900s. The grotesquely awful accounts of the symptoms of the malady, and of the surgical procedures required to halt its progress, are not easily forgotten.[2,11,12]

Two solid forms of white phosphorus are known, with the cubic α-form converting to the β-form at 197 K. The basic molecular structure of both consists of the P_4 tetrahedron (**1**). Recent work has raised the intriguing suggestion that liquid phosphorus, consisting of the P_4 molecules, undergoes a high-pressure transformation to a polymeric form. Indications are

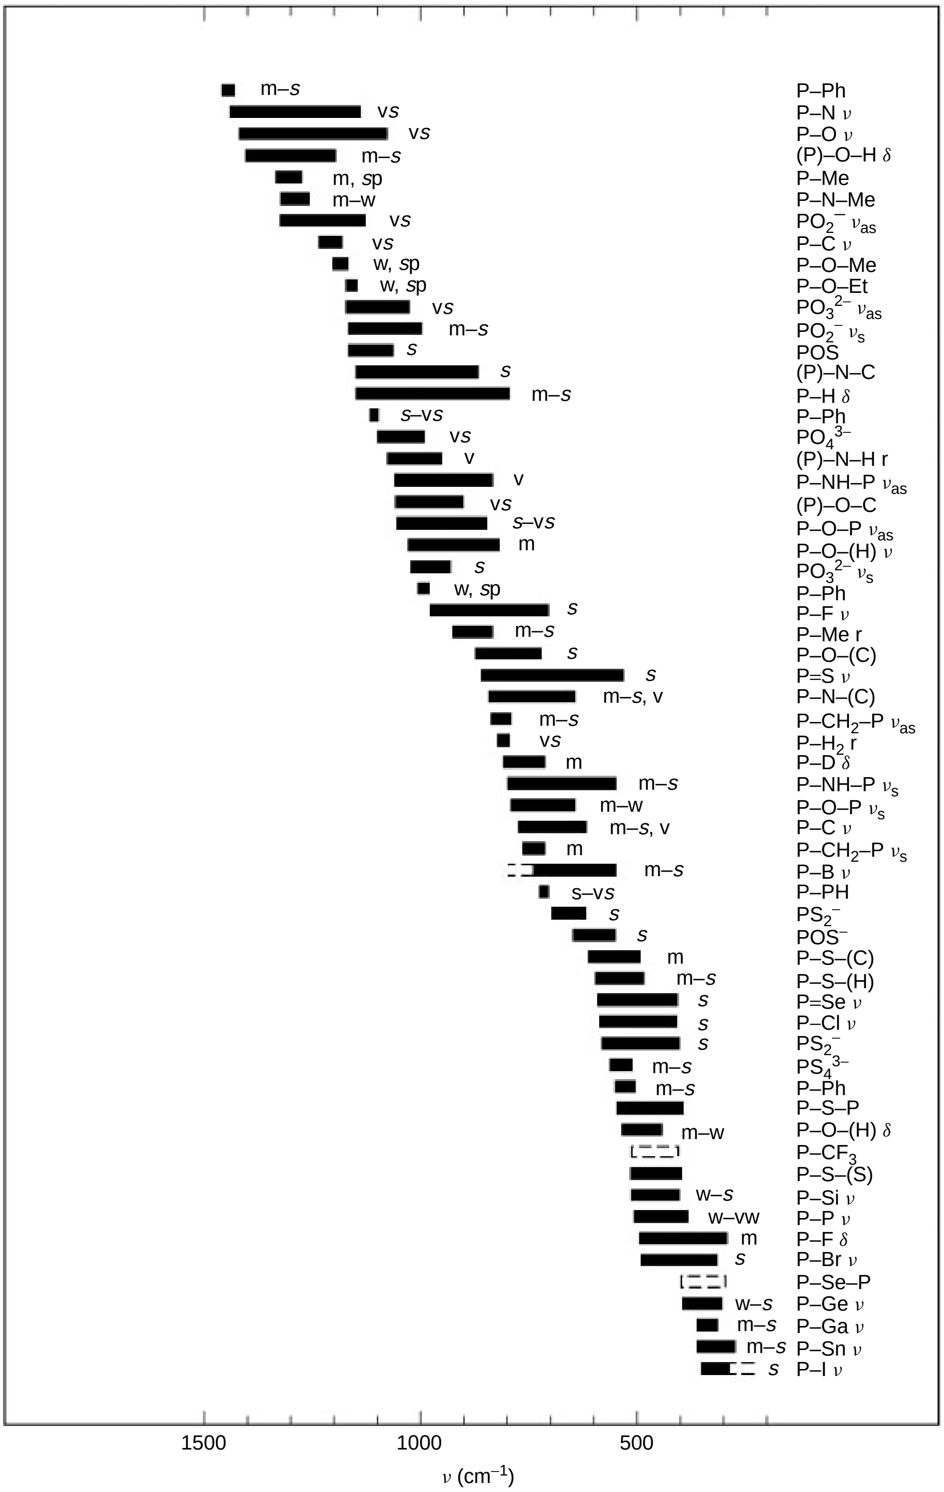

Figure 3 Infrared correlation chart for phosphorus compounds[3]

that this is a rare example of a first-order liquid–liquid phase transition.[13]

Though white phosphorus is the most commonly used form of the element, it is thermodynamically less stable than the other allotropes.

3.2 Red Phosphorus

Amorphous red phosphorus was first obtained by Anton von Schrötter in 1845 through heating white phosphorus with exclusion of air for several days, and is now made on a

commercial scale by a similar route. In the modern process, the conversion is carried out in massive, high-temperature ball mills in which multitonne quantities of iron shot act as the milling agents. The white phosphorus is fed into the ball mill at such a speed as to maintain the reaction temperature through the heat of reaction. After cooling, the reactor is filled with water, the product milled to a fine powder and then pumped into vessels to be washed with sodium hydroxide (to remove traces of white phosphorus), filtered and dried under inert gas. Of worldwide production in 1999, the distribution

Table 2 Physical properties of phosphorus (α-white form)

Atomic number	15
Atomic mass	30.973762
Crystal system	cubic
Unit cell	$a = 185.1$ pm; 58 P_4 per cell
Density (solid)	1.83 g cm^{-3}
Density (liquid)	1.74 g cm^{-3}
Melting point	44.1 °C
Boiling point	280.5 °C
Heat of fusion	2.51 kJ mol^{-1}
Heat of vaporization	51.9 kJ mol^{-1}
Heat of sublimation	56.3 kJ mol^{-1} (P_4)
Critical temperature	675 °C
Critical pressure	8 Mpa
Coefficient of thermal expansion, 0–44 °C, per °C	125 × 10^{-6}
Hardness (Moh's scale)	0.5
Thermal conductivity	0.235 W m^{-1} K^{-1}

of products utilizing red phosphorus has been estimated as: matches (44%), aluminium phosphide (24%), flame retardants (18%), and pyrotechnics (6%), with the remaining 8% used for a variety of other products. The utilization in safety matches comes in the formulation of the striking surface on the matchbox; in contrast, when mixed with plastics (usually to the extent of 5–10% by weight), red phosphorus imparts flame retardant properties and such materials find widespread use in the electronics industry. Aluminium phosphide finds use as a fumigant in grain silos (thanks to its tendency to release phosphine, PH_3, as it breaks down), while in pyrotechnics, red phosphorus is used to generate smoke.

This allotrope is denser than white P_4 (≈2.16 g cm^{-3}), has a much higher melting point (≈600 °C), and is much less reactive; it is therefore safer and easier to handle and is essentially nontoxic. The amorphous material can be transformed into various crystalline red modifications by suitable heat treatment. At 723 K, two distinct crystalline forms can be generated, while a third forms upon taking the temperature up to 800 K. While there is still apparent uncertainty about the structure of these modifications (with work of the structure of the amorphous material, e.g. continuing apace),[14] another form – generated at still higher temperatures (or – as originally performed in 1865 – by crystallization from molten lead) has been fully elucidated. This product is often referred to as Hittorf's violet allotrope (**2**) and its monoclinic structure consists of alternating P_8 and P_9 subunits linked by P_2 groups to generate tubular like chain arrangements with P_{21} as the effective repeat unit. These chains then interact with other chains, generating a complicated overall arrangement.

3.3 Black Phosphorus

Black phosphorus is actually thermodynamically the most stable form of the element and may be prepared in both

amorphous and orthorhombic (**3**) forms by the action of temperatures and pressure upon white phosphorus. Increasing the pressure results in rhombohedral (**4**) and cubic forms. All are even more highly polymeric than the red form and have correspondingly higher densities (orthorhombic $d = 2.69\,\mathrm{g\,cm^{-3}}$; rhombohedral $d = 3.56\,\mathrm{g\,cm^{-3}}$; cubic $d = 3.88\,\mathrm{g\,cm^{-3}}$). The structure of this allotrope has recently led to theoretical predictions that black phosphorus analogues of carbon nanotubes may be feasible.[15]

4 CHEMICAL PROPERTIES OF PHOSPHORUS – INTRODUCTION

4.1 Coordination Number and Geometry

In one way or another, the whole of the periodic table barring the Noble Gases can become involved in the chemistry of phosphorus. In the resulting compounds, the phosphorus atoms may adopt a whole range of coordination numbers (CN) and geometries, although as one might imagine some are substantially more common than others. For example, a CN of 3 is one of the most common coordination numbers for phosphorus, with a massive range of examples corresponding to a general formula P(X)(Y)(Z). In such cases, X, Y, and Z may be H, halogen, organic substituents, OR, NR_2, PR_2, SR, or SiR_3 groups, and so on. This tendency towards a CN of 3 is also exhibited by phosphorus within molecules containing more than one phosphorus atom, such as the P_4 allotrope or P_4S_3. In most cases, the geometry at the phosphorus for CN species will be pyramidal, with a lone pair on the P.

The ubiquity of compounds of the type P(X)(Y)(Z), together with the lone pair on the phosphorus leads invariably to a vast array of concomitant compounds of the type (A)P(X)(Y)(Z), wherein the phosphorus exhibits CN of 4. Thus the enormous range of phosphanes of the type PR_3, coupled with their ability to coordinate with metal centers and the many catalytic properties of the resulting complexes, ensures that 4-coordinate phosphorus is of utmost chemical and industrial importance. Away from metal chemistry, $POCl_3$ and P_4S_{10} also exhibit 4-coordinate phosphorus atoms and, as we will see, they both have enormous technological relevance. The basic geometry for phosphorus of CN 4 will be tetrahedral.

Higher CN values are also possible and, indeed, important for phosphorus. Thus, PF_5 exhibits a trigonal bipyramidal structure while addition of fluoride generates the octahedral, 6-coordinate $[PF_6]^-$ anion. Care needs to be taken when assessing formulations though; as we will see, the structural chemistry of PCl_5 varies between its vapor state and when it is in solution. Still higher CN values are rarer as are CN values of <3. Both extremes are possible, however, as in the high coordinate structure of transition metal phosphides or the doubly coordinate phosphorus present in the first stable phosphabismuthene (Section 6.3). An even lower CN is found in compounds such as MeCP and indeed, as already noted, the ultimate example of low-coordination number phosphorus – the naked P atom – is attainable, but only at high temperatures.

4.2 Phosphorus Compounds – Overview

The following review (over the subsequent five chapters) does not profess to be an all-encompassing listing of every type of phosphorus compound. That would clearly take up far too much space and would duplicate the efforts of more comprehensive works and, indeed, of other entries to this encyclopedia. Rather, after looking at the formation of phosphorus anions and cations, the entries are listed in order of the Main Group of the periodic table and in each case give a flavor of the phosphorus chemistry associated with that Group. That said, there is no specific entry for groups 1 and 2 as they are involved in the formation of the aforementioned phosphide anions, nor have examples of compounds with Noble Gas – P bonds been reported yet for group 18.

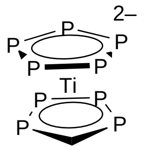
The main impetus behind inclusion of systems is to highlight the following:

1. industrially important compounds;
2. systems that are the subject of great current interest;
3. systems that result in unusual bonding arrangements, thereby highlighting the ability of phosphorus to exhibit great structural diversity in all areas of its chemistry and to assist in the stabilization of unusual arrangements of *other* elements.

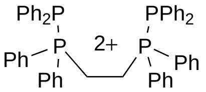
5 PHOSPHORUS ANIONS, CATIONS, AND HYDRIDES

5.1 Phosphorus Anions and Cations

Reduction of elemental phosphorus gives rise to a range of phosphide species. As might be expected, this is the chemistry that dominates group 1 elements' reactivity towards phosphorus, and all form phosphides of the stoichiometry M_3P_7 and MP_{15}. Likewise, all of the group 2 metals form phosphides of formula M_3P_2. The ability to react directly with phosphorus is not limited to these elements though – in fact, a majority of the rest of the periodic table can react likewise. Overall, the variety of stoichiometries known for metal phosphides is enormous, ranging from metal-rich systems (such as $M_{12}P_5$) to 1:1 arrangements and right through to very phosphorus rich systems such as M_4P_{26}. In general, these materials can be generated by direct reaction of the elements, though many other synthetic techniques can be employed. The structural aspects of phosphides are discussed in great detail elsewhere in this encyclopedia (*see* ***Phosphides: Solid-state Chemistry***). Suffice to say here that one of the most important



(8)



(9)

Figure 5 The structures of $[Ti(P_5)_2]^{2-}$ and 1,2-$[Ph_2(PPPh_2)_2(CH_2)_2]^{2+}$

aspects of this area stems from the ability of phosphorus to form extended catenated arrangements. This is apparent in the structure of the elemental forms and provides the basis for the buildup of large anionic structures such as $[P_{16}]^{2-}$ (**5**), $[P_{21}]^{3-}$ (**6**) and $[P_{26}]^{4-}$ (**7**).

Smaller structures can also provoke extreme interest and a good example comes in the form of the cyclic $[P_5]^-$ ion that has been shown to bind to metals in a manner analogous to the cylcopentadienyl anion as exemplified by the $[Ti(P_5)_2]^{2-}$ anion (**8**) (see Figure 5).[16]

In some cases, the phosphide anions produced in reactions also contain hydrogen atoms bound to the structure. Thus, a recent example has shown that direct reduction of white phosphorus with sodium in liquid ammonia generates the catena-trihydrogen triphosphide $[P_3H_3]^{2-}$.[17]

Surprisingly, oxidation to 'naked' cations is yet to be unambiguously achieved, at least in terms of material that may be isolated (many examples of cations have been witnessed in mass spectrometric measurements on vaporized samples of the element);[18] the $[P_5]^+$ cation has, however, been postulated as an intermediate in the reactions that generate $[P_5I_2]^+$ and $[P_3I_6]^+$.[19] Introducing organic groups does allow cationic systems containing P–P bonds to be prepared; the $[dppe(PPh_2)]^{2+}$ dication (**9**) is a good example.[20]

5.2 Hydrides of Phosphorus

Although the simple hydride phosphane, PH_3, is by far the most important of these compounds, many other examples of compounds containing only P and H are known; this range is made even larger if one also includes species detected by mass spectrometry or ^{31}P nmr, but not isolated in pure form (Ref. 21 lists 85 such species for example, ranging from hydrogen rich PH_3 to phosphorus rich $P_{22}H_4$ via 1:1 ratio examples such as $P_{10}H_{10}$).[21] Hydrides of the type P_nH_{n+2} are open chains; P_nH_n are simple rings, whilst the more phosphorus rich compounds are cages. Most of the phosphanes are obtained from thermolysis reactions of diphosphane, although methanolysis of silyl derivatives provides a good route to P_5H_5 and P_7H_3.

Diphosphane P_2H_4 can be generated by passing a high voltage electric discharge through PH_3; it can be isolated as a colorless, volatile liquid (mp −99 °C, bp 56 °C). It is relatively unstable and decomposes to give PH_3 among other hydrides; with liquid ammonia, it generates a range of ammonium polyphosphides, including $[NH_4]_3[P_{19}]$ and $[NH_4]_3[P_{21}]$, as well as the anionic hydride $[H_2P_{14}]^{2-}$.[22] The triphosphane P_3H_5 is isolated as a white solid, also by the decomposition of diphosphane.

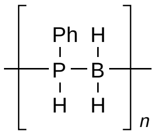
The most stable hydride of phosphorus is phosphane (PH_3). It is an extremely poisonous, highly reactive, colorless gas that has a faint garlic odor at concentrations about 2 ppm by volume. It can be generated in a number of ways, including the alkaline hydrolysis of white phosphorus, which is the industrial process. It also forms in the pyrolysis of P_4O_6 and by hydrolysis of some phosphides such as AlP (which forms the basis of the use of the latter phosphide as fumigant). As would be expected for a PX_3 molecule, phosphane has a pyramidal structure with P–H distance of 142 pm and an angle of 93.6°; it melts at −133.5 °C and boils at −87.7 °C. Phosphane undergoes gradual decomposition in water; products include phosphorus and hydrogen. In liquid ammonia, however, phosphane dissolves to give NH_4^+ PH_2^-, and with potassium gives KPH_2 in the same solvent.

Phosphane burns readily in air; the pure gas ignites in air at about 150 °C but when contaminated with traces of P_2H_4 it is spontaneously flammable. It also photodissociates, under flash photolysis at above 195 nm, generating PH and PH_2 radicals. PH_3 is also a strong reducing agent; many metal salts are reduced to the metal. When heated with sulfur, PH_3 yields H_2S and a mixture of phosphorus sulfides. Probably the most important reaction industrially is the hydrophosphorylation of formic acid in aqueous hydrochloric acid; the tetrakis (hydroxymethyl) phosphonium chloride so formed is the major ingredient with urea – formaldehyde or melamine – formaldehyde resins for the permanent flameproofing of cotton cloth.

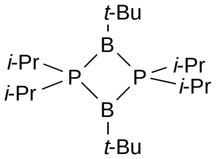
6 COMPOUNDS WITH GROUP 13, 14, AND 15 ELEMENTS

6.1 Group 13 Elements

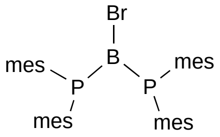
As with all group 13 elements (Figure 6), boron forms a 1:1 phosphide, that is, BP; in addition, unlike its congeners it also forms a lower phosphide, namely $B_{13}P_2$. Given the Lewis acidity of alkyl boron species, it is not surprising that phosphane adducts are known; one interesting example comes in the form of $(C_6F_5)_3BPH_3$ that has been shown to release the phosphane above room temperature, providing a potential safe storage form for the latter gas.[23] While it has long been known that thermolysis of adducts of the type $R_2PH{\cdot}BH_3$ generates cyclic phosphinoboranes, usually trimers of the type $(R_2P\text{-}BH_2)_3$, it is only recently that conversion to high molecular weight poly(phosphinoboranes) (**10**) has been achieved via a rhodium catalyzed reaction.[24] Thus, by way of example,



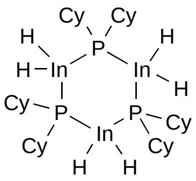
(**10**)



(**11**)



(**12**)



(**13**)

Figure 6 The structure of some P-Group 13 species

refluxing $PhPH_2.BH_3$ with the rhodium catalyst in toluene for 14 hours generates an air and water stable polymer with average molecular weight of 5600 (i.e. 46 repeat units). Heating in the absence of toluene generates a higher molecular weight material. Such observations add a new class of compounds to the already significant number area of main group, phosphorus-based polymers, the subject of a 2002 review.[25]

The four-membered cyclic compound $(^iPr_2P)_2(B^tBu)_2$ (**11**) has elicited much interest, thanks to it being a rare example of a singlet diradical, which is indefinitely stable at ambient temperatures.[26] As noted above, phosphinoboranes tend to be oligomeric rings; monomeric species may be isolated though if large substituent groups are employed. Thus, $(mes_2P)_2BBr$ is an orange solid with the structure shown (**12**).[27] The introduction of phosphorus into borane (and carborane) structures has yielded a wealth of chemistry.[28,29] This can be done either by building from small B and P constituents (thus pyrolysis of B_2Cl_4/PCl_3 mixtures leads to [*closo*-1,2-$P_2B_4Cl_4$])[30] or by reaction of large boranes with, for example, PCl_3.[31] For the heavier members of the group, similar acid-base chemistry is possible – by way of example, the trimeric phosphido-indium hydride complex $[\{InH_2(Pcy_2)\}_3]$ (**13**) has been reported.[32]

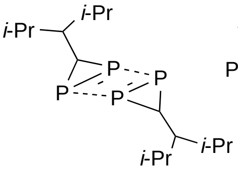
The most important aspect of the phosphorus chemistry of Al, Ga, and In stems from the fact that their phosphides exhibit unusual (and desirable!) electrical properties. All act as semiconductors, with band gap energies that drop as the group is descended (236, 218 and 130 $kJ\,mol^{-1}$ for AlP, GaP and InP respectively). They have found extensive use in LED technology and are inextricably linked to the history of LED development. Indeed, the first red LEDs utilized gallium arsenide phosphide (GaAsP); subsequent switching to gallium phosphide (GaP) paved the way for the introduction of new colors. Introduction of gallium aluminium arsenide phosphide (GaAlAsP) LEDs in the 1980s led to brighter colors, a process that continued in the next decade thanks to the introduction of indium gallium aluminium phosphide (InGaAlP) systems.

As already mentioned, aluminium phosphide finds use as a fumigant thanks to its ability to slowly release PH_3. Its effectiveness comes at a price; for example, it has been estimated that 10 000 deaths by deliberate ingestion occur per annum in India alone.[33]

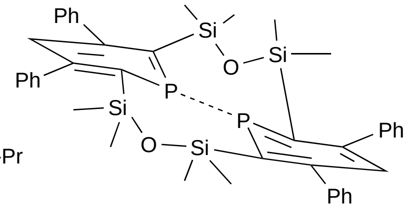
6.2 Compounds with Group 14 Elements

The organic chemistry of phosphorus is dealt with elsewhere in this encyclopedia. In the case of phosphanes PR_3 and their coordination chemistry, their importance cannot be overstated.[34] In fact, it is fair to say that development of transition metal phosphane complexes as catalysts for a range of transformations has had a profound effect upon the way the interface between organic and inorganic chemistry is viewed. After all, here we have organic ligands generating inorganic complexes which then catalyze organic transformations. As such, they have been one of the driving forces in the breaking down of traditional barriers between the disciplines, resulting in the growing tendency to unite inorganic and organic work together under the banner of ‘synthetic chemistry’.

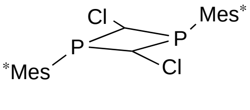
It is worth just considering some materials that are undoubtedly organic in nature but whose properties tell us something fundamental about the behavior of phosphorus.[35] These are very much at the forefront, not only of the chemistry of the element but also in bonding models in general (Figure 7). An excellent example comes in the form of 4-membered phosphorus ring within $(^iPrNCP_2)_2$ (**14**); as indicated, the structure consists of a dimer held together by two 1-electron P–P bonds (the difference in bond order within the system is easily confirmed by the bond lengths).[36]



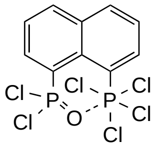
(**14**)



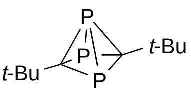
(**15**)



(**16**)



(**17**)



(**18**)

Figure 7 The structure of some P–C species with unusual bonding arrangements

Compound (**15**) also exhibits a 2-centre, 1e bond between P atoms and again the bond is long (about 2.76 Å),[37] while the unusual biradicaloid (**16**) is thermally stable up to 150 °C.[38] The constraints placed upon the phosphorus atoms in compound (**17**) result in hypercoordination of the phosphorus adjacent to the oxygen,[39] while (**18**) constitutes the first cationic phosphorus-carbon cluster, namely *nido*-[3,5-^{t}Bu$_2$-1,2,4-C_2P_3]$^+$.[40] All such observations show great promise for future development.

The first example of a silylphosphane, H_2PSiH_3, was reported in 1953[41] and a vast amount of work has gone into the preparation of Si–P systems since then, resulting in a wide range of synthetic strategies and structural motifs (Figure 8).[42] Examples of the general formula RR′PSiR′R″R‴ are now known for all manner of combinations of substituent. Silyl species may also take the place of the R and R′ groups on the phosphorus atoms in the aforementioned formulation; thus $P(SiMe_3)_3$, for example, is an important ligand. Many intriguing structures have resulted from work in this area, such as the four-membered ring within (**19**).[43] Reaction of Me_2SiCl_2 with LiPH^{t}Bu results in $(Me_2Si)_3P_2(P^tBu)_2$[44] (**20**), while $P_2(PSi^tBu_3)_2$ (**21**) and $P_7(Si^tBu_3)_3$ (**22**) form in the reaction of white phosphorus with $(Si^tBu_3)_2$.[45] An even higher phosphorus content is found in $P_{11}(SiMe_3)_3$ (**23**), which results from the reaction of Na_3P_{11} with Me_3SiCl.[46]

Phosphasilenes RR′Si=PR″, wherein the substituents are bulky stabilizing groups, are also known. Addition across the Si–P double bond – with concomitant cycle formation – can be achieved by many species including nitriles, sulfur, and phosphorus itself.

Systems based on single bonds between the heavier group 14 elements and phosphorus are well documented – (**24**) is a nice example of the stabilization of a Ge(I) species this way.[47] It is even possible to obtain multiple bonds to the heavier elements; thus the chemistry of double-bonded germaphosphines and stannaphosphines – bearing Ge=P and Sn=P bonds – has been developed thanks again to the use of bulky, stabilizing substituents.[48] There has even been recent speculation to the possibility of stabilizing the analogous triple bond.[49]

6.3 Compounds with Group 15 Elements

Extensive chemistry of P–N systems is known and many such compounds – for example, the polyphosphazenes – are of intense industrial importance. The chemistry of all such systems is covered elsewhere (*see* ***Phosphorus–Nitrogen Compounds***).

As with group 14 elements, it is possible to form double bonds between the heavier group 15 atoms and phosphorus. While the first examples of phosphaarsenes and phosphastilbenes were prepared as early as 1983,[50] it was only in 2002 that the first phosphabismuthene of the type RP=BiR′ was reported.[4] The key to the stability of the product in this case is the use of bulky groups: R = 2,4,6-(^{t}Bu)$_3C_6H_2$ and R′ = 2,6-{$(Me_3Si)_2CH$}-4-{$(Me_3Si)_3C$}C_6H_2. The P–Bi distance in this case is 2.454 Å.

7 COMPOUNDS WITH GROUP 16 ELEMENTS

7.1 Phosphorus Oxides

P_4O_{10}, commonly referred to as phosphorus pentoxide (Figure 9), is the most important oxide of phosphorus. It is generated by the burning of white phosphorus in aerated towers; if condensed rapidly from the vapor phase, it is obtained in the hexagonal form, which in turn may be transformed into other modifications by suitable thermal and high-pressure treatment. The molecular structure of P_4O_{10} (**25**) is based upon the tetrahedron within P_4, but with O inserted into all P–P bonds and a terminal oxygen added to all phosphorus atoms, though its most stable, orthorhombic form has a sheet polymeric structure.

In the laboratory, P_4O_{10} often finds use as a powerful dehydrating agent – so powerful in fact that it can convert ethanol to ethylene, H_2SO_4 to SO_3, HNO_3 to N_2O_5, and

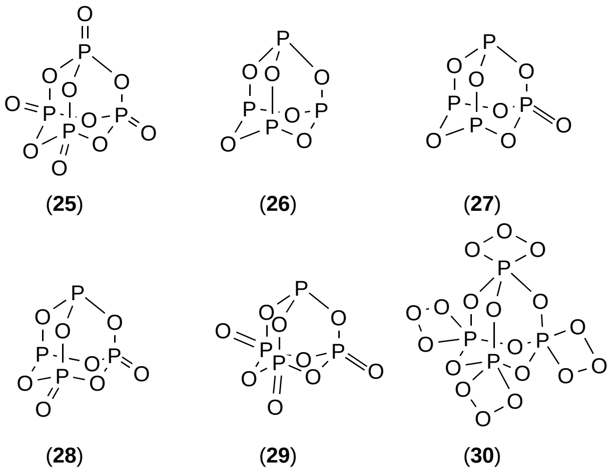

Figure 9 The structure of phosphorus oxides

amides (RCONH$_2$) to nitriles (RCN). It is this desire for water, which fuels its main industrial use – the conversion to phosphoric acid. The acid produced in this manner (i.e. ultimately from phosphate rocks via the 'thermal route') is very pure, with only the removal of arsenic being required before it is available for a variety of technical, food, and pharmaceutical applications.

Other industrially important uses of P_4O_{10} include the reactions with ethers, an example of which is the formation of triethyl phosphate via reaction with diethyl ether followed by pyrolysis. The product (which has a worldwide production of many thousands of tons per annum) finds use as ketene synthesis, a flame retardant, and a plasticizer within the plastics industry; a less 'conventional' use is as a simulant for the sarin when modeling situations involving the latter nerve agent.

The second most commonly studied oxide is P_4O_6 (**26**), which is obtained by controlled oxidation of phosphorus in an atmosphere of 75% O_2 and 25% N_2 at low pressure. Heating P_4O_6 under vacuum in a sealed tube gives a mixture of red phosphorus and the oxides P_4O_7 (**27**), P_4O_8 (**28**), and P_4O_9 (**29**). These oxides have structures in between those of P_4O_6 and P_4O_{10}, in that they have one, two, or three apical oxygen atoms attached to phosphorus atoms (cf the higher sulfides). In terms of specific preparations, P_4O_7 is best prepared from P_4O_6 dissolved in THF, using Ph_3PO as a catalyst at room temperature, while P_4O_8 has been made in pure form via the high-temperature reaction of P_4O_9 with red phosphorus.[51] Recently, a new oxide of formulation P_4O_{18} has been prepared (**30**) – this remarkable compound is actually an ozonide of P_4O_6.[52]

7.2 Oxoacids and Anions of Phosphorus

A diverse range of oxoacids of phosphorus is known. The presence of hydrogen in such systems is either in the form of POH groups (in which the hydrogen atom is ionizable) or P–H groups (from which a proton cannot be ionized). Overall, the acids can be divided into two series of oxoacid, namely, the phosphoric and phosphorous acids, in which the oxidation state of phosphorus is (V) and (III) respectively. In all of these, phosphorus is four-coordinate and tetrahedrally surrounded wherever possible. Deprotonation of the acids leads to families of anions.

Phosphoric acid, H_3PO_4, is by far the most important of these acids. Indeed, of all the inorganic acids, it is second only to sulfuric acid in terms of volume of production (and in fact in terms of net value of production it probably exceeds the latter). We have already seen how it can be produced via phosphorus abstraction and then burning/hydration, that is, the so-called 'thermal' route, and that this generates high purity material. The other main – and now most important in terms of volume – route is via the 'wet' process. Here phosphate rock is mixed with sulfuric acid and some recycled phosphoric acid; this slurry is then filtered (removing the calcium sulfate) leaving the impure phosphoric acid. The heavy-metal content of the acid at this stage means that it can only be used within fertilizers; further purification is needed to take the material to food grade, for example, and this is performed via solvent extraction techniques.

As might be expected from its structure, phosphoric acid is tribasic; the dissociation constants at 25 °C are: $pK_1 = 2.15$, $pK_2 = 7.20$, $pK_3 = 12.37$. As a result of this, the acid gives three series of salts, for example, NaH_2PO_4, Na_2HPO_4, Na_3PO_4. While its greatest use is undoubtedly in the manufacture of phosphates for use as fertilizers (accounting for 85% of the total usage of material made by the 'wet' route) and animal feed, its phosphate derivatives are also utilized in water treatment, detergents, toothpastes, fire control chemicals, and many more. In addition, the acid itself is added to colas and soft drinks in general (giving a sharp, sour taste) and is used (in the presence of metal ions such as zinc) to impart corrosion resistance to metal surfaces and to polish aluminium bodies.

Phosphorous acid, H_3PO_3, is generated by hydrolysis of PCl_3 – industrially this is carried out by spraying the chloride into steam at 190 °C. Esters of the acid, both the trialkyl esters [P(OR)$_3$] and the dialkyl esters [(RO)$_2$P(O)H], can be produced directly by substituting the appropriate acid for the water. The esters find much use; thus, triphenyl phosphite is most widely used in the manufacture of polyvinyl chloride, while trinonylphenyl phosphite is an excellent stabilizer for the same polymer.

Hypophosphoric acid ($H_4P_2O_6$) can be generated by removal of water from its 'dihydrate' (which is actually a hydroxonium salt), which in turn is formed by reacting red phosphorus with sodium chlorite followed by ion exchange on an acid column. In the absence of moisture, the acid is stable at low temperatures but at room temperature it undergoes rearrangement and disproportionation to give a mixture of pyrophosphorous acid [(HO)$_2$POP(OH)$_2$],

pyrophosphoric acid ($H_4P_2O_7$), and isohypophosphoric acid [H(HO)(O)POP(O)(OH)$_2$].[53]

Hypophosphorous acid is generated by acidification of the calcium salt Ca[H_2PO_2], itself prepared by the action of calcium hydroxide on phosphorus. Its sodium salt ($NaH_2PO_2{\cdot}H_2O$) finds use as a reducing agent for the electrodeless nickel plating on metallic parts such as steel or aluminum.[54] The possibility of P–H and P–P bonds in phosphorus oxoacids, coupled with the ease of polymerization via P–O linkages, enables a large range of acids to be synthesized. Deprotonation of such acids will allow the formation of phospho-anions. Isolation of simple monophosphates is possible, though even in such simple systems the degree of protonation of the anions is variable, as the recent isolation of [$Ga_4(C_{10}H_9N_2)_2(PO_4)(H_{0.5}PO_4)_2(HPO_4)_2(H_2PO_4)_2(H_2O)_2$], in which four types of monophosphates are present in the same compound, attests.[55] The number of acids allied to their polybasicity and the multiple possible ways such anionic units can link together (via P–O–P bonds) results in a vast range of structural types. As these are covered in another section (*see* ***Phosphates: Solid-state Chemistry***), we will not go into any great detail here – suffice to say that the classification of inorganic phosphates is based upon the geometrical configuration of their anions. In the area corresponding to the classical condensed phosphates, anions can be represented by the formula $[P_nO_{3n+1}]^{(n+2)-}$. They are usually called *linear polyphosphates*. When n becomes very large, the ratio is P:O $\rightarrow$ 1:3. For this limiting value, two geometrical configurations are possible:

1. a long-chain polyphosphate
2. a cyclic configuration with anions corresponding to the formula $[P_nO_{3n}]^{n-}$ describing all *cyclo*-metaphosphates.

Cations containing P–O units can also be generated – an unusual example being the $[P(OH)_4]^+$ ion, recently isolated and characterized by X-ray crystallography for the first time.[56]

One of the most important aspects of phosphate chemistry is the use of sodium tripolyphosphate (STPP), $Na_5P_3O_{10}$, in the detergent market. It acts, for example, as a water softener by sequestering Mg^{2+} and Ca^{2+} (e.g. it will bind the equivalent of 158 mg CaO/g).[57] Ecological concerns relating to eutrophication of lakes induced by phosphate waste has meant that restrictions imposed on its use over the last few decades has resulted in a dramatic decline of its use. Thus in the space of a decade, the use of STPP in detergents dropped by 50% within the United States, Europe, and Japan; now, 95% of all detergents sold in Japan are STPP free and contain zeolite instead.[57] Studies have suggested, however, that the effect of phosphates may not be as dramatic as was first feared and that the algal blooms in eutrophicated lakes may have actually stemmed from a lack of zooplankton brought about by other means of industrial poisoning.[2]

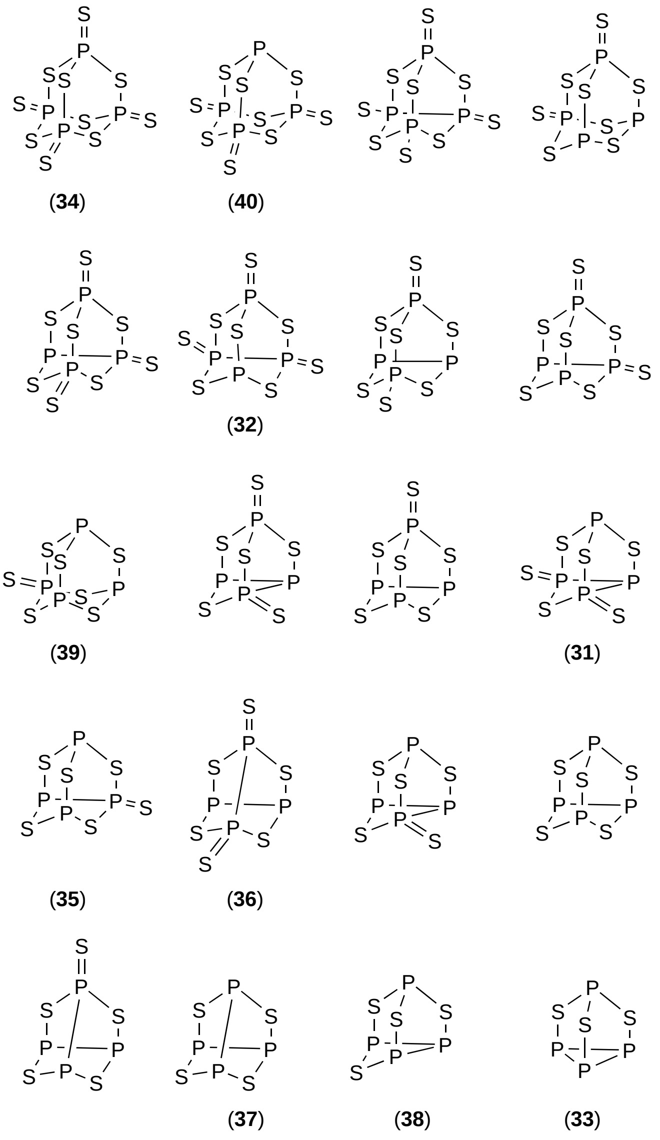

Figure 10 The structure of all currently known phosphorus sulfides

7.3 Phosphorus Sulfides and Selenides

Many areas of main group chemistry continue to provide contemporary challenges and novel chemistry despite a having a significantly long history of investigation. A perfect example of such a system comes with the binary phosphorus sulfides. Though work in this area stretches back into the nineteenth century, new examples continue to come to light (thanks in no small part to the facile and now routine use of ^{31}P nmr to monitor reaction systems). By way of example, the ostensibly straightforward reaction brought about by photolyzing a mixture of the elements at 0 °C has been the subject of a recent study, which revealed no fewer than 12 phosphorus sulfides in the reaction mixtures, two of which (**31** and **32**) were novel.[58] All values of n (from 3–10) within the general formula P_4S_n are now known (Figure 10), though only those at

Table 3 Physical properties of some phosphorus sulfides

Property	P_4S_3	α-P_4S_4	P_4S_5	P_4S_7	P_4S_{10}
Color	Yellow	Pale yellow	Bright yellow	V. pale yellow	Yellow
Mp (°C)	174	230 (d)	170–220 (d)	308	288
Bp (°C)	408	–	–	523	514
Density ($g\,cm^{-3}$)	2.03	2.22	2.17	2.19	2.09
Solubility in CS_2 (g per 100 g CS_2)	100	sol.	0.5	0.029	0.222

the extreme n values – that is, P_4S_3 (**33**) and P_4S_{10} (**34**) – have industrial significance, and of these P_4S_{10} is by far the most important. Physical properties of some of these compounds are listed in Table 3.

The structures of the known phosphorus sulfides are provided in Figure 10. Interconversion between them can be carried out in a number of ways. One conceptually obvious way is to add sulfur to a low sulfur content example, and this has been achieved in some cases by simply adding more elemental sulfur with heating. A more subtle technique has been developed recently wherein Ph_3SbS acts as sulfur source; in this way two new polymorphs (δ (**35**) and ε (**36**) forms) of P_4S_6 were generated from α-P_4S_4 in CS_2.[59] The multistep formation of two forms of P_4S_4 (**37**, **38**) from P_4S_3 via two forms of $P_4S_3I_2$, and the sulfur source $[Me_3Sn]_2S$ has been known for some time.

A logical reversal of the above process would involve removal of sulfur from a higher sulfide and indeed this can be done. Triphenylphosphine is an effective scavenger of sulfur – via concomitant formation of Ph_3PS – and this technique was recently used to generate (**39**) for the first time.[60] This process can also be achieved by direct reaction of a lower sulfide with a higher sulfur content example; thus, P_4S_9 (**40**) is formed reversibly by heating a 2:1 mixture of P_4S_7 and $2P_4S_{10}$, for example. Likewise, high-temperature reaction of phosphorus with a high-sulfur content phosphorus sulfide acts as a source of lower sulfides.

Industrially, P_4S_{10} (often referred to as phosphorus pentasulfide, P_2S_5) is generated by direct combination of the elements. Both are introduced in liquid form into a cast-iron reactor under a nitrogen atmosphere. Here initial temperatures may be in the region of 200 °C but this rises due to the exothermic nature of the reaction. Finally, the product is flushed from the system and vacuum distilled from residues. Though worldwide production is undoubtedly still high, concerns over the two main products – zinc dialkyldithiophosphates (ZDDP) engine oil additives, and organophosphorus pesticides – have reduced demand. By way of illustration, pesticide production in the United States consumed about 43 600 tons of P_4S_{10} in 1979; by the turn of the millennium this was down by about 30 000 tons per annum.[61]

Although the aforementioned products – engine oil additives and pesticides – could not be more different in terms of the nature of their utilization, their preparation stems from the same reaction, namely the alcoholysis of P_4S_{10}. The resulting dialkyldithiophosphoric acids, $SS(H)P(OR)_2$, can react with zinc salts to generate ZDDP. These have structures based on the ability of the $[S_2P(OR)_2]^-$ anion to act as bidentate ligand towards zinc, and when added to engine oils they act as both antiwear and, to a less important degree, antioxidizing agents. Their antiwear capability stems from the fact that degradation of the ZDDPs within the extreme environment of the engine results in the formation of a protective layer over engine parts. Varying the precise group on the original alcohol allows the properties of the ZDDPs to be adjusted; secondary alcohol–based ZDDPs account for about 85% of the market.

Organophosphorus pesticides are formed via further derivatization of the dialkyldithiophosphoric acids, resulting in compounds such as $(EtO)_2P(S)OC_6H_4NO_2$ (parathion) and $(MeO)_2P(S)SC(CH_2CO_2Et)HCO_2Et$ (malathion). As with ZDDPs, their effectiveness is tempered by environmental concerns. In the case of the pesticides, the long-term health risks associated with their use are still a matter of debate; certainly they require careful handling and it would appear that sensitivity towards them can vary from person to person. Concerns over ZDDPs stem from the fact that they have a detrimental effect on catalytic converters fitted to exhausts, with phosphorus deposits interfering with the active metal surfaces. Even so, ZDDPs are still used in great quantities, with the North American market alone amounting to about $180 million worth of the material.

Fewer examples are known of molecular phosphorus selenides than sulfides. P_4Se_3[62] (**41**) and P_4Se_5[63] (**42**) have both been prepared as have P_2Se_5[64] and a range of polymeric species. This tendency towards polymerization is actually quite marked for PSe systems – thus, *catena*-P_4Se_4 is known in which terminal selenium atoms link to the next unit (**43**).[65] The range of molecular units is increased if one also considers PSe units stabilized within CuI matrices, an example of which is the β-P_4Se_4 cage (**44**) within $(CuI)_3P_4Se_4$, which is prepared by the high-temperature reaction of CuI with phosphorus and selenium in silica ampules.[66] The ability of such techniques to result in formation of unusual products is further exemplified by the isolation of $(CuI)_2P_8Se_3$ (**45**) from a similar reaction.[67] Using polyselenophosphates as flux for high-temperature reactions involving metals also allows the isolation of unusual species such as the mercury anion (**46**) in Figure 11.[68]

In addition, mixed sulfide selenide systems such as P_4S_2Se are also known, while P–Te bonds are found in BaP_4Te_2. This new material is generated by direct reaction of the elements at 475 °C and consists of P_4Te_2 chains made up of six-membered phosphorus rings linked to tellurium atoms (**47**). The P–Te

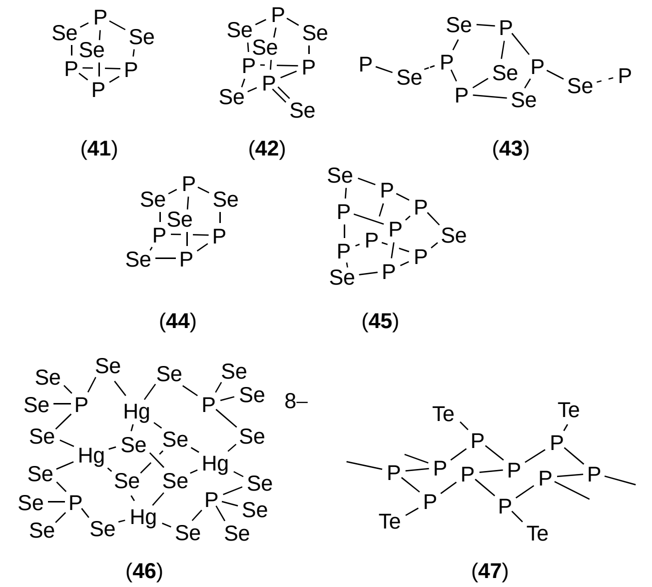

Figure 11 The structure of a range of P–Se and P–Te species

bond length is 2.54 Å.[69] No simple, direct molecular analogues of the phosphorus sulfides or selenides are yet known.

8 PHOSPHORUS HALIDES

Phosphorus combines with halogens in various ratios to form phosphorus halides – three key stoichiometries are known, P_2X_4, PX_3, and PX_5, together with a small number of subhalides such as P_7Br_3. In addition, compounds in which other atoms (such as sulfur or oxygen) have replaced one or more of the halogens in the above formulations are well known and often of great importance. Transient PX monohalides can be generated and work on the spectroscopic properties of PI, for example, is still ongoing.[70]

8.1 Diphosphorus Tetrahalides, P_2X_4 and Subhalides

The most stable of these compounds is the iodide and it is the only one that may be readily prepared by direct reaction of the elements (using red phosphorus at high temperature or white phosphorus in CS_2), though P_2Br_4 is one of the products of the reaction of phosphorus and bromine in CS_2.[71] Formation of the fluoride is via mercury-induced coupling of the PF_2 units in PF_2I, while the chloride forms after the microwave discharge through PCl_3 vapor. All are sensitive to hydrolysis, though the products of such reactions vary (with the fluoride, e.g. giving F_2POPF_2). The chloride slowly decomposes at room temperature to products including PCl_3.

As already noted, the reaction of iodine with phosphorus can generate P_2I_4; P_3I_5 has also been identified as an additional

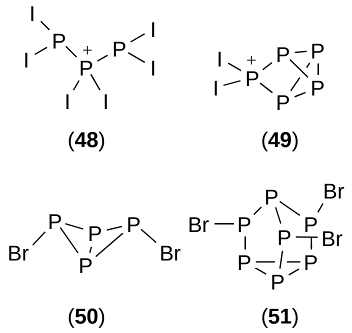

Figure 12 The structure of some phosphorus–halogen species containing P–P bonds

product of the reaction,[72] while if performed in the presence of $[Ag(CH_2Cl_2)][Al(OC(CF_3)_3)_4]$ the low-temperature reaction has been shown to generate the transient $[P_2I_5]^+$ cation, which in turn leads to $[P_3I_6]^+$ (**48**) (Figure 12).[73,74] The structure of the latter consists of two terminal PI_2 units bridged by a further PI_2. The same work also led to the isolation of salts of the $[P_5I_2]^+$ cation (**49**) via reactions of $[Ag(P_4)_2][Al(OC(CF_3)_3)_4]$ with iodine; analogous $[P_5Br_2]^+$ also forms in this way, in this case via a $[PBr_2]^+$ intermediate. $[P_2Br_5]^+$, P_4Br_2 (**50**), and P_7Br_3 (**51**) are also known, the latter two having been identified in solution.

8.2 Phosphorus Trihalides

Trihalides of formula PX_3 are known for all the halogens and their physical properties are shown in Table 4. Apart from the fluoride, they are all generated by direct reaction of the elements; PF_3 is made by fluorination of PCl_3. PF_3 is harder to handle than the others thanks to both its gaseous nature at normal temperature and pressure and also to its high toxicity (via interaction with blood hemoglobin). Though it fumes in air (and has appreciable toxicity), PCl_3 is more readily handled and finds massive use industrially; indeed, in 2001 the demand in the United States alone amounted to 305 000 tons.[75] Pesticide production accounted for 70% of this; other uses included the manufacture of $POCl_3$ (12%); surfactants and sequestrations agents for water treatment chemicals (11%); plastics additives, including flame retardants, plasticizers, and phosphite antioxidants and stabilizers (5%). It is generated by direct chlorination of elemental phosphorus suspended in preprepared phosphorus trichloride – as the system refluxes, the resulting PCl_3 is continuously removed. Its usefulness in the laboratory and in the industry stems from the ready substitution and/or oxidation reactions that can be applied to it. Typically, salt elimination or the production of HCl acts as driving force to the substitution reactions; thus PCl_3 is a prime starting material for the preparation of phosphanes via reaction with Grignard reagents. Its ready oxidation to important compounds such as H_3PO_3 and $POCl_3$ is also of great importance; thus a total of about 36 000 tons of PCl_3

Table 4 Some physical properties and ^{31}P NMR chemical shifts of the phosphorus trihalides and pentahalides

Compound	Physical state at 25 °C	Mp (°C)	Bp (°C)	P–X (pm)	δ (ppm)
PF_3	Colorless gas	−151.5	−101.8	156	−97
PCl_3	Colorless liquid	−93.6	76.1	204	−219
PBr_3	Colorless liquid	−41.5	173.2	222	−227
PI_3	Red solid	61.2	decomp. >200	243	−178
PF_5	Colorless gas	−93.7	−84.5	153 (eq) 158 (ax)	35
PCl_5	Off-white solid	167	160 (subl.)	202 (eq) 214 (ax)	80
PBr_5	Red–yellow solid	<100 (d.)	106 (d.)		101
PI_5	Brown–black solid	41			

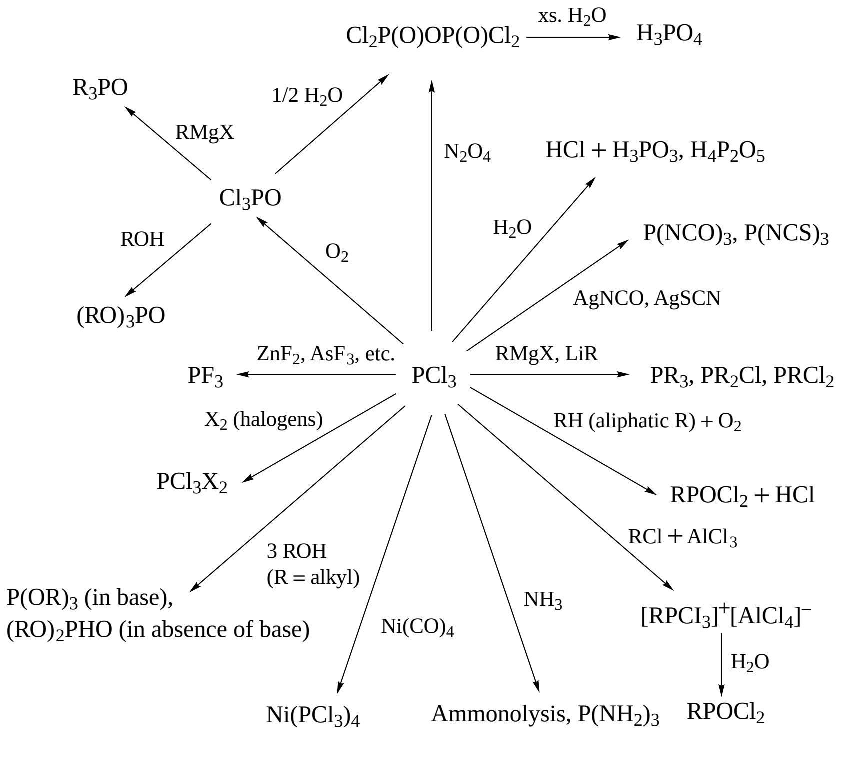
was converted to $POCl_3$ in the United States in 2001, for example. Examples of further reactions of PCl_3 are given in Scheme 1.

The chemical properties of PBr_3 are similar to those of PCl_3, although there is a difference in reactivity due to the difference in the degree of polarity of the phosphorus–halogen bonds. PI_3 is a powerful and versatile deoxygenating agent, effecting the conversion of selenoxides (R,R′SeO) into selenides, for example.[76]

It is also worth noting that mixed trihalides are known. One example comes in the form of PF_2Cl, which is best made (93% yield) by the reaction of Et_2NPF_2 with PCl_3.[77] The greater reactivity of the P–Cl bond means that it can be used as a source of the PF_2 fragment. The mixed species PCl_2Br, $PClBr_2$, PCl_2I, $PClI_2$, PBr_2I, $PBrI_2$, and PClBrI are formed by the rearrangement of a mixture of the pure trihalides.

8.3 Phosphorus Pentahalides, PX_5

Pentahalides of formula PX_5 are known for all the halogens. PF_5 can be made either by fluorinating PCl_5 with AsF_3 (or CaF_2), or by thermal decomposition of $NaPF_6$ or $Ba(PF_6)_2$, while the industrial demands for PCl_5 are met by reaction involving the action of chlorine upon phosphorus trichloride. PBr_5 is prepared by the reaction of equimolar amounts of PBr_3 and bromine in an appropriate solvent, while PI_5 forms by the action of HI, LiI, NaI, or KI on PCl_5 dissolved in MeI.



Scheme 1 Reactions of PCl_3

The simple formulation 'PX_5' belies the complex structural features these compounds exhibit. Electron diffraction data for PF_5 indicates a trigonal bipyramidal structure; however, the ^{19}F NMR spectrum shows only a single fluorine resonance peak (with concomitant ^{31}P coupling) indicative of a fast exchange by Berry Pseudorotation.[78] When dissolved in nonpolar solvents, PCl_5 is monomeric and molecular, whereas in ionizing solvents such as CH_3NO_2 there are two competing ionizing equilibria generating $[PCl_4][PCl_6]$ and $[PCl_4]Cl$. Solid PBr_5 exists as $[PBr_4]^+Br^-$ which then dissociates completely to PBr_3 and Br_2 in the vapor phase. PI_5 appears to exist as $[PI_4]^+I^-$ in solution.

In terms of physical properties, PF_5 is a thermally stable and chemically reactive colorless gas that fumes on contact with moist air and immediately hydrolyzes with water. PCl_5 reacts violently with water to give HCl and H_3PO_4, but in equimolar amounts the reaction can be moderated to give $POCl_3$. PCl_5 chlorinates alcohols to alkyl halides, and carboxylic acids to the corresponding RCOCl, and examples of further reactivity are given in Scheme 2; PBr_5 is an effective bromination agent, as expected from the weakness of the axial P–Br bond.

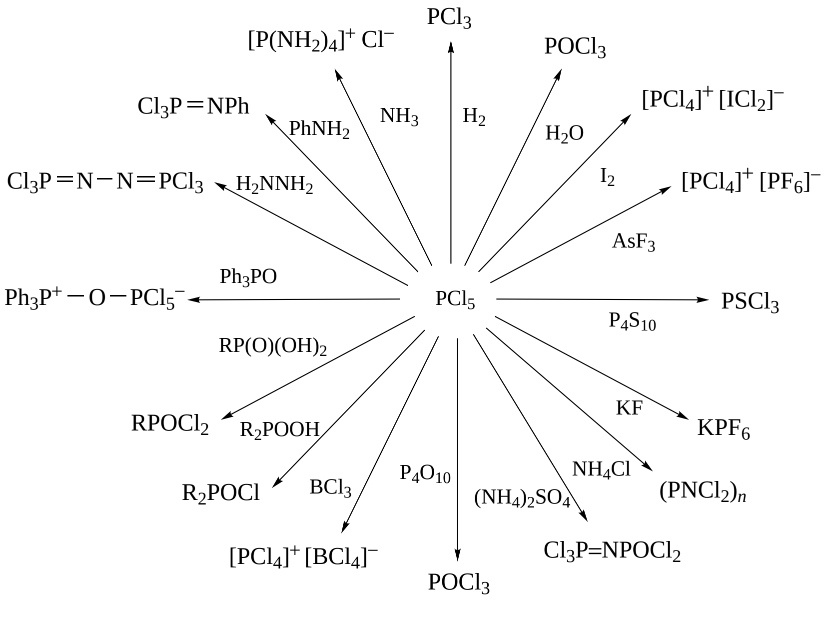
In terms of mixed species, all the molecular chlorofluorides, PCl_xF_{5-x}, are known, as is PBr_2F_3. The latter forms both as an unstable liquid (decomp. 15 °C) and as a white crystalline powder $[PBr_4]^+[PF_6]^-$ (subl. 135 °C with decomposition).

In addition to the aforementioned sulfides and oxides of phosphorus, all the oxohalides POX_3 and thiohalides SPX_3 have been made and fully characterized, with phosphoryl oxide $POCl_3$ being by far the most important. It is made in large quantities (about 47 000 tons in 2001 in the USA alone) by the action of oxygen upon PCl_3, and finds use in the manufacture of phosphate esters for plasticizers, flame retardants, hydraulic fluids, and other applications. POF_3 may be prepared by the fluorination of $POCl_3$ with metallic fluorides, $POBr_3$ by the action of PBr_5 on P_4O_{10}, and POI_3 by iodinating $POCl_3$ with LiI. In the appropriate conditions, sulfur reacts with PX_3 to produce PSX_3. Most of the phosphoryl and thiophosphoryl halides produced are colorless gases or volatile liquids, though POI_3 (violet) $PSBr_3$ (yellow) and PSI_3 (red) (mp 48 °C) form as colored solids. All these compounds (Table 5) hydrolyze readily on contact with water.

9 TRANSITION METAL CHEMISTRY

In terms of the total number of species known, the transition metals chemistry of phosphorus is dominated by the metal phosphides and by complexes of organo-substituted phosphanes. Both are dealt with in some detail in other sections; suffice to say here that transition metal phosphane complexes are of paramount importance in terms of catalytic behavior in all manner of industrial and academic-related scenarios – and as such have been extensively reviewed.[34]

Molecular complexes of 'naked' phosphorus ligands can be generated and the area has been well reviewed.[79] Figure 13 provides examples containing progressively larger phosphorus units; thus we see examples of ligands bearing the following number of P atoms: 1,[80] 2,[81] 3,[82] 4,[83,84] 5,[85] 6,[86] 7,[87] 8,[88] 10,[89] 12 and 14.[90] This list is only a fraction of the total number of examples known – bearing in mind that for many of the units there are numerous coordination modes known.



Scheme 2 Reactions of PCl_5

Table 5 Some physical properties and ^{31}P NMR chemical shifts δ of phosphoric and thiophosphoric trihalides and mixed halides

Compound	Physical state at 25 °C	Mp (°C)	Bp (°C)	Density (g cm^{-3})	δ (ppm)
POF_3	Colorless gas	−39.1	−39.7	–	−35.5
$POCl_3$	Colorless liquid	1.25	105.1	1.645	−2.2
$POBr_3$	Solid	55	191.7	–	−102.9
POI_3	Dark violet cryst.	53	–	–	–
$POFCl_2$	Colorless liquid	−80.1	52.2	1.5931	0
POF_2Cl	Colorless gas	−96.4	3.1	1.6555	−15

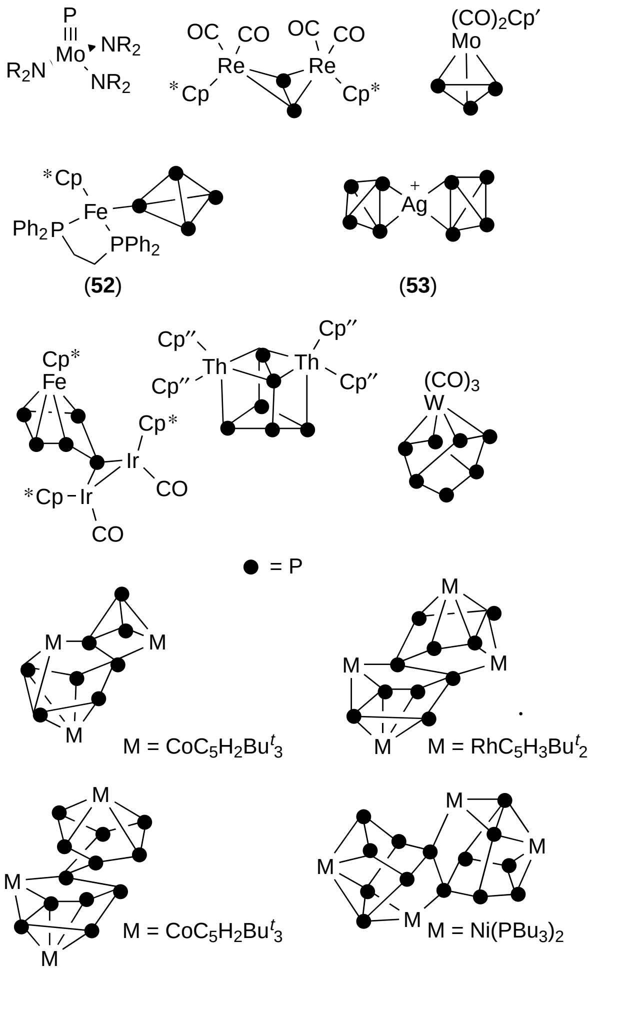

Figure 13 The structure of a range of metal-phosphide complexes

To highlight but two of them (both recent): first, the isolation of the iron complex (**52**) provided the first example of a perfectly air stable complex within which P_4 binds through just one atom.[83] This well illustrates the effect that coordination can have on the properties of compounds (consider the air-sensitivity of the free P_4 unit found in white phosphorus). The second is a similar complex of silver in which the P_4 unit now binds side as shown (**53**); this is the first example of such a binding mode and has elicited much interest.[84]

10 SUMMARY – AND THE FUTURE

Even from such a brief overview of its chemistry, it should be clear that phosphorus is an element still at the forefront of all areas of practical chemistry – from purely academic right to decidedly industrial. Though many of the latter uses are declining because of environmental concerns – witness the decrease in the use of phosphate detergents, ZDDP oil additives and organophosphorus pesticides – the fact remains that demand for the element is still enormous. Eventually, as the twenty-first century progresses, this demand will impact upon resources, and economics will dictate that phosphate recovery, – for example, from sewage – becomes vital. Much work to this end is already underway.[91]

In the laboratory, use of the phosphorus and its compounds continues apace, either in the form of well-known ligands (such as phosphanes) imparting unusual and often desirable properties upon their complexes, or more fundamental reactions, often of the element itself. As some of the structures shown in this report attest, it may be 335 years since Brandt's first forays into elemental phosphorus chemistry but the material continues to intrigue, perplex, and surprise in equal measure – and it shows no sign of abating on that front.

1 INTRODUCTION

Phosphorus–nitrogen chemistry is a very fertile area of chemistry. There is a great variety of compounds with phosphorus–nitrogen molecular skeletons, with both inorganic and organic substituents at either or each of the two sites. The progress in phosphorus–nitrogen chemistry is continuous and novel and interesting compounds are frequently reported. The routine use of single crystal X-ray structure determinations in the last decade contributed greatly to a new surge in phosphorus–nitrogen chemistry. This article cannot cover exhaustively the field and emphasis will be placed upon new results. Classical phosphorus–nitrogen chemistry will not, however, be ignored. Whenever possible, references to review literature will be cited, to open the gate to more detailed information for the interested reader.

Purely inorganic phosphorus–nitrogen compounds are relatively few and little studied. These include the phosphorus nitrides $(PN)_x$, $(P_3N_5)_x$, and the so-called 'phospham' $[PN_2H]_x$, all of which are ill-defined amorphous polymeric materials.[1,2] Recently, such materials have been receiving increased attention.[3] Thus, a reaction product of P_3N_5 with $RbNH_2$ at 400 °C, namely, $Rb_8[P_4N_6(NH)_4](NH_2)_2$, was found to contain an adamantane-like anion $[P_4N_6(NH)_4]^{6-}$ isostructural with P_4O_{10}.[4] A series of lithium phosphazo ceramic materials, Li_7PN_4, $Li_{12}P_3N_9$, $Li_{10}P_4N_{10}$, and $LiPN_2$, have been obtained and characterized. The latter contains an anionic network isostructural with SiO_2 (β-cristobalite), whereas $Zn_7[P_{12}N_{24}]Cl_2$ has a zeolite-type tridimensional crystal structure.[5]

Well characterized purely inorganic P–N compounds are the cyclic and polymeric halocyclophosphazenes $(X_2PN)_n$ (X = F, Cl, Br, $n = 3, 4, 5, 6\ldots$, characterized as discrete compounds up to $n = 19$ in the case of X = F and up to $n = 8$ in the case of X = Cl), the amides $[(NH_2)_2PN]_n$ ($n = 3$, 4),[6] the metaphosphimic acids and their salts $[(HO)(O)PN]_n$ ($n = 3, 4\ldots$).

The introduction of organic substituents at phosphorus or/and nitrogen gave rise to a very extensive field, displaying a broad diversity of compounds, based on variation of oxidation states (mainly +III and +V, but also +II, +IV, and so on, in compounds with P–P bonds) and coordination numbers, from the rare coordination numbers 1 and 2, to common coordination numbers 3, 4, 5, and 6. The ability of phosphorus to form single P–N, double P=N, and sometimes even triple P≡N bonds is an additional feature contributing to the great diversity of phosphorus–nitrogen compounds.

A few chemical reactions leading to P–N compounds are rather general and versatile, and can be performed with compounds in any of the oxydation states and coordination numbers. These include: (a) elimination of halogen or metal halides between a phosphorus–halogen bond and an amine or metalated amine; (b) elimination of an organosilicon halide (usually Me_3SiCl) between a P–X (X = F, Cl, Br) and a Si–N compound; (c) elimination of dinitrogen between a phosphorus(III) compound and an organic or element–organic azide (oxidative addition) with formation of a P(V) compound (Scheme 1). Intelligent use of these reactions affords the synthesis of an immense number of P–N compounds.

The chemistry of phosphorus–nitrogen compounds is well covered in a series of specialized monographs (some concentrating on phosphazenes), the Royal Chemical Society's Specialist Periodical Reports (annual surveys), and numerous review articles (to be cited in the appropriate place of this chapter).

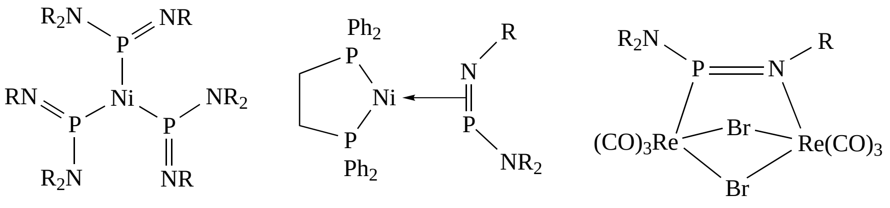
2 MONOPHOSPHORUS–NITROGEN COMPOUNDS

2.1 Mono-coordinate Phosphorus(III)

Iminophosphenium cations, $[:P{\equiv}N{-}Mes^*]^+$, can be generated from $ClP{=}NMes^*$ with anhydrous $AlCl_3$ or

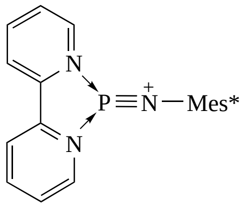
$$\text{P–X} + \text{H–N} \longrightarrow \text{P–N} + \text{HX}$$
$$\text{P–X} + \text{Li–N} \longrightarrow \text{P–N} + \text{LiX}$$
$$\text{P}^{\text{III}} + \text{RN}_3 \longrightarrow \text{P}^{\text{V}}\text{–NR} + \text{N}_2$$
$$\text{P–X} + \text{Si–N} \longrightarrow \text{P–N} + \text{Si–X}$$

Scheme 1



Scheme 2

$GaCl_3$. The presence of the triple bond is supported by the very short phosphorus–nitrogen interatomic distance of 1.475(8) Å measured by x-ray diffraction in the solid.[7] A trifloromethanesulfonate salt [P≡N–Mes*]$^+$ [OSO_2CF_3]$^-$ (**1**) is also known and can be stabilized by further coordination with 2,2′-bipyridyl and other donors, which make the phosphorus atom three-coordinate.[8]



(**1**)

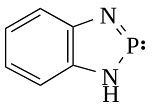
2.2 Two-coordinate Phosphorus(III)

2.2.1 Phosphinimines (iminophosphines) RP=NR′

Phosphinimines, RP=NR′, are expected as products of reaction between dihalogenophosphines and primary amines, but they can be obtained as monomers only with very bulky R groups (R = Mes*, Dipp) and cyclic phosph(III)azanes are isolated in most cases depending upon reaction conditions.[9,10] For a review including their interesting chemistry, see Reference[11] They can act as ligands, with formation of unusual metal complexes, including some in which the P=N bond is coordinated as dihapto, or as M–P=N–M bridging through both phosphorus and nitrogen (Scheme 2).[12]

Silylated aminophosphinimines, R_2N–P=NR (R = $SiMe_3$) are obtained from $LiNR_2$ with PX_3 (X = F, Cl, Br)[13] or R_2N–PF_2, or in reactions involving elimination of chlorotrimethylsilane.[14] They dimerize slowly to cyclic phosphazanes.[15]

A phosphorus analog of benzimidazole (**2**), containing dicoordinate phosphorus, is mentioned as the reaction product between triethylphosphite, $P(OEt)_3$, and *ortho*-phenylenediamine.[16]

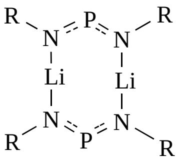


(**2**)

2.2.2 Phosphinedi(imino) Anions [RN–P–NR]$^-$

Dicoordinate phosphorus is present in the anion [RN–P–NR]$^-$, which can be formulated with the aid of two resonance structures; the anion can be also isolated in dimeric form, containing a P_2N_2 ring (Scheme 3):

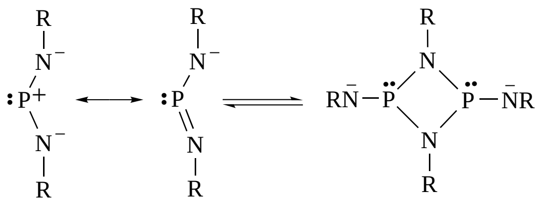
The reaction of phosphorus trichloride with *tert*-butylamine was reported to give a dicoordinate phosph(III)azene Bu^tN=P–$NHBu^t$, which can be deprotonated to the [Bu^tNPNBu^t] anion.[17] The crystal structure of K[Bu^tNPNBu^t] has been determined.[18] The anion has also been found in a gallium[19] and a lithium[20] complex. In monomeric form, the [RN–P–NMes]$^-$ anion can be obtained when R = mesityl (Mes = 2,4,6-$Me_3C_6H_2$), *tert*-butyl and 1-adamantanyl, as dimeric lithium ring compounds (**3**)[21]



(**3**)

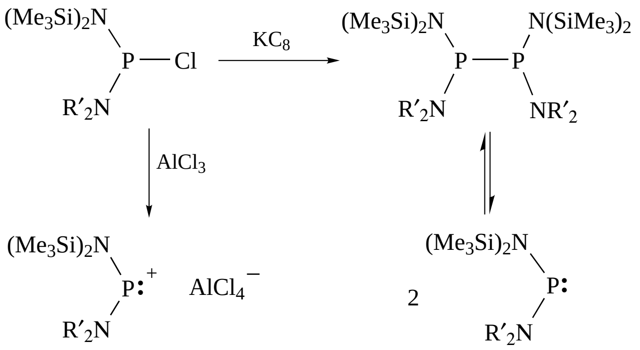
2.2.3 Aminophosphenium Cations [R–P–NR′$_2$]$^+$

A variety of aminophosphenium cations and their coordination chemistry have been reported.[22] Examples are



Scheme 3

Scheme 4



Scheme 5

$[Mes–P–NPr^i_2]^+$, and $[Mes^*NH–P–NR_2]^+$ among others.[23] The cations $[Mes^*Q–P–NHMes^*]^+$ (Q = O, NH) are formed by addition of Mes^*QH to the triple bond of $Mes^*N{\equiv}P$ molecule (Scheme 4).[24]

Radicalic and cationic $[(Pr^i_2N)–P–N(SiMe_3)_2]^{n+}$ ($n = 0$ and 1) have been obtained by treating the corresponding chloride with potassium graphite and aluminum chloride, respectively (Scheme 5).[25]

2.3 Three-coordinate Phosphorus(III)

2.3.1 *Aminophosphines $R_2P–NR'_2$, Diaminophosphines $RP(–NR')_2$ and Triaminophosphines $P(–NR'_2)_3$*

The prototype of this class, aminophosphine, $H_2P–NH_2$, cannot be isolated because of the tendency of condensation with formation of P–NH–P compounds The primary product of the reaction between PCl_3 and ammonia is $P(NH_2)_3$, but it readily undergoes elimination of ammonia and condensation to a series of PNP compounds, ending up with a polymeric material of composition $P_2(NH)_3$. Derivatives substituted either at phosphorus or nitrogen have been reported, for example, $R_2P–NH_2$ with R = F, CF_3 and $RP(NH_2)_2$ where R = MeO, EtO, PhO, Et_2N and MePhN, as ammonolysis products of the corresponding substituted phosphorus chlorides.[26]

Phosphorus trichloride reacts with primary amines in various modes, depending on the nature and bulkiness of the organic groups and reaction condition (solvent, temperature, duration) and amino derivatives Cl_2PNHR, $ClP(NHR)_2$ or $P(NHR)_3$ can be isolated only in particular cases. An added difficulty is the condensation tendency of the P–NHR groups, with elimination of amine and formation of bis(phosphino)amine derivatives or cyclic compounds. Alkylaminodichlorophosphines, $Cl_2P–NHR$ (R = Et, *n*-Pr, *iso*-Pr, *iso*-Bu, Am), and tris(aminophosphines), $P(NHR)_3$ (R = *iso*-Bu, CH_2Ph), can be isolated (Scheme 6).[27]

Aminofluorides, $F_2P–NR_2$ (R = Me, Et, C_5H_{10}), can be obtained from the corresponding chlorides with SbF_3 or NaF in tetramethylsulfone.[28]

Derivatives of secondary amines are more readily available and can be prepared by using substitution[29,30,31,32] or redistribution[33,34] reactions in a solvent, preferably in the presence of an acid scavenger, which can be excess amine (Scheme 7).

Fully substituted derivatives, such as $R_2P–NR_2$ (R = Me),[35] can be prepared from $Cl_2P–NR_2$ by using organometallic alkylating agents or from organodihalides, RPX_2 (X = F, Cl, Br, I) with secondary amines.[36] A convenient method is based on the reaction of organophosphine dichlorides, $RPCl_2$, with diorganoaminosilanes, $Me_3SiNR'_2$, with elimination of trimethylchlorosilane (Scheme 8).[37]

Alkylamino derivatives of trivalent phosphorus exist in a prototropic equilibrium with P–H iminophosphoranes. The

$$PCl_3 + 2RNH_2 \longrightarrow Cl_2P{-}NHR + RNH_2{\cdot}HCl$$
$$PCl_3 + 6RNH_2 \longrightarrow P(NHR)_3 + 3RNH_2{\cdot}HCl$$

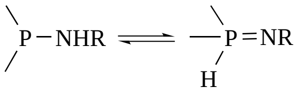
Scheme 6

$$PCl_3 + R_2NH.HCl \longrightarrow Cl_2P{-}NR_2 + 2HCl$$
$$PCl_3 + 2nHNR_2 \longrightarrow P(NR_2)nCl_{3-n} + nR_2NH{\cdot}HCl$$
$$P(NR_2)_2 + PCl_3 \longrightarrow Cl_2P{-}NR_2 + ClP(NR_2)_2$$
$$ClP(NR_2)_2 + PCl_3 \longrightarrow 2Cl_2P{-}NR_2$$

Scheme 7

$$Cl_2P{-}NMe_2 + 2MeMgBr \longrightarrow Me_2P{-}NMe_2 + MgBr_2 + MgCl_2$$
$$RPX_2 + 4HNR'2 \longrightarrow RP(NR'_2)_2 + 2HX{\cdot}HNR'_2$$
$$RPCl_2 + 2Me_3SiNR'_2 \longrightarrow RP(NR'_2)_2 + 2Me_3SiCl$$

Scheme 8



Scheme 9

position of the equilibrium depends on the nature of solvents and substituents at phosphorus and nitrogen sites and is shifted towards the tautomeric form with the least mobile proton (Scheme 9).[38]

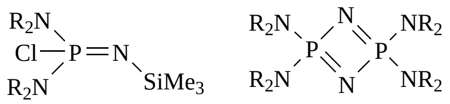
Triamino derivatives $(R_2N)_2PNH_2$ can be deprotonated with LiBu and the salts can further react with organometallic chlorides (Scheme 10).[39]

Silylated aminophosphines, for example, $R_2P–N(SiMe_3)_2$ and $R_2P–NR'(SiMe_3)$, are cleanly prepared from lithiated disilazane and aminosilanes, $LiN(SiMe_3)_2$ and $LiNR'(SiMe_3)$, (R = Me, Ph, Cl, F; R′ = alkyl, Ph) and R_2PCl,[40] respectively. A series of sterically hindered silylaminophosphines, $Bu^tR_2Si(Me_3Si)NPMeR$ (R = Me, Ph), displaying interesting chemistry, have been recently reported.[41]

2.4 Three-coordinate Phosphorus(V)

2.4.1 Monomeric (amino)Phosphonitriles, N≡P(–NR$_2$)$_2$

Compounds containing a phosphorus–nitrogen triple bond are rare, but an unstable species $N{\equiv}P(NPr^i{}_2)_2$ can be generated at −40 °C by photolysis of $(Pr^i{}_2N)_2PN_3$. Its existence was demonstrated by trapping reactions (e.g. insertion into the Si–Cl bond of Me_3SiCl with formation of $Cl(Pr^i{}_2N)_2P{=}NSiMe_3$). In the absence of a trapping agent, it dimerizes to form a unique dimeric cyclodiphosphazene (Scheme 11, R = *iso*-Pr).[42] Other monomeric phosphonitriles are unknown so far, but their cyclic oligomers (cyclophosphazenes) and high polymers (polyphosphazenes) are extremely well known.



Scheme 11

2.4.2 Bis(imino)Phosphoranes RP(=NR′)$_2$, Phosphonic Acid Imides RP(O)(=NR′) and Chalcogeno Analogs

Bis(imino)phosphoranes, $R\text{-}P(=NR')_2$ of various types, methylene-iminophosphoranes, $R\text{-}P(=CR_2)(=NR')$ as well as numerous iminooxo, iminothio, and iminoseleno derivatives, RP(Q)(=NR′) (Q = O, S, Se), are known and have been reviewed.[43,44]

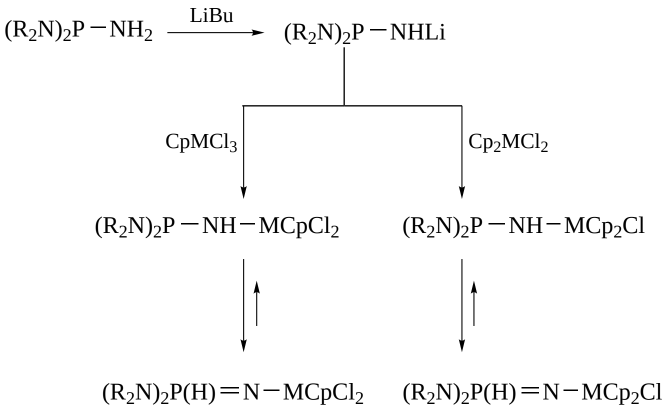
The bis(imino)phosphoranes are prepared by a reaction sequence involving iminophosphine and cyclophosphatetrazenes, but readily dimerize to cyclic four-coordinate compounds (diiminocyclodiphosphazanes) even with bulky organic substituents at nitrogen *R* = *tert*-Bu, CEt_3, 1-Ad (Scheme 12).[45]

Silylated bis(imino)phosphoranes, $(Me_3Si)_2N–P(=NSiMe_3)_2$, can be prepared by a Staudinger reaction, from $(Me_3Si)_2N–P{=}NSiMe_3$ with Me_3SiN_3.[46]

2.5 Four-coordinate phosphorus(V)

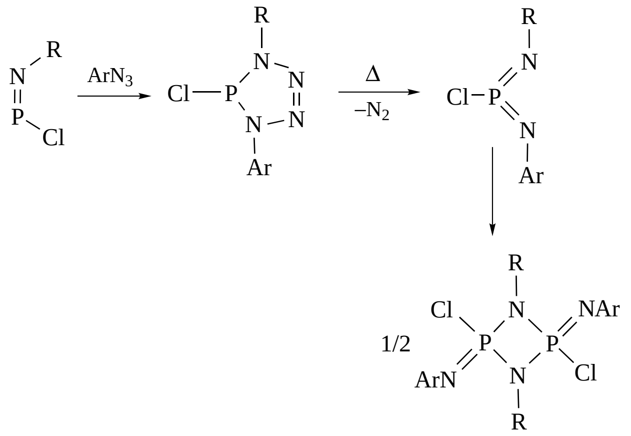
The four-coordinate phosphorus(V)–nitrogen compounds are extremely numerous and detailed data about phosphonic[47] and phosphinic[48] acid derivatives and others[49] can be found in the handbook literature.

The formal replacement of oxygen in phosphorus(V) oxoacids results in a family of imino derivatives, including iminophosphoranes, $R_3P{=}NR'$, diiminophosphinates, $[R_2P(NR')_2]^-$, triiminophosphonates, $[RP(NR')_3]^{-2}$,

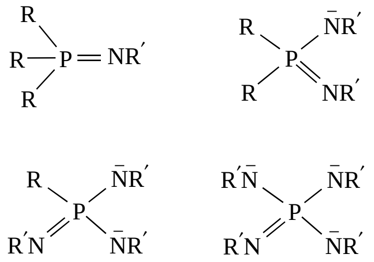


M = Ti, Zr, Hf; R = Pr^i, Cy

Scheme 10



Scheme 12



Scheme 13

and tetraiminophosphates $[P(NR')_4]^{-3}$, which have been reviewed (Scheme 13).[50,51]

2.5.1 *Phosphoraneimines (iminophosphoranes) $R_3P{=}NR'$*

Numerous phosphoraneimines (iminophosphoranes), R_3-$P{=}NR'$, are known.[52]

Triphenylphosphoraneimine, $Ph_3P{=}NH$, is obtained in the reaction of triphenylphosphine with chloramine, through a phosphonium intermediate (Scheme 14).[53]

Trichlorophosphoraneimines, $Cl_3P{=}NR$, are the most accessible compounds of this class. They can be prepared by reacting phosphorus pentachloride with primary amines or their hydrochlorides, usually in carbon tetrachloride as solvent. The intermediate aminotetrachlorophosphorane Cl_4P–NHR is seldom isolated. With aromatic amines the products are monomeric only when the aromatic amine is weakly basic, otherwise the phosphoraneimine will dimerize to cyclic dimers $[Cl_3PNR]_2$ (see Section 5.4).[54]

$$PPh_3 + NH_2Cl \longrightarrow [Ph_3P{-}NH_2]^+Cl^- \xrightarrow{\text{base}} Ph_3P{=}NH$$

Scheme 14

$$PCl_5 + RNH_2 \xrightarrow[-HCl]{} Cl_4P{-}NHR \xrightarrow[-HCl]{} Cl_3P{=}NR$$

Scheme 15

N-Alkyl derivatives, $Cl_3P{=}$Nalk, can be similarly prepared (Scheme 15).[55]

Halogenoiminophosphoranes, $ClPh_2P{=}NAr'$, can be prepared by heating Ph_2PCl_3 with arylamine hydrochlorides, to form phosphonium salts, $[ClPh_2P(NHAr)]^+Cl^-$, which can be further dehydrochlorinated with pyridine to give the desired products.[56] This reaction, known as Kirsanov reaction, is very general and can also be used with trialkoxy(aroxy)dichlorophosphoranes, $(RO)_3PCl_2$,[57] carboxylic acid amides, $ArCONH_2$,[58] sulfonamides, RSO_2NH_2,[59] and many other compounds containing primary amino groups, to form the corresponding derivatives bearing trichlorophosphazo moieties. A very large number of such compounds is listed in Reference[60] The reaction also works with phosphorus compounds bearing NH_2 groups; thus, for example, $(ArO)_2P(Q)NH_2$ (Q = O, S) react with PCl_5 to form $(ArO)_2P(Q)$–$N{=}PCl_3$ derivatives.[61]

Thionyliminophosphoranes, $(RO)R'_2P{=}N{-}SR(O){=}N{-}R''$ (R'' = H, $SiMe_3$) (and polymers derived from them) have been prepared by elimination of Me_3SiOR from $(RO)R'_2P{=}N{-}SiMe_3$ and $RO{-}SR(O){=}N{-}SiMe_3$.[62]

P, N-Organosubstituted iminophosphoranes are important synthetic reagents in organic chemistry. A good method for their synthesis is the reaction of tertiary phosphines with organic azides (known as Staudinger reaction, equation 1).[63] The reaction is much used for the formation of P=N bonds.[64]

$$PR_3 + R'N_3 \longrightarrow R_3P{=}NR' + N_2 \qquad (1)$$

Dibromotriphenylphosphorane reacts with arylamines in the presence of triethylamine (in benzene) to form N-aryliminophosphoranes (equation 2).[65]

$$Ph_3PBr_2 + ArNH_2 + NEt_3 \longrightarrow Ph_3P{=}NAr + [Et_3NH]^+Br^- \qquad (2)$$

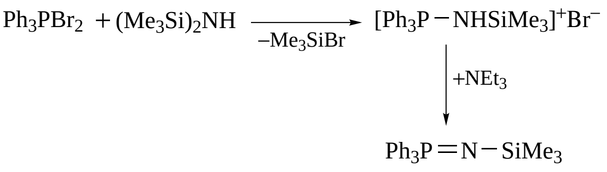
With alkylamines, the primary reaction products are aminophosphonium salts, $[Ph_3PNHR]^+Br^-$, which need to be dehydrobrominated with ammonia or sodium amide.[66] In a similar manner, dichlorotriphenylphosphorane reacts with hydrazine dihydrochloride, at 180–220 °C, to form a bis(phosphorane)diimine after treatment with a strong base (liquid ammonia or potassium *tert*-butoxide), equation (3).[67]

$$Ph_3PCl_2 + H_2N{-}NH_2{\cdot}2HCl \longrightarrow [Ph_3P{-}NHNH{-}PPh_3]^{+2}2Cl^- \longrightarrow Ph_3P{=}N{-}N{=}PPh_3 \qquad (3)$$

Dichlorotriphenylphosphorane also reacts with sulfonylamides, on heating, to form $Ph_3P{=}N{-}SO_2Ar$.[68] A N-trimethylsilyl derivative, $Ph_3P{=}N{-}SiMe_3$, can be obtained from Ph_3PBr_2 and hexamethyldisilazane (Scheme 16)[69] and a series of other N-silylated iminophosphoranes, $R_3P{=}N{-}SiMe_3$ (R = alkyl, aryl, OR′, NR'_2) has been obtained by the Staudinger reaction, from PR_3 with Me_3SiN_3.[70]

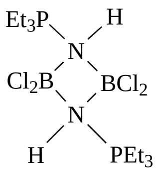
Arylaminophosphoranes are formed in very good yields from aromatic amines, $ArNH_2$ (Ar = Ph, *p*-MeC_6H_4, *p*-BrC_6H_4, *p*-$O_2NMeC_6H_4$, *p*-$MeCOC_6H_4$, 1-$C_{10}H_7$, 2-pyridyl) with triphenylphosphine and acetylenedicarboxylate in 1:1:1 ratio, in boiling toluene or *p*-xylene.[71]

The deprotonation of phosphoraneimines, $R_3P{=}NH$, generates an anionic ligand $[R_3P{=}N]^-$ (not known as discrete species) capable of fascinating coordination chemistry, owing to its bonding versatility; it can coordinate as monodentate terminal group (with both linear $M{\equiv}N{-}PR_3$ and bent $M{-}N{-}PR_3$ structures), symmetrical and unsymmetrical bridging (to form four-membered M_2N_2 rings with $-PR_3$ exocyclic groups) and μ_3-bridging leading to formation of cubane structures (Scheme 17).[72] Interesting compounds are formed with $-N{=}PR_3$ moieties as substituents in main group chemistry.[73] Polymetallic clusters with R_3PN ligands are also known.[74]



Scheme 16

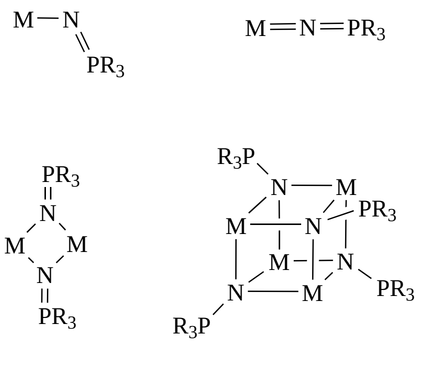
Iminophosphoranes can also coordinate in protonated form, for example, in $[Cl_2Be(\mu\text{-}HNPEt_3)]_2$ (**4**).[75]



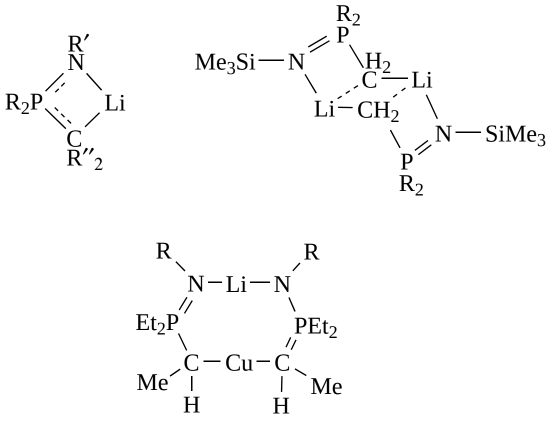
(**4**)

N-Substituted iminophosphoranes, $R_3P{=}NR'$, also coordinate through nitrogen to magnesium,[76] group 13 metals (M = Al, Ga, In),[77] copper(I)[78] and other metals (Scheme 18).

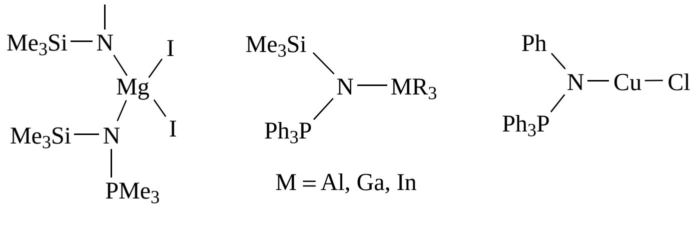
Alkyliminophosphoranes can be deprotonated at α-carbon position with LiR reagents and the resulting anions can act as chelating or bridging ligands, to form a variety of unusual compounds (Scheme 19).



Scheme 17



Scheme 19



Scheme 18

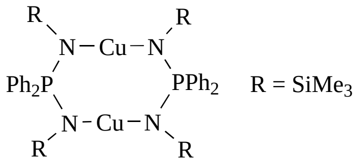
2.5.2 *Phosphinimidoamines $R_2P(=NR')(NR'_2)$ and Diimidophosphinic Anions $[R_2P(NR')_2]^-$*

Phosphinimidoamides, $R_2P(=NR')(NR'_2)$, and their chlorides, are prepared by reactions of azides with various secondary phosphines derivatives (Scheme 20).[79]

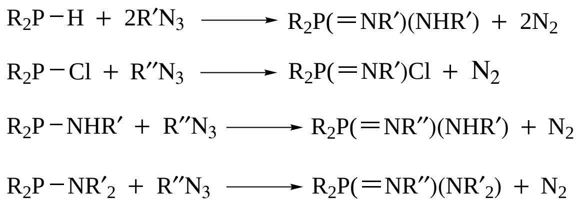
A similar reaction with arylsulfonyl azides yields $R_2P(=N–SO_2Ar)X$ (X = Cl, OR, NH_2, $NHNH_2$, etc.).[80] Secondary phosphines also react with silylazides, to form N-silylated imidoamino derivatives (Scheme 21).[81]

Other useful reactions for the synthesis of $Ph_2P(NSiMe_3)(NHSiMe_3)$ involve diphenyldiaminophosphonium intermediates (Scheme 22).[82]

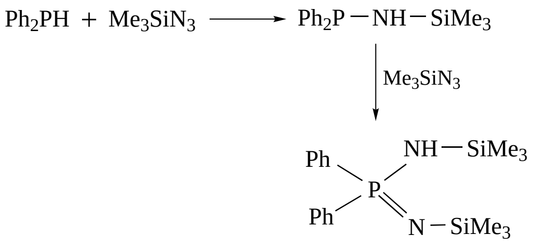
Deprotonation of $R_2P(=NR')(NHR')$ produces $[R_2P(NR)_2]^-$ anions, which can be interesting ligands and numerous metal complexes of methylated diiminophosphinato anions, have been characterized structurally.[83] Thus, the diiminophosphinic anion, $[Me_2P(NMe)_2]^-$ forms a platinum chelate in a reaction with Zeise's salt.[84] A useful ligand of this class is the anion $[Bu^t_2P(NSiMe_3)_2]^-$, which is highly basic and forms very stable metal complexes.[85] Cyclic compound (**5**) (R = $SiMe_3$) with bridging diimidodiphosphinato ligands is formed with copper(I).[86]



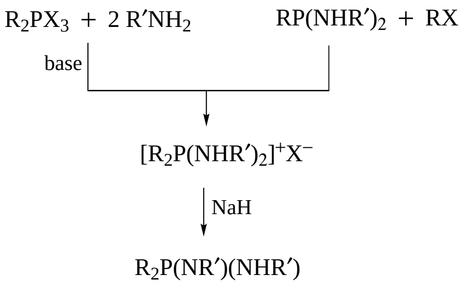
(**5**)



Scheme 20



Scheme 21



Scheme 22

2.5.3 *Phosphonimidodiamines $RP(=NR')(–NR'_2)_2$ and Triimidophosphonic Anions $[RP(NR')_2]^{2-}$*

A representative of this class, $PhP(=NPh)(NHPh)_2$, has been prepared by the reaction of phenylphosphine with phenylazide (equation 4). Deprotonation affords triimidophosphonic anions $[RP(NR')_2]^-$.[87]

$$PhPH_2 + 3PhN_3 \longrightarrow Ph–P(=NPh)(NHPh)_2 + 3N_2 \qquad (4)$$

The $[HP(NR)_3]^{-2}$ anion (R = 2-methoxyphenyl) can be regarded as an imido analog of phosphite $[HPO_3]^{-2}$ and is obtained by lithiation of the reaction product between phosphorus trichloride and 2-methoxyaniline. The lithium 'salt' is in fact a polycyclic cage compound.[88]

2.5.4 *Amidophosphoric Triamines $P(=NR')(–NR'_2)_3$ and Tetraimidophosphato Anions $[P(NR')_4]^{-3}$*

Compounds of this class can be prepared with the aid of Staudinger reaction, for example, $P(=NPh)(NMe_2)_3$.[89] The derived anions $[P(NHR)_4]^{-3}$ are imido analogs of phosphate. The anion with R = Ph is formed by deprotonation of tetraaminophosphonium halides $[P(NHPh)_4]^+X^-$ with butylithium.

2.5.5 *Phosphinic Acid Amides $R_2P(=O)(–NR'_2)$ and Thio Analogs*

Phosphinic acid chlorides react with concentrated. aqueous ammonia to form amides, $R_2P(O)NH_2$,[90] and with primary and secondary amines, in the presence of HCl scavengers (pyridine, triethylamine, etc.) to form $R_2P(Q)(NR'_2)$ (Q = O or S), for example, R = Ph, Q = O, R′Et, Pr, *iso*-Pr, Bu, *tert*-Bu, $PhCH_2$.[91] Oxidation and addition of sulfur to $R_2P–NR'_2$ also yield phosphinic acid amides, $R_2P(Q)(NR'_2)$ (Q = O or S).[92] Related compounds are the hydrazides, $R_2P(Q)NHNHR'$ (Q = O, S; R′ = H, alkyl).[93]

2.5.6 *Phosphonic Acid Diamides RP(=O)(NR′₂)₂ and Thio Analogs*

Phosphonic acid diamides, $RP(=O)(NR'_2)_2$ are obtained by reacting the dichlorides, $RP(=O)Cl_2$ with ammonia, primary or secondary amines.[94] The number of known compounds of this class is legion[95] and typical examples can be cited, for example, $MeP(O)(NH_2)_2$,[96] $PhP(O)(NH_2)_2$,[97] $MeP(O)(NHR')_2$, with R′ = Me, Ph, *p*-MeC_6H_4, *p*-ClC_6H_4,[98,99] $EtP(O)(NR_2)_2$ (R = Me, Et, Pr),[100] $PhP(O)(NHR)_2$ (R = Et, Bu, But, C5H11, Ph, other aryls)[101] and many others. Numerous mixed amide-halides, $RP(O)(X)(NR'_2)$ and amide-esters, $RP(O)(NR')(OR'')$ are also known.[95] Related compounds are the hydrazides, for example, $PhP(O)(NHNH_2)_2$,[102] and $PhP(O)(NHNHPh)_2$.[103]

Alkoxyaminophosphines react with alkyl halides in an Arbuzov–Michaelis type reaction to form phosphonic acid diamides via thermally unstable phosphonium intermediates (equation 5).[104]

$$P(OR)(NR'_2)_2 + RX \longrightarrow [RP(OR)(NR'_2)_2]^+X^- \longrightarrow RP(O)(NR'_2)_2 + RX \qquad (5)$$

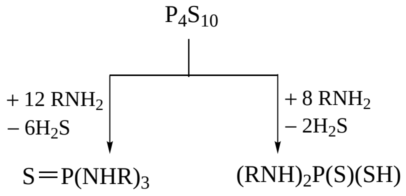
Thio analogs of these compounds, for example, $PhP(S)(NHR)_2$ can also be prepared similarly, from the corresponding thiophosphonic halides and amines[105] or by oxidative addition of sulfur to diaminophosphines, $RP(NR'_2)_2$.[106]

Phenylphosphonic acid diamides, $PhP(Q)(NHBu^t)_2$ (Q = S, Se) were prepared from $PhP(NHBu^t)_2$ by oxidative addition of sulfur or selenium and the oxo derivative $PhP(O)(NHBu^t)_2$ by oxidation with *tert*-butyl peroxide. Their lithiation produces unusual cyclic or polycyclic dilithium salts of the phosphonate dianions $[PhP(Q)(NBu^t)_2]^{-2}$ (Q = O, S, Se). The dimethylaluminum derivatives $PhP(Q)(NBu^t)_2AlMe_2$ (Q = S, Se) obtained from $PhP(Q)(NHBu^t)_2$ with $AlMe_3$ are four-membered chelate rings.[107]

2.5.7 *Phosphoric Acid Triamides O=P(NR′₂)₃ and Thio Analogs*

The prototype of this class, $OP(NH_2)_3$, is formed in the reaction of $OPCl_3$ with liquid ammonia[108] or with gaseous NH_3 in trichloromethane solution at low temperature.[109] Substituted phosphoric acid triamides $O{=}P(NR_2)_3$ are prepared in the reaction of phosphorus oxotrichloride with secondary amines, under heating or in the presence of acid scavengers; under milder conditions the mono- and diamido chlorides can be easily obtained (equation 6).[110] Hexamethylphosphoric acid triamide, $OP(NMe_2)_3$, an excellent aprotic organic solvent prepared from $OPCl_3$ and dimethylamine, deserves to be mentioned here.[111]

$$OPCl_3 + HNR_2 \longrightarrow Cl_2P(O){-}NR_2 \longrightarrow ClP(O)(NR_2)_2 \longrightarrow P(O)(NR_2)_3 \qquad (6)$$



Scheme 23

Phosphorus oxotrifluoride, OPF_3, reacts under milder conditions (at room temperature) to form $F_2(O)P{=}NR_2$ and $F_2(O)P{-}NHR$. Similar reactions of $SPCl_3$ (on prolonged heating) or SPF_3 (under milder conditions) with secondary amines give $SP(NR_2)_3$.[112,113,114] Hydrazides, for example, $OP(NHNHAr)_3$ can be similarly prepared. With primary amines (e.g. arylamines), the final products can be dimeric cyclic compounds $[(ArNH)(Q)PNAr]_2$ (Q = O, S) especially after prolonged heating.[115]

Alternative preparations for phosphoric acid triamides, $QP(NR_2)_3$, Q = O, S, include oxidative additions of tris(amino)phosphines, $P(NR_2)_3$, with oxygen and sulfur.[116]

In the solid state, tris(alkylamido) derivatives $OP(NHMe)_3$ and $OP(NHBu^t)_3$ form supramolecular architectures through hydrogen bond self-assembly. Lithiation of $OP(NHR)_3$ and $SP(NHR)_3$ also yields self-assembled structures, formed through Li–O and Li–S interactions.[117]

The reaction of tetraphosphorus decasulfide with primary amines (1:12 M ratio) gives thiophosphoryltriamides, $SP(NHR_2)_3$; with a 1:8 ratio, the product is a dithiophosphoric acid diamide $(RNH)_2P(S)(SH)$ (Scheme 23).[118] The dithioacid diamides form metal complexes, for example, $Ni[S_2P(NHPh)_2]_2$.[119]

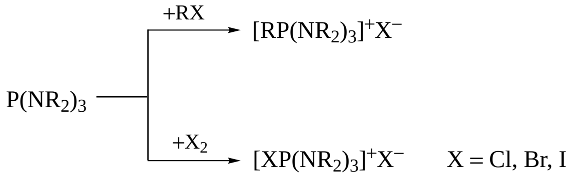
Numerous phosphoric acid ester amides and thio analogs, $(RO)P(Q)(NR'_2)_2$ and $(RO)_2P(Q)(NR'_2)$ are also known. Among these, $(ArO)P(S)(NH_2)_2$ are cited; they can be prepared from the dichloride in liquid ammonia.[120]

2.5.8 *Aminophosphonium Salts $[R_{4-n}P(NR'_2)_n]^+X^-$ (n = 1 – 3)*

Triphenyl(amino)phosphonium chloride, $[Ph_3PNH_2]^+Cl^-$, is formed in a Staudinger reaction of PPh_3 with Me_3SiNH_2 in the presence of water, obviously through hydrolysis of the normal product $Ph_3P{=}NSiMe_3$ obtained under anhydrous conditions.[121]

Diaminophosphonium salts, $[R_2P(NR'_2)_2]^+X^-$, can be prepared by reactions of bis(dialkylamino)phosphines, $RP(NR'_2)_2$, with alkyl halides.[122] Diphosphines are cleaved by chloramine to form diaminophosphonium salts (equation 7).[123]

$$R_2P - PR_2 + 4NH_2Cl \longrightarrow 2[R_2P(NH_2)_2]^+Cl^- + 2Cl^- \qquad (7)$$



Scheme 24

Dihalogenodiaminophosphonium salts, $[PX_2(NR_2)_2]^+X^-$, are formed by oxidative addition of halogens to $[P(NR_2)_2]^+X^-$ (equation 8).[124]

$$[P(NR_2)_2]^+X^- + X_2 \longrightarrow [PX_2(NR_2)_2]^+X^- \quad (8)$$

Tris(amino)phosphines, $P(NR_2)_3$, react with alkyl halides and with halogens to form triaminophosphonium salts (Scheme 24).[125,126]

Bis(dialkylaminophosphines, $RP(NR'_2)_2$, with chloramine, NH_2Cl, also form tris(amino)phosphonium salts $[RP(NR'_2)_2(NH_2)]^+Cl^-$.[127]

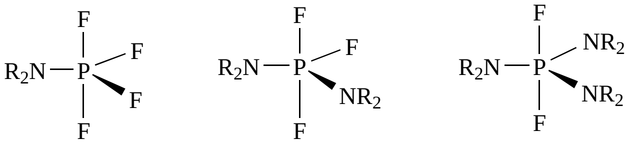
The inorganic cation $[P(NH_2)_4]^+$ is known[128] but substituted derivatives at either phosphorus or nitrogen sites are more common. Some interesting chemistry of tetra(anilino)phosphonium cation, $[P(NHPh)_4]^+$, which can be deprotonated stepwise to end up with the trianionic $[P(NPh)_4]^{3-}$ species, has been described.[129]

Triamino-halogenophosphonium halides, $[(R_2N)_3PX]^+X^-$, on heating eliminate alkyl halides with formation of phosphinoamioimines, which in turn dimerize to cyclic derivatives containing the tetraazaphosphonium moiety $[PN_4]^+$ moiety (R = Et, X = Br) (Scheme 25).[130]

2.6 Five-coordinate Phosphorus(V)

2.6.1 *Aminophosphoranes $R_4P–NR'_2$ and Diaminophosphoranes $R_3P(NR'_2)_2$*

Aminotetrafluorophosphoranes, F_4P-NR_2 can be prepared from phosphorus pentafluoride and secondary amines,[131] aminosilanes[132] or disilazanes,[133] and by redistribution between PF_5 and $P(NMe_2)_3$.[134] Thus, phosphorus pentafluoride reacts with $Me_3Si–NEt_2$ at −78 °C with Me_3SiF elimination to form $F_4P–NEt_2$, which further eliminates Me_3SiF at 150–170 °C to form $F_3P(NEt_2)_2$ (Scheme 26).[135] In the gas phase, phosphorus pentafluoride reacts with ammonia to form *cis*-$F_3P(NH_2)_2$.[136]

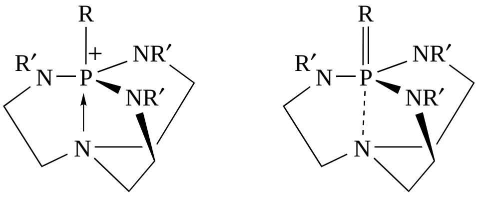


Scheme 26

With primary amines, aminotetrafluorophosphoranes are formed only if R is a bulky organic group or an aromatic group in the presence of a tertiary amine. Otherwise, cyclic dimers $[F_3PNR]_2$ are formed.[137] Fluorination of $P(NMe_2)_3$ with sulfur tetrafluoride yields triaminodifluorophosphorane, $F_2P(NMe_2)_3$.[138]

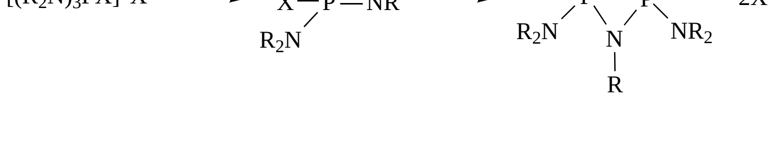
2.6.2 *Phosphatranes*

Phosphatranes are tricyclic compounds, with phosphorus and nitrogen as bridgeheads, which can be prepared by reaction of $P(NMe_2)_3$ with triethanolamine $(CH_2CH_2OH)_3$. The phosphatranes contain a transannular P–N bond, but a weaker interaction leads to quasiphosphatranes (Scheme 27, R = Me, R′ = Cl, Br, I, CH_2Br, CH_2I). Their nonconventional chemistry of phosphatranes and quasiphosphatranes has been reviewed.[139] Some of these compounds are highly basic (‘superbases’).[140]

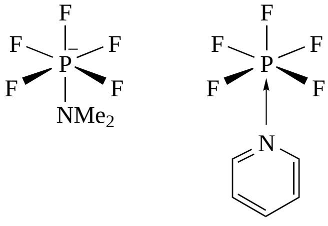


Q = O, S, NR

Scheme 27



Scheme 25



Scheme 28

2.7 Six-coordinate Phosphorus(V)

2.7.1 Aminophosphates $[R_5P–NR'_2]^-$ and Phosphorus(V) Halide Amine Adducts $R'_3N.PX_5$

Addition of fluoride anion to five-coordinate tetrafluoroaminophosphines $Me_2N–PF_4$ leads to anionic dialkylaminopentafluorophosphates $[Me_2N–PF_5]^-$. Organophosphorus tetrafluorides form tertiary amine adducts $R_3N{\cdot}R'PF_4$ (R = F, Ph, CF_3) and phosphorus pentafluoride forms a six-coordinate pyridine adduct, $PF_5{\cdot}NC_5H_5$ (Scheme 28).[141]

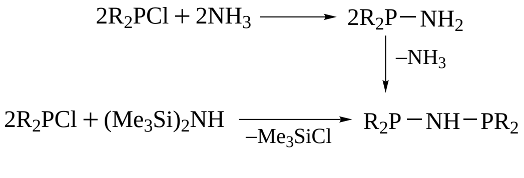
3 ACYCLIC DIPHOSPHORUS–NITROGEN COMPOUNDS

3.1 Three-coordinate Phosphorus(III)

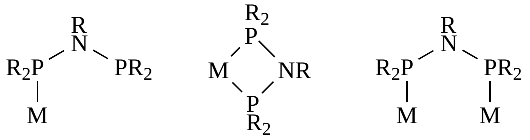
3.1.1 Bis(Phosphino)amines $R_2P–NR'–PR_2$

The bis(phosphino)amines or diphosph(III)azanes, $R_2P–NH–PR_2$, can be readily prepared by ammonolysis of R_2PCl (R = Ph)[142] or by reactions between R_2PCl and silazanes. The usual product of the reaction between Ph_2PCl with $(Me_3Si)_2NH$ is $Ph_2PNHPPh_2$, but this may further react with excess Ph_2PCl to form P–P bond compounds, $[Ph_2P–PPh_2–NHPPh_2]^+Cl^-$ and $[Ph_2P–PPh_2{=}N–PPh_2–PPh_2]^+Cl^-$ (Scheme 29).[143]

The bis(phosphino)amines are versatile ligands and an extensive coordination chemistry, based on variable coordination patterns (Scheme 30), has been developed on this basis.[144–157]



Scheme 29



Scheme 30

$$(Ph_2P)_2NH + RLi \longrightarrow (Ph_2P)_2NLi + RH$$
$$(Ph_2P)_2NH + NaH \longrightarrow (Ph_2P)_2NNa + H_2$$

Scheme 31

Bis(phosphino)amines (R = H) can be easily deprotonated with lithium alkyls or sodium hydride in THF or other basic solvents (Scheme 31), and the N-lithiated derivatives react with metal and organometallic halides to give a broad variety of metal compounds.

An unusual reaction of $LiN(PPh_2)_2$ with $PbCl_2$ gives an unique dilead bicyclic complex, in addition to a linear tetraphosphadiazene (Scheme 32).[158]

Polynuclear clusters with Ph_2PNHPh_2 external ligands, for example, $[Cu_6(Ph_2PNHPPh_2)_4(\mu_3\text{-SePh})_4][BF_4]_2$ have been structurally characterized.[159]

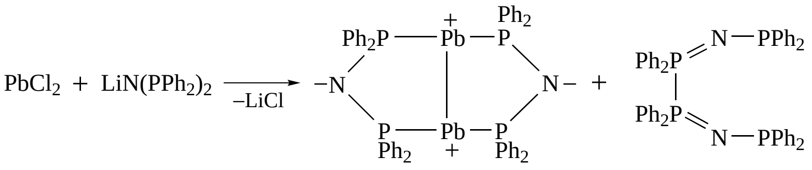
A rare coordination pattern of the $[Ph_2PNPPh_2]^-$ ligand is observed in the lanthanide complexes (Scheme 33).[160]

Lithium, potassium, and sodium $[Ph_2PNPPh_2]^-$ salts have been characterized structurally and display different molecular architectures.[161]

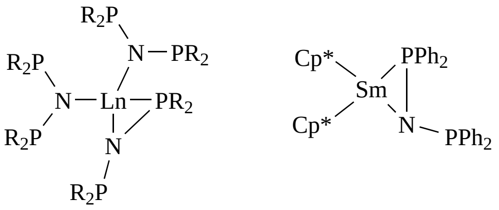
In some cases, the reactions of $LiN(PPh_2)_2$ with metal salts are not straightforward. Thus, this reagents reacts with anhydrous MCl_2 (M = Co, Ni, Pd) in boiling toluene, to form bis(chelate) complexes of a new ligand $[Ph_2PNPPh_2NPPh_2]^-$, in addition to $N(PPh_2)_3$, as a result of complex redistribution of the building units.[162] The reactions of $LiN(PPh_2)_2$ with AsI_3, $BiBr_3$ and SbI_3 result in the serendipitous formation of a P–P bond compound $Ph_2P–NPh_2P–PPh_2N–PPh_2$, in addition to elemental As, Sb or Bi; under different reaction conditions, AsI_3 may also produce eight-membered ring $Ph_8P_4N_2As_2$ or seven-membered ring $Ph_8P_4N_2As$ derivatives (Scheme 34).[163]

N-Organosubstituted derivatives are also known. Heating aniline hydrochloride with excess PCl_3 gives crystalline $Cl_2P–NPh–PCl_2$[164] and N-alkyl derivatives (R = Me, Et) can be similarly prepared and further converted into tetrafluoro derivatives (Scheme 35).[165] Of these, N-methyl-bis(difluorophosphino)amine, $MeN(PF_2)_2$, has been extensively used as a chelating and bridging ligand.[166]

Depending upon conditions (steric and electronic properties of the substituents, stoichiometry, solvent, and basic acid scavenger used) the reactions of substituted anilines with Ph_2PCl can afford in good yields either aminophosphines $Ph_2P–NHAr$, diphosphinoamines $(Ph_2P)_2N$ and even iminobiphosphines (containing P–P bonds) $RN{=}PPh_2–PPh_2$.[167]



Scheme 32



Ln = La, Nd, Er

Scheme 33

A complex of $(PhNH)_2P$–NPh–$(NHPh)_2$ (unknown in free state) is formed in the reaction of *cis*-$[Mo(CO)_4(Cl_2PNPhPCl_2)]$ or *cis*-$[Mo(CO)_4(PCl_3)_2]$ with aniline, and from $[Mo(CO)_4(NBD)]$ (NBD = norbornadiene) with $P(NHPh)_3$.[168]

3.1.2 Aminoderivatives of Diphosphines, $(R_2N)_2P$–$P(NR_2)_2$

Diaminochlorophospines, $(R_2N)_2PCl$, can be coupled with the aid of sodium metal to form tetrakis(dialylamino)diphosphines, $(R_2N)_2P$–$P(NR_2)_2$, albeit in moderate yield. These are readily oxidized to four-coordinate oxo and thio derivatives, $(R_2N)_2(Q)P$–$P(Q)(NR_2)_2$ (R = Me; Q = O or S) in controlled reactions with oxygen and sulfur, respectively.[169]

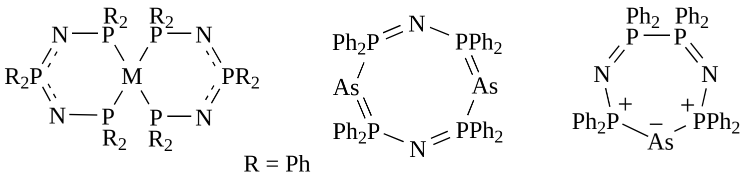
3.1.3 Other Related Compounds

Interesting compounds containing N–PR_2 donor moieties, very useful as inorganic chelate ring forming ligands, include bis(phosphinamino)phosphines, $RP(NR'PR_2)_2$ (which can be deprotonated when R′ = H to form the corresponding dianions), bis(phosphinamino)silanes, $R_2Si(NR'PR_2)_2$, bis(phosphino)thioimides, $S({=}NPR_2)_2$ and others. Their coordination chemistry has been reviewed.[170]

3.2 Four-coordinate Phosphorus(V)

3.2.1 Bis(phosphorane)immonium Cations $[R_3P{=}N{=}PR_3]^+$

The hexachloro cation $[Cl_3P{=}N{=}PCl_3]^+$ can be prepared in several ways. Thus, the reaction of PCl_5 with NH_4Cl under strictly controlled conditions (to avoid formation of cyclophosphazenes) yields $[Cl_3PNPCl_3]^+$ $[PCl_6]^-$.[171] The later salt can be conveniently converted to the chloride $[Cl_3PNPCl_3]^+Cl^-$ by reacting it with 4-(dimethylamino)pyridine, and the phosphazenium chain can be grown to $[Cl_3P{=}N(Cl_2P{=}N)_n = PCl_3]$ (n = 1, 2 and 3) by further reactions with $Cl_3P{=}NSiMe_3$.[172] The salt $[Cl_3PNPCl_3]^+Cl^-$ is also formed in the chlorination of $Cl_3P{=}N$–$P(S)Cl_2$ with gaseous chlorine,[173] and a hexachloroantimonate, $[Cl_3PNPCl_3]^+$ $[SbCl_6]^-$ is obtained in the reaction of $[NH_4]^+$ $[SbCl_6]^-$ with PCl_5.[174]



Scheme 34

$$3RNH_2{\cdot}HCl + 2PCl_3 \longrightarrow Cl_2P{-}NH{-}PCl_2 + 3RNH_2{\cdot}HCl$$

$$3Cl_2P{-}NR{-}PCl_2 + 4SbF_3 \longrightarrow 3F_2P{-}NR{-}PF_2 + 4SbCl_3$$

Scheme 35

The pyrolysis of tetraaminophosphonium halides, $[P(NH_2)_4]^+X^-$, yields a hexaaminodiphosphazenium cation $[(H_2N)_3PNP(NH_2)_3]^+X^-$ (X = Cl, I).[175]

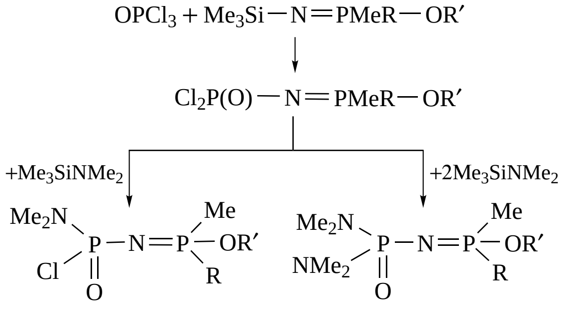
Phenylsubstituted cations (as chloride salts)), $[PhCl_2PNPCl_2Ph]^+Cl^-$ and $[Ph_2ClPNPClPh_2]^+Cl^-$, are prepared from $PhPCl_4$ and Ph_2PCl_3, respectively, on heating with ammonium chloride in refluxing tetrachloroethane.[176] The hexaphenyl cation, $[Ph_3PNPPh_3]^+$ (known as PPN), is remarkable owing to its ability to facilitate crystallization of its salts.[177]

3.2.2 *Phosphoryl–phosphoranimines, $XR_2P{=}N{-}P({=}Q)R_2$*

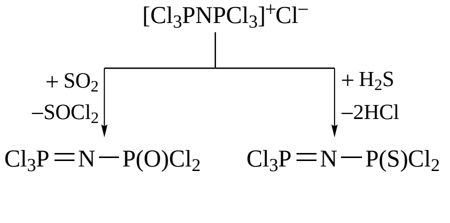
A broad variety of compounds of general composition $XR_2P{=}N{-}P({=}Q)R_2$, for example, with R = alkyl, Ph; X = Oalkyl, Q = O and R = Ph, X = Cl, OMe, SMe, Q = O or S are known.[178] Several phosphorylphosphoraneimines have been prepared by Si–N bond cleavage (Scheme 36).[179]

Related compounds of the type $(Me_2N)_2P(Q){-}N{=}P(NMe_2)_3$ have been obtained from $P(NMe_2)_3$ with $(Me_2N)_2P(X)N_3$ in a Staudinger type reaction.[180]

Chloro-substituted phosphorylphosphoranimines, $Cl_3P{=}N{-}P(Q)Cl_2$ (Q = O, S) are readily obtained from $[Cl_3PNPCl_3]^+Cl^-$ with sulfur dioxide and hydrogen sulfide, respectively (Scheme 37).[181] These compounds are useful starting materials for a series of PNP derivatives.[182]



Scheme 36



Scheme 37

3.2.3 *Phosphonium-phosphoranimines $[XR_2P{=}N{-}PR_2X]^+Y^-$*

Compounds of the type $[XR_2P{=}N{-}PR_2X]^+Y^-$ with R = Me, Ph; X = Cl, Br, NH_2, OMe, SMe (in various combinations) have been prepared by reactions similar to those described above.[183]

3.2.4 *Di(imino)imidodiphosphinates $R_2(R'N{=})P{-}NH{-}P({=}NR')R_2$*

Di(imino)diphosphazenates can be deprotonated and the resulting anions can serve as versatile ligands.[184] Sodium, potassium, calcium complex salts of $[N\{P(NMe_2)_2{=}NSiMe_3\}_2]^{2-}$ anion[185] and metal complexes (e.g. zinc)[186] have been prepared and investigated structurally.

3.2.5 *Di(chalcogeno)imidodiphosphinates $R_2P({=}Q){-}NR'{-}P({=}Q)R_2$, (Q = O, S, Se, Te) and Related Compounds*

Dichalcogenoimidodiphosphinates and -phosphates, $R_2(Q)P{-}NH{-}P(Q)R_2$ (R = alkyl, aryl, alkoxy; Q = O, S, Se) became very popular as excellent ligands and display an extensive coordination chemistry based on a broad diversity of coordination patterns (Scheme 38).[187]

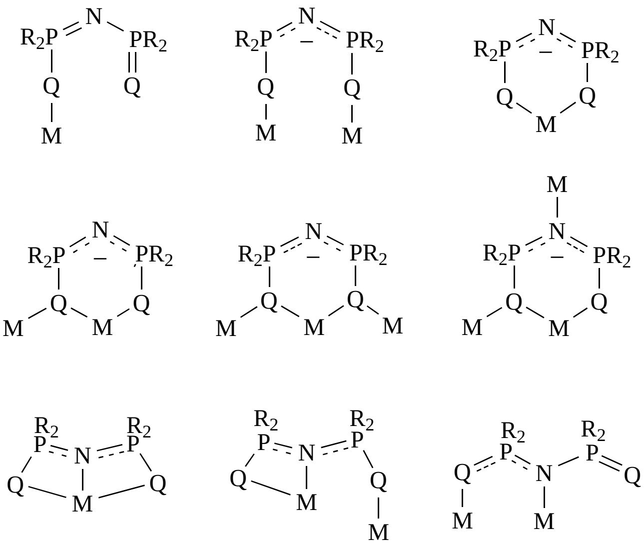
N-Substituted di(chalcogeno)diphosphates $(RO)_2(Q)P{-}NR'{-}P(Q)(OR)_2$ (Q = O, S) and amides $(R_2N)_2(O)P{-}NR'{-}P(O)(NR_2)_2$ are best prepared by alkali metal halide elimination between $(RO)_2P(Q)Cl$ and $MNR'P(Q)(OR)_2$ (M = Na, Li).[188] Coupling of chlorides, $X_2(Q)PCl$, with amides, $X'_2(Q)PNHR'$ can also be used for the synthesis of a variety of dichalcogenodiphosphazanes, $X_2(Q)P{=}NR'{-}P(Q)X'_2$ (X, X′ = OR, NR_2, in various combinations).[189]

Diphosphazane dioxides, $R_2P(O)R_2{-}NR'{-}P(O)R_2$ are excellent ligands for actinides (Th, U).[190]

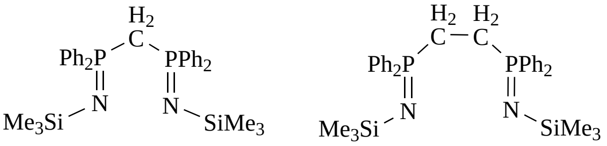
3.2.6 *Bis(iminophosphoryl)methanes, $R'N{=}PR_2CH_2PR_2{=}NR'$ and Bis(iminophosphoryl)ethanes, $R'N{=}PR_2CH_2CH_2PR_2{=}NR'$*

The compounds of this class, mostly silyl derivatives (R′ = $SiMe_3$), prepared by Staudinger reactions from the corresponding diphosphines and silyl azides (Scheme 39), received recent attention owing to their versatility as nitrogen-donor ligands.[191]

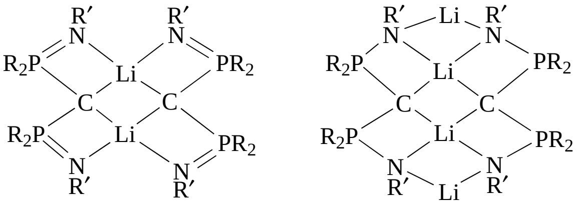
A peculiar property of the bis(iminophosphoryl)methanes is the facile mono and deprotonation of the methyene bridge with organolithium reagents.[192] Thus, with $H_2C(NPPh_2NSiMe_3)_2$ unusual dimeric lithium complexes were obtained (Scheme 40)[193] and Ti, Zr, Hf carbene complexes were formed with the same doubly deprotonated ligands.[194]



Scheme 38



Scheme 39



Scheme 40

Related complexes of titanium and zirconium, derived from bis(iminophosphoryl)ethanes, $R'N{=}PR_2CH_2CH_2PR_2{=}NR'$ ($R = Ph$, $R' = SiMe_3$) have been reported.[195]

3.3 Mixed Phosphorus(III)-Phosphorus(V) Compounds

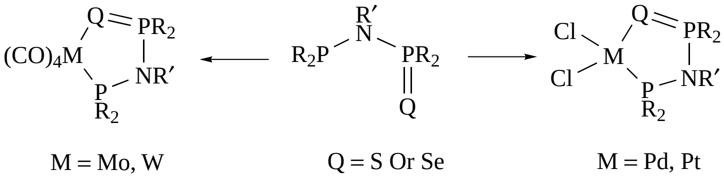
3.3.1 *Chalcogenophosphinylaminophosphines $R_2(Q)P\text{–}NR\text{–}PR_2$ (Q = O, S)*

Hybrid compounds, containing both P(III) and P(V) groups, $R_2P\text{–}NR'\text{–}P(Q)R_2$ (Q = O, S, Se′; R′=H or alkyl, aryl), are also versatile ligands and can act as chelating to form five-membered rings or as bridging, to form eight-membered rings (Scheme 41).[196]

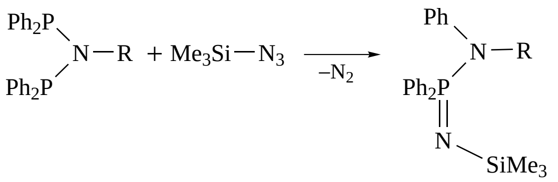
Chiral N-phosphine substituted iminophosphoranes, $R_2P\text{–}N{=}PR_3$, are unexpectedly formed on attempted metallation of cyclopropyl(triphenyl)phosphonium bromide with sodium amide.[197]

3.3.2 *Iminophosphorano(amino)phosphines, $R'N{=}PR_2\text{–}NR''\text{–}PR_2$*

This class is illustrated by some silylated derivatives, $Me_3SiN{=}PPh_2\text{–}NR'\text{–}PPh_2$ with R′ = Et, *n*-Pr, *n*-Bu, prepared from $Ph_2PNR'PPh_2$ with trimethylsilylazide (Scheme 42). Theses compounds can be readily undergo oxidative addition of sulfur and selenium to the P(III) site and react with



Scheme 41



Scheme 42

phosphoryl azide to form $Me_3Si–N{=}PPh_2–NR–P(Q)Ph_2$ with Q = S, Se and =N–P(O)(OPh)$_2$, respectively.[198]

4 OLIGOMERIC LINEAR AND BRANCHED P–N CHAINS; DENDRIMERS

Short phosphorus–nitrogen chains containing P=N bonds can be synthesized by several routes. A triphosphadiazenium cation, as chloride salt, $[Cl_3P{=}N–PCl_2{=}N–PCl_3]^+Cl^-$, is formed on heating $[Cl_3PNPCl_3]^+$ $[PCl_6]^-$ with ammonium chloride.[199] Surprisingly, the treatment of the silylated phosphaneimine $Me_3SiNPEt_3$ with xenon difluoride yields an octaethyltriphosphadiazenium trifluorodimethylsilicate $[Et_3PNPEt_2NPEt_3]^+$ $[Me_2SiF_3]^-$.[200] Related cationic chains containing four and five phosphorus atoms, $[Cl(Cl_2P{=}N)_nPCl_3]^+$ are formed in thermal reactions of cyclophosphazenes $(Cl_2PN)_n$ ($n = 3$ and 4) with phosphorus pentachloride.[201]

The tetraphosphadiazene compound $Ph_2P–N{=}PPh_2PPh_2$ $N–PPh_2$ forms both linear dinuclear complexes and rare seven-membered chelate ring complexes with various metals. It can be oxidized by sulfur and selenium, to form $Ph_2(Q)P–N{=}PPh_2PPh_2{=}NP(Q)Ph_2$ (Q = S, Se), which are also interesting ligands.[202]

The diselenium derivative reacts with $Ru_3(CO)_{12}$ to produce a complex of the $[Ph_2P–N{=}PPh_2–N{=}PPh_2]^-$ ligand.[203]

A dinuclear compound, $(Me_2N)_3P{=}N–P({=}NH)(NMe_2)_2$, with a high nitrogen:phosphorus ratio[204] is the first member of a series of strongly basic, branched polyamino-imino phosphazenes (Scheme 43).[205]

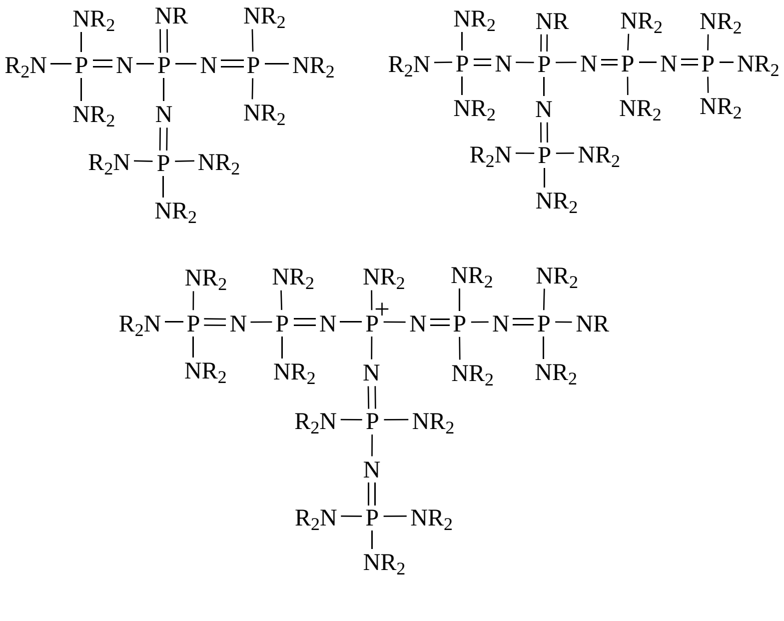
Step-by-step growth of phosphazene chains can be achieved and the five-phosphorus chain can be converted into a dendrimeric structure.[206] The fascinating chemistry of dendrimeric phosphors–nitrogen molecular architecture has been reviewed.[207]

5 CYCLIC PHOSPHORUS–NITROGEN COMPOUNDS

5.1 Two-coordinate Phosphorus

Some cyclic four- and five-membered inorganic rings may contain two-coordinate phosphorus. Their synthesis is based on cycloaddition reactions of amino-iminophosphines or alkyl azides to iminophosphenium cations (Scheme 44).[208]

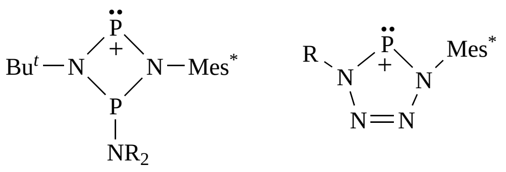
The silylated aminoiminophosphine $(Me_3Si)_2N–P{=}N–SiMe_3$ reacts with anhydrous aluminum chloride at 40 °C with elimination of Me_3SiCl to form a dicoordinate phosphorus–nitrogen ligand, in a four-membered chelate ring complex.[209] Anhydrous aluminum chloride extracts a chlorine ion from $[ClPNR]_2$ to form a cyclic cation with a dicoordinated



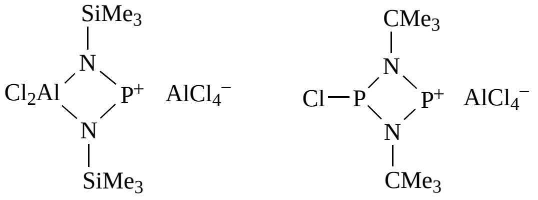
Scheme 43

phosphorus,[210] which displays interesting derivative chemistry (Scheme 45).[211]

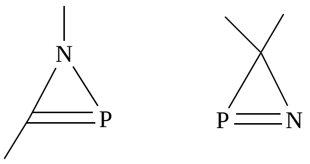
Two-coordinate phosphorus is also present in some three-membered P–N–C heterocycles, azaphosphirenes (Scheme 46), which have been reviewed.[212]



Scheme 44



Scheme 45



Scheme 46

5.2 Three-coordinate Phosphorus(III)

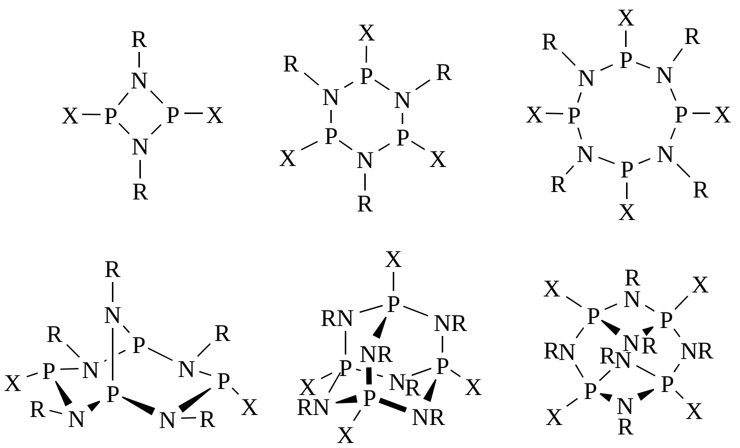
There are several (sometimes interconvertible) cyclophosph(III)azanes, illustrated in Scheme 47. Bicyclic, tricyclic, adamantane cage, and more complex structures can be obtained by minor variations of the reaction conditions, also depending on the nature of the substituents at phosphorus and nitrogen sites.[213] For reviews see Reference 214.

Generally, the phosphorus(III)–nitrogen rings are formed in reactions of primary amines with phosphorus(III) compounds containing at least two halogen atoms. Primary amines or lithiated silyamines such as $LiNRSiMe_3$ react with PCl_3 to yield dimeric $[ClPNR]_2$ (e.g. R = *tert*-Bu).[215]

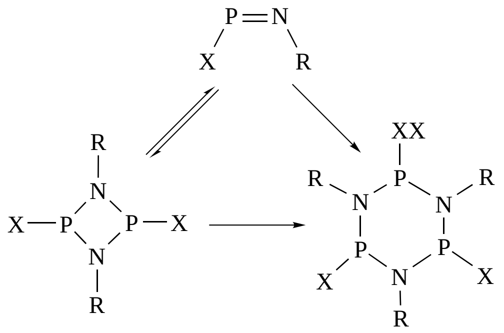
The reaction of phenyldichlorophosphine, $PhPCl_2$, with aniline is complex and the products depend on several factors. In the presence of triethylamine as acid scavenger a cyclic trimer $(PhPNPh)_3$ is formed.[216] Six-and eight-membered cyclophosph(III)azanes $(ClPNR)_n$ (R = Et, $n = 3$ and 4) were reported as products of reactions between N-ethylhexamethyldisilazane with phosphorus trichloride.[217] The reaction of PCl_3 with primary amines in excess yields dimeric $[(RHN)PNR]_2$,[218] but methylamine forms a cage compound with adamantane structure.[219] A bicyclic compound is obtained in the reaction of $MeN(PCl_2)_2$ with methylamine, whereas ethylamine forms the trimer $(ClPNEt)_3$.[220]

Monomeric iminophosphines, which can be prepared with bulky R groups (R = Mes* or Dipp; X = Cl or $CF_3SO_3^-$), are in equilibrium with their cyclic dimers, and both can be converted to the corresponding cyclic phosphazane trimers (Scheme 48).[221,222]

Cyclodiphosph(III)azanes are versatile ligands[223–225] and their coordination chemistry has been reviewed.[226] Imidoderivatives in particular, in deprotonated form, produce interesting cage compounds with a series of metals[227] and toroidal macrocycles formed from P_2N_2 rings have been described.[228] Some macrocyclic tetramers made of four P_2N_2



Scheme 47



Scheme 48

rings connected through nitrogen and oxygen are versatile ligands forming unusual complexes.[229]

Molybdenum carbonyl complexes of cyclotriphosph(III)azanes, $[(RO)PNEt]_3$ (R = CH_2CF_3 or $C_6H_3Me_2$-2,6)[230] and metal complexes of $[ArOPNEt]_3$ (Ar = 2,6-$Pr^i_2C_6H_3$)[231] have been described.

The tetraphosphorus(III)hexaazaadamantane derivative, $P_4(NMe)_6$, is obtained from phosphorus trichloride and methylamine,[232] and a tricyclic compound of composition $P_4(NPr^i)_6$ is formed from $ClP(NPr^i)_2PNPr^iSiMe_3$ by elimination of Me_3SiCl. It isomerizes on heating into the adamantane structure.[233] Another tricyclic compound, $P_4(NBu^t)_6$ with nonadamantane structure is formed by reacting $[ClPNBu^t]_2$ with $[(LiNBu^t)PNBu^t]_2$.[234]

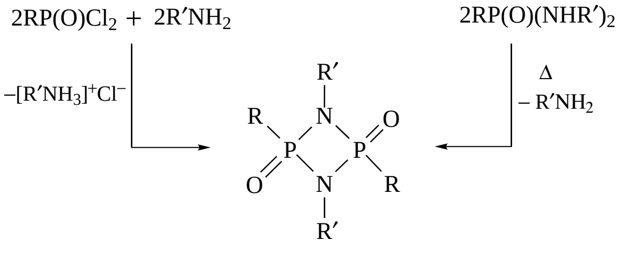
There are interesting interconversion reactions between monocyclic four-membered Cyclodiphosph(III)azanes, bicyclic, tricyclic, and adamantoid polycyclics.[235]

5.3 Four-coordinate Phosphorus

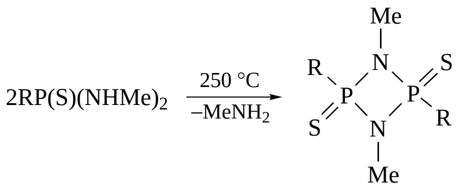
5.3.1 Cyclophosph(V)azanes

These are cyclic compounds consisting of ‘saturated’ $[PN]_n$ ($n = 2, 3, 4\ldots$) alternant rings, with exocyclic double bonds at phosphorus.[236]

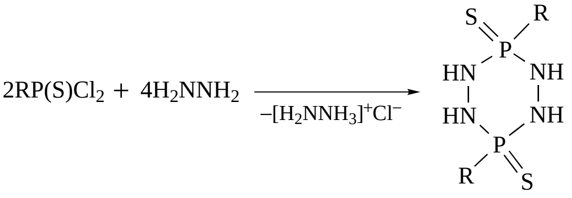
Cyclic dioxodiphosphazanes, $[R(O)PNR']_2$, are obtained from phosphonic acid dichlorides and primary amines,[237]



Scheme 49



Scheme 50



Scheme 51

and by thermal condensation of phosphonic acid diamides (Scheme 49).[238]

Oxidative addition of chalcogens to cyclodiphosph(III)-azanes, $[RPNR']_2$, leads to dichalcogeno cyclodiphosph(V)azanes, $[R(Q)PNR']_2$ (Q = O, S, Se) with preservation of the four-membered P_2N_2 ring.[239] Similar compounds are obtained by substitution of chlorine in reactions of five-coordinate cyclodiphosph(V)azanes, $[Cl_3PNR]_2$ with sulfur dioxide[240] and hydrogen sulfide,[241] respectively. Staudinger reactions with organic azides afford bis(imino)Cyclodiphosph(V)azanes $[R(R''N)PNR']_2$.[242]

Thermal condensation of thiophosphonic acid amides upon heating produces a mixture of cis and trans isomers of cyclodiphosph(V)azane derivatives (Scheme 50).[243]

Thiophosphonic acid dichlorides react with hydrazine to form six-membered ring compounds (Scheme 51).[244]

The anionic derivatives of cyclodiphosph(V)azanes, obtained by deprotonation of $[RNH(Q)PNR]_2$ (Q = O, S, Se) with organolithium reagents are versatile ligands, forming unusual metal complexes. These cyclic dimers also react with $AlMe_3$ to form dimethylaluminum derivatives.[245,246]

5.3.2 Cyclophosph(V)azenes

Cyclophosph(V)azenes are a family of rings formed by alternation of four-coordinate phosphorus and dicoordinate nitrogen atoms, also involving a formal alternation of single and double bonds in the ring (*see* ***Inorganic Ring Systems***). Whether this alternation results in an aromatic delocalization is a subject of much debate, but it seems that a view based on p_π-d_π bonds conjugations is now widely accepted. The best studied are the six-membered and eight-membered ring derivatives, that is, the trimers and tetramers of the X_2PN building units. Chloro derivatives $[Cl_2PN]_n$, with n from 3 to 8, have been isolated and

characterized,[247] and fluoro derivatives $[F_2PN]_n$, with n from 3 to19, were isolated by fractional distillation and vapor phase chromatography.[248] Historically, the cyclophosphazenes were among the first phosphorus–nitrogen compounds discovered and characterized. They were first obtained as early as 1834[249] and first characterized as cyclic compounds, remarkably, in 1895.[250] The subject is extensively covered in several books and numerous reviews[251] and only the basics and a few recent highlights can be mentioned here.

The chloro derivatives $[Cl_2PN]_n$ (especially the trimer and tetramer) are readily available from the reaction of phosphorus pentachloride with ammonium chloride (in a chlorinated solvent, at 140–150 °C) (equation 9).[252]

$$PCl_5 + NH_4Cl \longrightarrow \frac{1}{n}[Cl_2PN]n + 4HCl \quad (9)$$

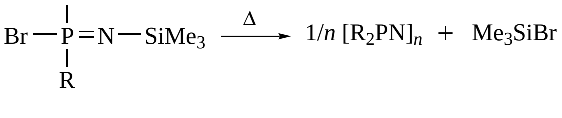
Reactions based on Si–N bond cleavage can be also very useful, especially for the synthesis of organosubstituted derivatives (Scheme 52).[253]

The synthesis of the trimer $[Cl_2PN]_3$ from PCl_5 and $N(SiMe_3)_3$ (in 76% yield) is described as an improved route to this cyclic compound, although under different condition the same reaction can give $Cl_3P{=}NSiMe_3$, which in turn is a useful precursor for chain-like polyphosphazenes.[254]

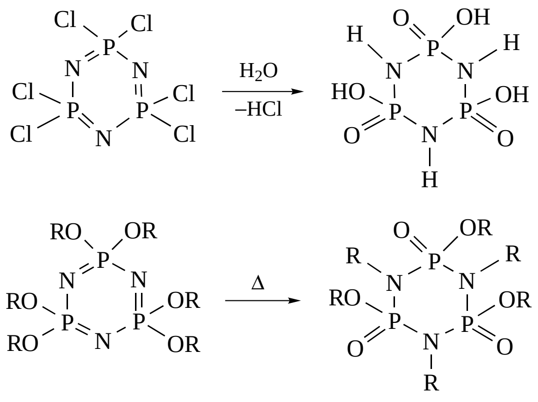
A surprising reaction leading to organosubstituted cyclotriphosphazenes, $[RMePN]_3$, involves Me_3SiOPh and PhOH elimination between $Me_3SiN{=}PMeR(OR')$ and R′OH (R = Me or Ph, R′ = Ph or CF_3CH_2O).[255] Interestingly, heating the pure cis or trans trimer $[MePhPN]_3$ results in a rearrangement with formation of a mixture of cis and trans trimer and all four geometric isomers of the tetramer $[MePhPN]_4$.[256]

An extensive chemistry based on nucleophilic substitution of chlorine with amino, alkoxo, thiolato, and organic groups has been developed. It cannot be covered here and the reader is directed to the review literature cited, which covers the subject in detail. Owing to the peculiar structure of the cyclophosphazene rings, several isomers, that is, geminal and nongeminal, cis and trans, can be formed in substitution reactions. The hexakis(amino)cyclophosphazenes derived from primary amines, $[(RNH)_2PN]_3$ display interesting supramolecular self-assembly in solid state through NH···N hydrogen bonds.[257]

A peculiar reaction is the hydrolysis of $(Cl_2PN)_n$, which yields no hydroxo derivatives, $[(HO)_2PN]_n$, as might be expected, but rather their tautomeric forms, $[HO(O)PNH]_n$ (n = 3–8), that is, the ‘metaphosphimic acids’.[258] Interestingly, the fully alkoxo substituted derivatives $[(RO)_2PN]_3$ can be converted to esters of metaphosphimic acids in a thermal Arbusov–Michaelis type rearrangement (Scheme 53).[259]



Scheme 52



Scheme 53

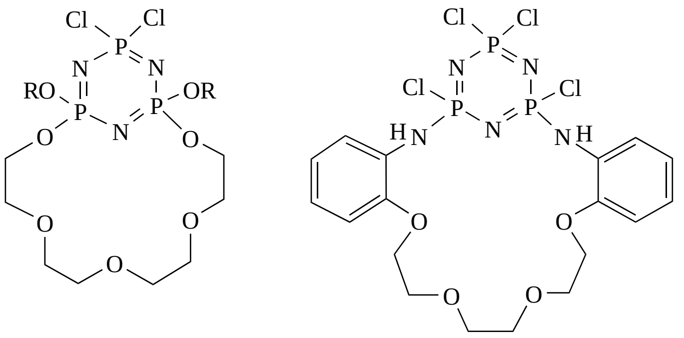
In addition to classical substituents such as NH_2, NHR, NR_2, OR, SR in various combinations, in recent years some more exotic groups have been attached to phosphazene rings. Among the novel cyclic phosphazenes the carborane substituted derivatives are worth mentioning.[260] Other unusual derivatives include chiral cyclophosphazenes,[261] cyano-,[262] ferrocenylphenoxy-,[263] and ferrocenylhydrazone-cyclophosphazenes.[264] Another interesting development is the synthesis of crown ethers with chlorocyclophosphazene subunits (Scheme 54).[265]

Polyfluororoalkoxy-cyclophosphazenes display high thermal and hydrolytic stability and do not rearrange to oxophosphazanes on heating.[266] They are promising high temperature lubricants.

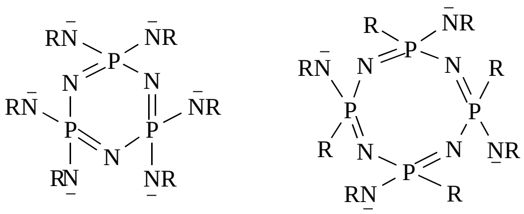
Some unusual compounds are the cyclophosphazenes with phosphazene side chains for example, neutral $F_5P_3N_3{-}N{=}PF_2{-}N{=}PCl_2{-}N{=}PCl_3$,[267] and the anionic -$[F_5P_3N_3{-}N{=}PF_2{-}N{=}PF_2{-}N{=}PF_5]^{2-}$ species, the latter obtained from $(F_2PN)_3$ and $[(Me_2N)_3S]^+$ $[Me_3SiF_2]^{2-}$ salt.[268]

An important recent achievement is the use of cyclophosphazenes as ligands, to form a variety of metal complexes.[269] Thus, the amino-substituted cyclophosphazenes,[270] the cyclophosphazenes bearing pyrazolyl substituents,[271] pyridyloxy-susbtituted cyclophosphazenes,[272] and those with phosphine side groups are versatile ligands.[273] Cyclophosphazenes containing ethynyl side groups form organometallic cobalt carbonyl complexes using the carbon–carbon triple bond.[274]

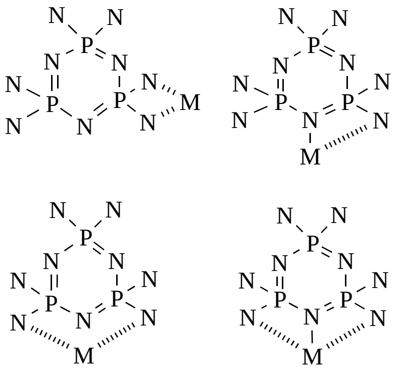
Cyclic iminophosphazenate anions (Scheme 55) are among the most interesting ligands and they display a broad diversity of coordination patterns.[275] Some are shown in Scheme 56. A hexakis(anisidyl) cyclotriphosphazenate anion, $[(2\text{-}MeOC_6H_4N)_6P_3N_3]^{6-}$, is unique in that it can chelate 12 lithium ions by a single ligand.[276]



Scheme 54



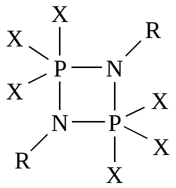
Scheme 55



Scheme 56

5.4 Five-coordinate Phosphorus

Cyclophosph(V)azanes with five-coordinate phosphorus are mostly dimeric, four-membered ring derivatives, $[X_3PNR]_2$ (**6**). Several reviews cover the subject.[277] A simple preparation of these compounds involves the reaction of PCl_5 with primary amines (or their hydrochlorides), the so-called Kirsanov reaction. Weakly basic amines form monomeric $Cl_3P{=}NR$, but with more basic amines (e.g. with R = alkyl), the products are the cyclic dimers. Various anilines give either a monomer or a cyclic dimer, depending upon their basicity.[278]

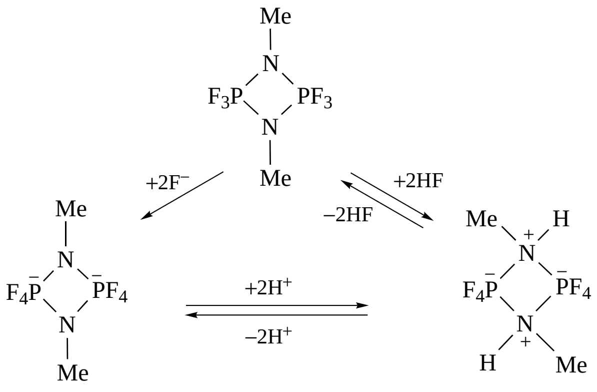


(**6**)

Cyclophosph(V)azanes containing six-coordinate phosphorus are rare.[279] Some can be obtained by treating $[F_3PNBu^t]_2$ with $LiBu^t$, resulting in zwitterionic compounds.[280] Addition of fluoride anions (from hydrogen, alkali metal or ammonium fluorides) to the dimer $[F_3PNMe]_2$ results in the formation of six-coordinate derivatives (Scheme 57).[281]

5.5 Heterocyclophosph(III)azanes

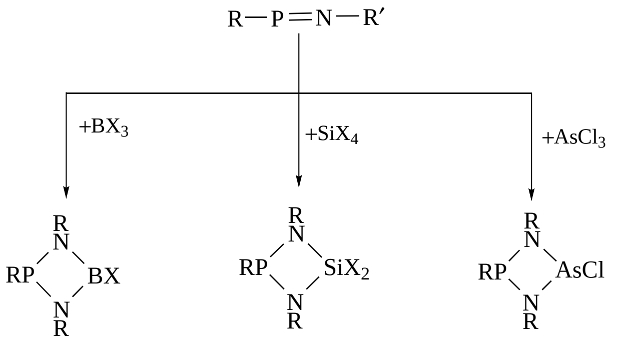
A series of four-membered rings containing phosphorus(III), two nitrogen atoms, and a heteroelement (boron, aluminum, silicon, arsenic) has been obtained by reactions of



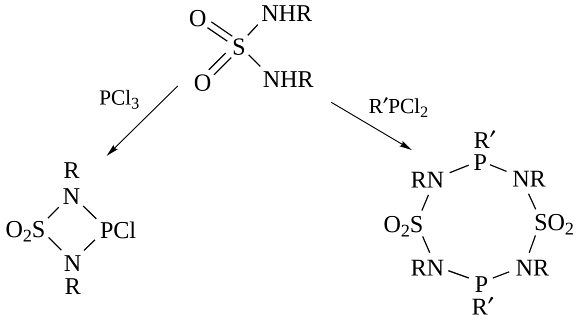
Scheme 57

$R_2N–P{=}NR$ (R = $SiMe_3$ or *tert*-Bu) with the corresponding element halides (Scheme 58).[282]

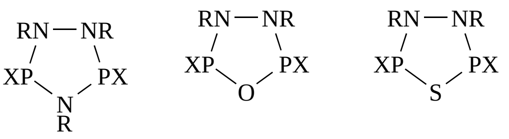
Four- and eight-membered heterocycles containing phosphorus(III), nitrogen and sulfur(VI) have been obtained by reacting phosphorus halides with dialkylsulfamide $O_2S(NHR')_2$ (Scheme 59).[283]



Scheme 58



Scheme 59



Scheme 60

Several five-membered heterocycles are derived from bis(dihalogenophosphinyl) hydrazines, $X_2PNMeNMePX_2$ (Scheme 60).[284]

5.6 Heterocyclophosph(V)azenes

Phosphorus can be partially replaced in cyclophosphazene rings by some heteroelements, for example, boron, silicon, arsenic, antimony, sulfur and the broad variety of such heterocycles cannot be discussed here in any detail, but their chemistry is well covered in several reviews.[285] Examples include boracyclophosphazenes,[286] numerous metal-containing heterocyclophosphazenes,[287] and sulfur-containing heterocyclophosphazenes,[288] to name only a few (Scheme 61).

6 HIGH MOLECULAR POLYMERIC P=N COMPOUNDS

The polymeric phosphazenes are treated in chapter (*see* ***Polyphosphazenes***) A recent monograph covers the chemistry of polyphosphazenes (nomenclature, synthesis of cyclic ‘monomers’, ring opening polymerization, condensation polymerization, substitution, polymer properties, and applications;[289] more than 1000 literature citations).[290] Other reviews have also been published recently.[291] Sulfur-containing polyphosphazenes have also been described.[292]

7 APPLICATIONS

Phosphorus–nitrogen compounds have numerous interesting applications, which cannot be covered here. Only a few are mentioned. Thus, the lithiated phosphorane imine $Ph_3P{=}NLi$ is a useful synthetic reagent in organic chemistry for the preparation of various nitriles.[293]

Applications of polyphosphazenes as flame retardants, electrolytes for special batteries, and biomaterials have been described.[294–295] Some cyclophosphazene derivatives can serve as hosts for small molecule Clathration.[296]

Polythionylphosphazenes can be applied as phosphorescent oxygen sensors.[297]

Glossary

Addition–elimination: an overall substitution reaction that takes place in two steps, the first being addition across an unsaturated linkage and the second an elimination involving one of the components added in the first step and one originally present
Cheleotropic fragmentation: a fragmentation reaction in which two σ bonds to a single atom are broken
Dehydrohalogenation: an elimination reaction in which the elements of a hydrogen halide molecule are eliminated from adjacent atoms leaving a π bond
Diastereoisomers: stereoisomers that are not enantiomers
Electrophilic reaction: a reaction in which an electron-rich species is attacked by an electron deficient site of another reagent to form a new covalent bond
Enantiomers: molecules whose structures are nonsuperimposable mirror images of each other
Exocyclic bond: a bond that is connected to and external to a ring structure
Nucleophile: an electron-rich species, generally with an unshared electron pair, that forms a new bond by attack of an electron deficient site other than a hydrogen
Pseudorotation: an internal motion of ligands about a central atom that exchanges several types of ligand positions and produces a permuted form of the original molecule without breaking and reforming bonds
Sigmatropic rearrangement: a rearrangement that occurs involving the concerted shift of electrons and the breaking and making of σ bonds
Stereogenic: a site within a molecule that imparts chirality to the molecule
Stereospecificity: a characteristic of a reaction in which one stereoisomer is formed or decomposed to the exclusion of other stereoisomers
Umpolung: a characteristic of a reaction system in which the polarity of a reactive functional group is inverted by a simple chemical transformation
Ylide: a zwitterion in which opposite charges are located on adjacent atoms and are not fully neutralized by bond formation

1 INTRODUCTION

The use of the term ‘organophosphorus compound’ has generally been limited to those materials that contain a direct carbon–phosphorus covalent bond. We continue this restriction in the present discussion. As a result, we will omit from this discussion the chemistry and nature of materials, while containing both carbon and phosphorus, that lack the direct covalent connection of the two elements. Other sources provide significant information on such materials as simple esters of phosphoric and phosphorous acid.[1,2]

The present consideration will be particularly concerned with the generation of those compounds containing at least one direct carbon–phosphorus covalent bond, with special emphasis given to the formation (and cleavage) of that type of bond. The organization of this treatment is based on the number of bonds present involving the phosphorus atom. Thus, phosphinidine (neutral, one carbon–phosphorus covalent bond) is considered first and working through hexacoordinate phosphorus. Included in the present consideration are reactions of elemental phosphorus that can lead to compounds with varying numbers of carbon–phosphorus covalent bonds depending on the reaction conditions.

2 PHOSPHINIDINE

For sometime, phosphinidines, monovalent organophosphorus species with the general formulation (R–P), have been postulated as reactive intermediates in the thermal and photochemical decomposition of several types of stable organophosphorus compounds. While not isolated as stable molecules, these monovalent species can be inferred on the basis of the isolation of products whose structures can be derived rationally from the postulation of such species, as well as on the mass spectra of the transient species themselves. We may view phosphinidines as the phosphorus analogues of nitrenes (R–N), highly reactive monovalent nitrogen species formed as transient intermediates in the thermal decomposition of azides and in the α-elimination reaction of N-tosylates.

Although there is a structural analogy of the two species, there are chemical and electronic differences between nitrenes and phosphinidines.

The production of a short series of organic phosphinidines by the thermolysis or photolysis of cyclophosphines $[R–P]_{4-6}$ (see Section 3.6) and by the reaction of organic phosphonous dichlorides ($RPCl_2$) (see Section 3.5) with electropositive metals has been reviewed by Schmidt.[3] While the noted reactions of phosphinidines lead to certain products attributable to phosphinidine intermediates, particular reactions are noteworthy by their failure to lead to products anticipated by analogy with nitrene and carbene chemistry. Although reactions involving the insertion of the phosphinidine into sulfur−sulfur bonds and the addition to the termini of conjugated dienes are observed, an anticipated addition to alkenes to form a three-membered ring fails to occur.[4] A phosphinidine intermediate has been postulated to be formed in the photolysis of a diphosphene (Ar–P=P–Ar) in which adjacent 1,1-dimethylethyl groups provide steric interaction, presumably preventing the monovalent phosphorus from undergoing intermolecular reaction. Rather, intramolecular insertion into a carbon−hydrogen bond occurs.[5] This type of reaction is common with nitrene and carbenoid intermediates. Matrix-isolation investigations should be useful for the investigation of the electronic nature of phosphinidines.

3 TRIVALENT ORGANOPHOSPHORUS COMPOUNDS

3.1 Overview

Several categories of organic phosphorus(III) compounds are of particular interest and will be considered here. In addition to differences in the nature of the bonding at phosphorus, these categories of compounds exhibit variations in chemical and physical properties owing simply to the nature of the ligands attached to phosphorus. For example, although they share some similarity in the mode of generation of the carbon−phosphorus bond, derivatives of the phosphonous acids $[R–P(OH)_2]$, such as the dihalide $[R–PCl_2]$, exhibit behavior quite different from that of phosphines $[R_3P]$ although the degree of substitution about phosphorus is the same.

3.2 Phosphines

In general, phosphines are tricoordinated phosphorus compounds that bear only hydrogen or carbon (alkyl, aryl, alkenyl) substituents at phosphorus. Subcategorization of phosphines is based on the degree of carbon substitution about phosphorus. Primary phosphines $[RPH_2]$ are those compounds that bear only a single carbon functionality attached to phosphorus. These compounds can be prepared by numerous methods, a common approach using the nucleophilic character of unsubstituted phosphine $[PH_3]$ or the phosphide anion $[PH_2^-]$. For example, methyl phosphine is prepared from sodium phosphide (itself derived from tetrasodium diphosphide or elemental phosphorus (*vide infra*)) and iodomethane in 62% yield by a nucleophilic substitution reaction. The reaction itself is presumed to occur quantitatively, but difficulties in isolation of the pure compound result in the observed decreased yield.[6]

The generation of phosphine (and the phosphide anion) from elemental phosphorus for use in this type of reaction is common. While unreactive with neutral water (although undergoing rapid oxidation with oxygen at 34 °C), elemental phosphorus (white, P_4) generates phosphine readily in basic medium.[7] On heating above 400 °C, white phosphorus $[P_4]$ generates a different allotropic form known as red phosphorus in which a P–P bond within the fundamental P_4 tetrahedron is broken and individual tetrahedra are linked in a polymeric chain. This form of elemental phosphorus is less reactive that white phosphorus, but still is quite useful for synthetic purposes.

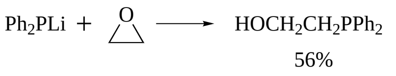
The direct reaction of organometallics such as organolithium or Grignard reagents with elemental phosphorus (white or red) can be used to generate the primary phosphines. The phosphide $[RPM_2]$ that is immediately formed reacts with water to generate the primary phosphine, or the addition of an alcohol to the reaction workup produces esters of phosphonous acids (see Section 3.5). Once the original organometallic has been used to generate the phosphide $[RPM_2]$, more highly substituted phosphines may be prepared by the addition of haloalkanes, or by reaction with appropriate carbonyl or epoxide reagents.[8–10]

Other approaches to the preparation of primary phosphines include the addition of phosphine itself to the carbonyl carbon of aldehydes or ketones (producing α-hydroxyalkylphosphonates),[11] or by conjugate addition reactions of phosphine to α, β-unsaturated reagents such as acrylonitrile or ethyl acrylate (equation 1).[12] Silylphosphines $[R_2PSiR'_3]$ also undergo conjugate addition reactions with acrylonitrile, replacing the phosphorus−silicon bond with a phosphorus−carbon bond.[13] Other organometallics, such as complex zirconium phosphides, undergo reaction with alkenes leading to preferential formation of primary phosphines by addition across the alkene linkage.[14] More highly substituted phosphines are formed as relatively minor side-products.

$$H_3P + H_2C{=}CHCN \xrightarrow{KOH} \underset{52\%}{H_2PCH_2CH_2CN} \qquad (1)$$

Secondary phosphines $[R_2PH]$ similarly can be derived from primary phosphines (and tertiary phosphines $[R_3P]$ from secondary phosphines) by way of nucleophilic attack by the electron-rich phosphorus of the phosphine on suitable

substrates such as haloalkanes or epoxides (equation 2).[15] Tertiary phosphines themselves remain quite nucleophilic, leading to the formation of quaternary phosphonium salts, the formation and reaction of which are discussed later (see Section 4.2).



(2)

An alternative approach to the synthesis of tertiary phosphines starting with phosphorus(III) reagents as the source of phosphorus involves the attack of organometallic species on phosphorus halides. Starting with phosphorus trichloride, symmetrical tertiary phosphines can be prepared through the use of an excess of the appropriate Grignard reagent, as in the preparation of triphenylphosphine (equation 3).[16] Esters or mixed ester acid halide derivatives of phosphorous acid [$P(OH)_3$] may also be used in this type of reaction. A degree of selectivity is noted for the attack of organometallic species on these types of phosphorus reagents;[17] in general, the acid halide linkages are more reactive than are the ester linkages.

$$\mathrm{PhMgBr + PCl_2 \longrightarrow \underset{76\%}{PPh_3}} \qquad (3)$$

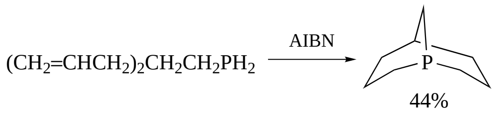
Unsymmetrical tertiary phosphines [RR'_2P] may similarly be prepared by reaction of the organometallic with $RPCl_2$ or R_2PCl. The generation of these latter materials use the reactive derivatives of phosphonous acids [$RP(OH)_2$] or phosphinous acids [R_2POH]. Early efforts for the generation of these acid halides generally involved the appropriate organomercury or organolead reagents in reaction with phosphorus trichloride, providing monoalkylation. However, more efficacious approaches are available through the use of organocadmium or organotin reagents.

Particularly high-yield preparations of both alkyl- and aryldichlorophosphines are obtained through the use of aluminum chloride. The aluminum chloride mediated reaction of phosphorus trichloride with haloalkanes generates an intermediate that can be reduced to the corresponding alkyldichlorophosphine (equation 4). For the preparation of aryldichlorophosphines, aluminum chloride serves a Friedel–Crafts catalyst for electrophilic aromatic substitution by phosphorus on the aromatic ring (equation 5). These synthetic approaches to dihalophosphines have been reviewed.[17]

$$\mathrm{CH_3I + PCl_3 + AlCl_3 \xrightarrow[Fe]{KCl} \underset{80\%}{H_3CPCl_2}} \qquad (4)$$

$$\mathrm{C_6H_6 + PCl_3 \xrightarrow{AlCl_3} \underset{70\%}{PhPCl_2}} \qquad (5)$$

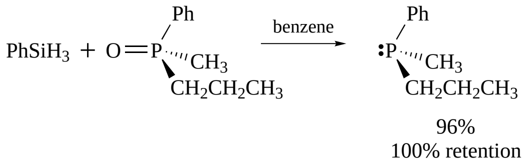
Primary and secondary phosphines are also capable of undergoing addition reactions across alkene linkages under the influence of radical initiators. In this way, more complex highly substituted phosphines can be generated. An illustration of this type of reaction is seen in the preparation of an unsymmetrically substituted tertiary phosphine, 1-phosphabicyclo[3.3.1]nonane, *via* two intramolecular addition reactions using a primary phosphine (equation 6).[18]



(6)

An additional approach toward the preparation of tertiary phosphines is by the reduction of more highly coordinated phosphorus species, particularly phosphine oxides [$O{=}PR_3$] and phosphine sulfides [$S{=}PR_3$] (see Section 5.2), but also phosphonium salts [$R_4P^+X^-$] and quasiphosphonium salts [$R_3P\text{-}YR'^+X^-$] (see Sections 4.2 and 4.4). Numerous reducing agents have been used to accomplish these conversions, including hexachlorodisilane [$Cl_3Si–SiCl_3$], trichlorosilane [$HSiCl_3$], phenylsilane [$PhSiH_3$], and lithium aluminum hydride [$LiAlH_4$].

When a phosphine oxide or sulfide bearing a stereogenic phosphorus atom is used, reduction of each of these reagents, except for lithium aluminum hydride, generally occurs with nearly complete stereospecificity. The nature of the stereospecificity (retention or inversion of the reaction) depends on the particular reaction conditions used. Alternatively, use of lithium aluminum hydride generally leads to racemization about phosphorus. The use of lithium aluminum hydride for stereospecific reduction of a tertiary phosphine oxide to the corresponding phosphine with retention of configuration has been accomplished with methyl triflate as an adjunct reactant. Up to 99% enantiomeric excess in the product has been obtained.[19] An example of the stereospecific reduction of a chiral tertiary phosphine oxide using phenylsilane is illustrated (equation 7). The nature of these reductions and their stereochemical outcomes has been reviewed.[20,21]



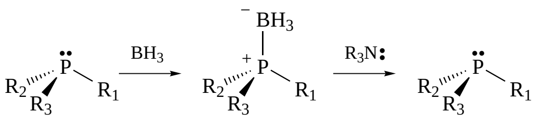
(7)

The stereochemical integrity of tertiary phosphines (their resistance to inversion of configuration) is significantly greater than that associated with tertiary amines of corresponding structure. For tertiary phosphines, the energy barrier for inversion is calculated to be somewhat higher than the 25 $\mathrm{kcal\,mol^{-1}}$ noted to be required for the spontaneous process to occur at room temperature. The 25 $\mathrm{kcal\,mol^{-1}}$ is significantly more than the value for tertiary amines. Such calculations appear to be validated by the experimental observations that simple (acyclic) unsymmetrical tertiary

amines are not capable of maintaining stereochemical integrity about nitrogen at room temperature, whereas maintenance of configuration about stereogenic phosphorus of tertiary phosphines is commonly found. The nature of stereogenic phosphorus in phosphines and other phosphorus species has been reviewed.[21]

In some instances, relatively mild nucleophilic agents are capable of generating tertiary phosphines from phosphonium or quasiphosphonium salts (see Section 4.4). Reagents such as KCN, alkoxide salts, or even tertiary amines are capable of attacking certain substituents to remove them from phosphorus leaving the tertiary phosphine with retention of configuration at phosphorus.[18]

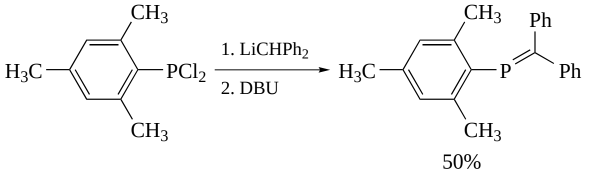
One mode of reactivity of phosphines that can be troublesome is their tendency to undergo oxidation readily, even by simple exposure to air, to generate phosphine oxides. The tendency to undergo this reaction is, of course, dependent on the structure of the substituents on phosphorus. One approach to stabilization of phosphines for storage, as well as during certain reactions, is their conversion to (and reversion from) phosphine-boranes. Tertiary phosphines, chiral or achiral at phosphorus, may readily be converted to the corresponding phosphine-borane (with retention of configuration if chiral) by reaction with borane and reverted to the original phosphine (again, with retention of configuration if chiral) by treatment with a tertiary amine (equation 8).[22,23]



(8)

3.3 Methylenephosphines

Although species of the general formulation R–P=CR$'_2$ wherein trivalent phosphorus is bound to only two (carbon) atoms have been proposed for many years as intermediates in a variety of chemical reactions, it was not until 1978 that a stable compound of this class was isolated.[24] This effort involved the generation of a sterically hindered system with three bulky aromatic rings bound around the P=C site (equation 9) that could reversibly add hydrogen chloride. The ^{31}P NMR spectrum exhibited a signal at relatively low field in accord with the postulation of such trivalent doubly coordinated phosphorus. Approaches toward this type of species have been reviewed.[25]

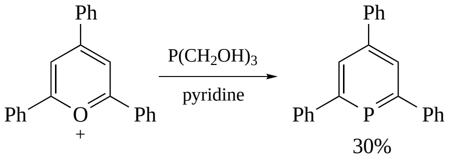


(9)

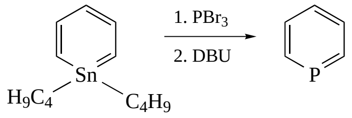
While such stable mono-phosphorus species have been prepared, emphasis continues to be given to transient systems[26] and those bearing metal complexation at phosphorus.[27,28] An intriguing cumulene analogue bearing the P=C=P linkage has been prepared,[29] as well as diphosphinidenecyclobutene species.[30] The preparation and properties of such species has recently been reviewed.[31]

3.4 Phosphabenzenes and Other Potential Aromatic Species

Phosphabenzene, the phosphorus analogue of pyridine, is a species that, as with the methylenephosphines, formally contains a doubly coordinated phosphorus singly bound to one carbon and doubly bound to another. The first isolation of a phosphabenzene derivative was reported in 1966 using the reaction as shown below (equation 10).[32] The parent phosphabenzene molecule was first isolated by the reaction (equation 11) of phosphorus tribromide with a stannane derivative, albeit in low yield.[33] Further spectroscopic investigation of this parent molecule indicated it to be planar with indications of multiple bond character between phosphorus and carbon and aromatic delocalization.[34]



(10)



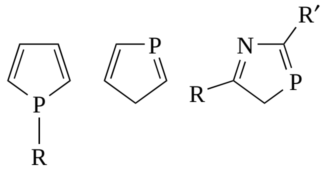
(11)

Although the phosphabenzene species exhibit ^{31}P and ^{1}H NMR spectra in accord with the postulation of aromatic character analogous to that of pyridine (the ^{31}P signal occurs at significantly low field), these materials lack the nucleophilic character at phosphorus commonly associated with the analogous nitrogen systems (pyridine). However, the substituted phosphabenzene system appears to act as a good electrophile in that it readily undergoes electrophilic aromatic substitution reactions, in accord with the postulation of aromatic character for the ring.

Recent efforts in regard to phosphabenzene derivatives have particularly been concerned with metal complexes[35] and theoretical considerations.[36] These areas have been reviewed recently.[31]

The preparation of phosphorus analogues of aromatic nitrogen-containing heterocycles has been extended as well to other systems than pyridine. Of particular interest are those compounds generally referred to as phospholes. These are five-membered ring systems bearing a phosphorus atom within the ring structure. The parent $\sigma^3\lambda^3$-phosphole in which a trigonal phosphorus atom is present is shown as (**1**). Such systems are formally analogues of pyrrole, although the

geometry of the phosphorus is clearly different from that of the actual nitrogen-containing pyrrole. Further, calculations and experimental data concerning aromaticity of the phosphole ring system are ambiguous regarding the aromatic character of phosphole, whereas pyrrole is clearly aromatic. In keeping with the ambiguous character of the $\sigma^3\lambda^3$-phospholes, they are found to undergo Diels–Alder reactions occurring within the coordination sphere of a metal, evidence of a decreased, but not necessarily absent, aromatic character of a conjugated system. Isomeric structures describable as $\sigma^2\lambda^3$-phospholes (**2**) may be generated from the $\sigma^3\lambda^3$-phospholes by [1,5] sigmatropic rearrangement, although, with few exceptions, these species exist only as transient intermediates. Of course, structures further substituted with heteroatoms (particularly nitrogen), such as that of the 1,2,3-σ^2-diazaphosphole type (**3**), are quite stable and exhibit typical aromatic ring chemistry such as undergoing electrophilic aromatic substitution reactions.[37] The preparations, structures, and reactions of phospholes have been reviewed.[38]

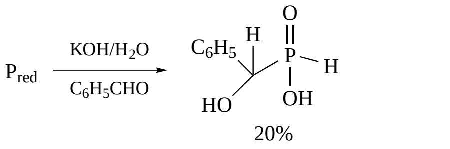


(**1**) (**2**) (**3**)

3.5 Phosphinous and Phosphonous Acids and Their Derivatives

Acid chloride derivatives of phosphinous acids [R_2POH] and phosphonous acids [$RP(OH)_2$] have been mentioned previously (see Section 3.2) as precursors in the preparation of phosphines. In addition to the common routes of preparation for these trivalent phosphorus acids, particularly through the use of organometallic reagents and Friedel–Crafts reactions as noted, several other routes have been developed for their syntheses that are worthy of note.

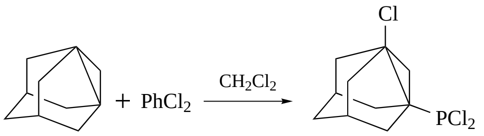
For example, two reports of preparation of such species from elemental (red) phosphorus have been noted. The direct preparation of 1-hydroxyphosphonous acids, albeit in moderate yield, is accomplished by the treatment of elemental phosphorus with aldehydes in aqueous basic medium (equation 12).[39] Using polar aprotic solvents, the double direct addition of elemental phosphorus to arylalkenes proceeds to form phosphinous acids in better yields.[40] Further, acid chloride derivatives are available also by the controlled reaction of elemental phosphorus with chloroalkanes.[8]



20% (12)

Unsaturated phosphonous dichlorides have been prepared by the photochemically induced addition of PCl_3 across conjugated dienes.[41] These adducts are quite susceptible to dehydrohalogenation to reform conjugated dienes with a phosphorus(III) site attached (equation 13). Several reports have also been made concerning the addition of phosphorus halides across the moderately strained cyclopropane ring contained in 1,3-dehydroadamantane, as shown (equation 14).[42] This result holds promise for the preparation of additional phosphinous and phosphonous halides using equally or more strained cyclopropane ring systems.

$$\mathrm{Cl_3P + H_2C{=}CH{-}CH{=}CH_2 \xrightarrow{h\nu} \underset{45\%}{Cl_2PCH_2CH{=}CHCH_2Cl} \xrightarrow{(C_2H_5)_3N} \underset{50\%}{Cl_2PCH{=}CH{-}CH{=}CH_2}} \quad (13)$$

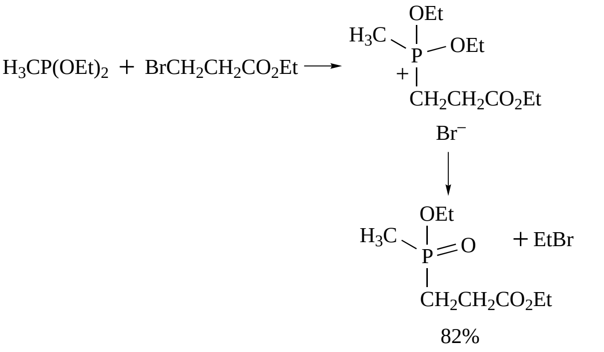


93% (14)

A different approach toward preparation of phosphinous and phosphonous iodides uses the reaction of iodoalkanes with either PI_3 or PI_5.[43] This reaction is specific for iodoalkanes and phosphorus iodides and is not applicable to other halides. From the resultant highly reactive phosphinous and phosphonous iodides, the full range of the parent acid derivatives may be prepared (esters, other acid halides, anhydrides, amides). We will not be concerned here with these preparations of derivatives of the parent acids, topics that are considered in other reports.[1,2]

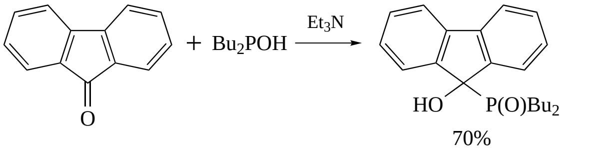
Esters of the phosphinous [$R_2P(OR')$] and phosphonous [$RP(OR')_2$] acids, as with phosphines, are capable of serving as nucleophiles. These compounds act as nucleophiles toward the normal range of electrophilic substrates including haloalkanes, tosylate esters, and carbonyl compounds, among others, to generate quasiphosphonium ion intermediate species (see Section 4.4). (In those instances where tertiary phosphines are acting as nucleophiles with one of the aforementioned substrates, the resultant phosphonium ion constitutes the product of the reaction.) However, the quasiphosphonium ions that result from reaction of alkyl or silyl esters of phosphinous and phosphonous acids are capable of continuing reaction by a further nucleophilic displacement reaction. This reaction involves cleavage of the ester linkage with concomitant formation of a tetracoordinated quinquevalent phosphorus site. The overall reaction, generally referred to as the Michaelis–Arbuzov reaction, is illustrated below (equation 15). The product in the reaction shown, starting with the diester of a phosphonous acid, is an ester of a phosphinic acid [$R_2P(O)OH$]. The corresponding product starting with the ester of a phosphinous acid would be a tertiary phosphine oxide [R_3PO]. Of course, the Michaelis–Arbuzov

reaction may be used to produce a new carbon–phosphorus bond in phosphonates $[(RO)_2P(O)R']$ starting with esters of phosphorous acid $[(RO)_3P]$, the latter of which are not truly organophosphorus species.



(15)

If a nucleophilic addition at a carbonyl or imine carbon occurs, the product is still a phosphinate (from a phosphonous ester) or a phosphine oxide (from a phosphinous ester), but the reaction is commonly referred to as an Abramov or Pudovik reaction. An example of the Pudovik reaction is shown below (equation 16). Addition of the phosphorus nucleophile to the β-carbon atom of an α, β-unsaturated substrate (Michael addition) is commonly referred to as a hydrophosphinylation reaction.[44]



(16)

A related reaction that yields the same types of products as does the Michaelis–Arbuzov reaction begins with either a phosphinous acid or a monoester of a phosphonous acid. (The corresponding reaction may also be performed with a diester of phosphorous acid.) By treatment with an appropriate base, the conjugate base of the phosphorus-containing acid is generated that serves as the nucleophilic reagent for direct formation of the phosphonate or phosphine oxide product (or phosphonate product from a phosphorous acid diester). This procedure is commonly referred to as the Michaelis–Becker reaction.[44]

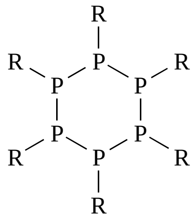
The several series of reactions noted here have recently been reviewed.[44,45] More will be noted concerning these reactions later in the present consideration (see Section 5.2).

3.6 Biphosphines and Cyclophosphines

Biphosphines are tricoordinated phosphorus(III) compounds that bear a single phosphorus–phosphorus bond, as in the general structure (**4**). Cyclophosphines may be considered to be expanded biphosphines in which a series of tricoordinated phosphorus(III) sites are connected to each other to complete a ring structure, as in structure (**5**). Additional substituents are present on each phosphorus atom to provide the tricoordinated status. Generally *not* included among these materials are polyphosphine compounds containing two or more tricoordinated phosphorus(III) sites *without* the phosphorus–phosphorus bond, or ring systems simply containing one or more phosphorus(III) sites without a phosphorus–phosphorus bond.

$R_2P\text{-}PR_2$

(**4**)



(**5**)

Biphosphines may be formed by several methods involving the treatment of phosphinous halides with either electropositive metals or organomercury compounds. An additional intriguing approach involves the reaction of metal organophosphides (see Section 3.2) with 1,2-dibromoethane to form the phosphorus–phosphorus bond and extrude ethylene (equation 17).

$$Et_2PLi + BrCH_2CH_2Br \longrightarrow \underset{84\%}{Et_2P\text{-}PEt_2} + H_2C{=}CH_2 \qquad (17)$$

The preparation of cyclophosphines has been accomplished starting with the corresponding primary phosphines and phosphonous dichlorides under a variety of conditions. Varying sizes of rings are generated depending on the reaction conditions.[46] The syntheses and characteristics of biphosphines and cyclophosphines have been reviewed.[2]

4 TETRAVALENT ORGANOPHOSPHORUS COMPOUNDS

4.1 Overview

Phosphorus(IV) compounds incorporate a positive charge formally located at the phosphorus site. In some instances, this is clearly a localized positive charge, as is found in simple tetraalkylphosphonium salts, with an associated gegenion. In other instances, the nature of the charge and its location are open to more complex considerations. For example, ylides, that may be generated from classical phosphonium salts, are not only zwitterions (as opposed to a more classical two component salt) but also may be described with formal positive and negative charges on adjacent atoms. Generally, the negative site is at a carbon atom directly bound to

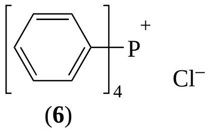
a phosphorus, which is the positive site. Such species are understood to have a significant π-covalent character to the carbon–phosphorus linkage with a corresponding diminution of the charge separation. In this section, we will consider not only the simple phosphonium salts, but also quasiphosphonium species in which at least one of the ligands bound directly to the positively charged phosphorus center through an atom other than carbon, as well as derived ylides.

4.2 Phosphonium Ions

Quaternary phosphonium salts, having the general formulation $[R_4P^+X^-]$, are formal analogues of quaternary ammonium salts. While there are structural similarities in structure (general tetrahedral) and modes of formation, there are also fundamental differences in the natures of the two types of compounds.

A fundamental route for the preparation of simple tetraalkylphosphonium salts is the reaction of a tertiary phosphine with a haloalkane or other substrate upon which a simple nucleophilic substitution reaction can occur. (In comparing phosphorus nucleophiles with the corresponding nitrogen-centered nucleophiles, it must be remembered that the phosphorus is significantly more nucleophilic than is the nitrogen. For example, while triphenylamine is devoid of nucleophilic character in reaction with ordinary haloalkanes, triphenylphosphine exhibits high reactivity.) Reactivity of the phosphorus in such nucleophilic substitution reactions, as with other types of nucleophiles, decreases with increasing substitution about the electrophilic site of the substrate.

The reaction of aromatic halides with tertiary phosphines requires special reaction conditions, as they are not susceptible to the simple nucleophilic substitution reaction. Strong heating, generally in a closed pressure tube, with the tertiary phosphine in the presence of a nickel(II) halide salt allows substitution of the halogen by phosphorus, probably by way of an addition–elimination reaction.[47–51] In this manner, tetraarylphosphonium halides, such as tetraphenylphosphonium chloride (**6**), may be produced in good yield. This approach has been used for the construction of an intriguing series of polyphosphonium ion dendrimer species.[52]



(**6**)

While tetraalkylphosphonium salts may be generated by the reaction of elemental phosphorus (white or red; see Section 3.2) with haloalkanes, the reaction is complicated by the concomitant formation of trialkylphosphine dihalides. The resultant mixture is generally converted to the corresponding trialkylphosphine oxide by treatment with ethanol under heating. This process consumes both phosphorus components of the mixture.

Recently, the major driving force for the investigation of methods for preparation of quaternary phosphonium salts has been their ability to serve as precursors for ylides in Wittig and related olefination reactions for organic syntheses. These materials will be surveyed in the following section.

4.3 Phosphonium Ylides and Related Species

The fundamental work of Wittig and his students from the early 1950s has provided organic chemists with a fundamental approach toward the facilitation of the syntheses of a wide range of chemical structures.[53] The reaction, as originally developed by Wittig and his students, and further modified by numerous researchers, involves the conversion of a carbonyl group of an aldehyde or a ketone to a substituted alkene linkage. This olefination reaction provides a direct method for what previously required a usually complex and highly inefficient series of reactions. This organic synthetic approach depends on the facile generation of quaternary phosphonium salts and their subsequent use in the formation of phosphorus ylides, as well as in the construction of structurally complex organophosphorus compounds for which stereochemical outcomes are predictable.[54]

Particularly notable modifications of the fundamental Wittig reaction are those described as a ‘phospha-Wittig’ process (as illustrated in equation 18)[55] and the ‘aza-Wittig’ process (as illustrated in equation 19) and useful for the preparation of secondary amines.[56]

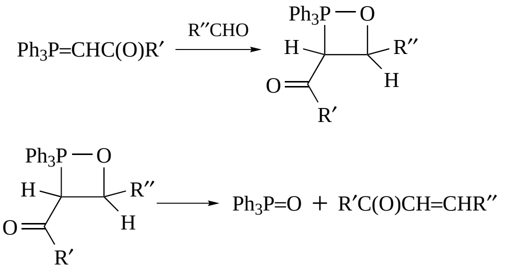
$$\mathrm{ArP{=}P(CH_3)_3 + RCHO \longrightarrow RCH{=}PAr} \quad (18)$$

$$\mathrm{RN{=}P(OR')_3 + R''CHO \longrightarrow RN{=}CHR''} \quad (19)$$

The Wittig olefination reaction, the modifications, and the nature of the organophosphorus intermediates has been reviewed.[57]

Stabilized species in the phosphorus ylide category are normally generated in a two-step sequence beginning with the formation of the quaternary phosphonium salt. This is usually accomplished with ease by the reaction of triphenylphosphine with the appropriate haloalkane. Salt formation is followed by deprotonation at the carbon adjacent to phosphorus using an appropriate base to generate a zwitterionic species stabilized by the adjacent functionality (illustrated in equation 20). The resultant phosphorus species reacts with an introduced carbonyl compound to generate an intermediate oxaphosphatane that undergoes decomposition to produce alkene and phosphine oxide at relatively low temperatures (equation 21).

$$\mathrm{Ph_3P + XCH_2C(O)R' \longrightarrow Ph_3\overset{+}{P}\text{-}CH_2C(O)R' \xrightarrow{\text{base}} Ph_3P{=}CHC(O)R'} \quad (20)$$



(21)

The stability of ylides such as shown in equations (20) and (21) can be significantly greater than those with simple alkyl groups attached. This stability depends on the degree to which the negative charge is delocalized by the substituent. Those species having a greater degree of stabilization by charge delocalization usually require only weaker basic reagents for their formation from the phosphonium salts than the unstabilized ylides require.[58]

4.4 Quasiphosphonium Ions

Quasiphosphonium ions are tetracoordinated phosphorus sites bearing a positive charge within which at least one of the substituents about phosphorus is a heteroatom. Such species may be generated in a variety of ways and have intriguing chemistry associated with them depending on the particular substituents.

In certain notable instances, attack by a phosphine on a halogenated organic compound occurs at the halogen atom rather than at carbon. Of particular significance here is the reaction of tertiary phosphines, commonly triphenylphosphine, with tetrahalomethanes that proceeds to form a quasiphosphonium ion intermediate. In the presence of an alcohol, such an intermediate continues to react with the alcohol to generate a new oxygen-containing quasiphosphonium species that subsequently undergoes decomposition to form the haloalkane and triphenylphosphine oxide (equation 22).[59] Overall, presupposing the judicious choice of solvent, this approach provides a clean and efficient method for the stereospecific conversion of alcohols to the corresponding haloalkanes without skeletal rearrangement or the involvement of acidic reagents.

$$Ph_3P + CCl_4 \longrightarrow [Ph_3P\text{-}Cl]^{+-}CCl_3 \xrightarrow{ROH} Ph_3P{=}O + RCl \quad (22)$$

Quasiphosphonium ions involving oxygen directly bound to the positive phosphorus site are generated as intermediates in numerous other reactions. For example, the Michaelis–Arbuzov reaction (see Section 3.5) produces a quasiphosphonium ion as an intermediate that undergoes attack by the associated anion at the carbon end of the C–O–P linkage.[7] The reaction follows a different course when aryl ester linkages are present on the starting trivalent phosphorus acid derivative. In such instances, a quasiphosphonium ion is generated that is capable of taking part in several competing processes, but generally not a simple displacement process as is found with alkyl esters.[59,60] With intense heating, the intermediate salt can decompose to give products formally analogous to those of the normal Michaelis–Arbuzov reaction (equation 23). However, complex equilibria are established that lead to several other types of products, including those of disproportionation.

$$(ArO)_3P + RX \longrightarrow (ArO)_3\overset{+}{P}R + X^- \xrightarrow{heat} ArX + (ArO)_2P(O)R \quad (23)$$

The formation of the diaryl ester of the phosphonic acid as shown in equation (23) requires stronger heating than for other Michaelis–Arbuzov reactions using alkyl esters. This is the result of difficulty in accomplishing the nucleophilic displacement reaction on the aromatic ring. More will be noted later (see Section 5.2) concerning the Michaelis–Arbuzov reaction of aryl esters of phosphorous acid.

A particularly interesting category of such oxygen-bound quasiphosphonium ion is that related to the stabilized ylides previously noted (see Section 4.3). If a Michaelis–Arbuzov reaction is performed involving a trialkyl phosphite and a haloalkane with α, β-unsaturation (generally a C=O linkage of a carbonyl or ester linkage), the quasiphosphonium salt generated has the ability to be converted readily to a stabilized anionic species. The preparations and uses of these reagents have been thoroughly reviewed.[57,58]

Several types of phosphoryl-containing stabilizing groups have been developed as reagents for the olefination process, as shown below. These include phosphonate-stabilized carbanions (**7**) and phosphine oxide-stabilized carbanions (**8**). Species containing two phosphorus centers, as with (**9**) and (**10**), are of great utility for the introduction of phosphorus-substituted olefinic linkages in place of a carbonyl oxygen.

$(RO)_2P(O)\bar{C}HCO_2R'$ (**7**)

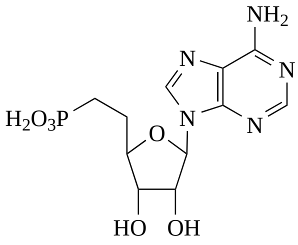
$Ph_2P(O)\bar{C}HCO_2R$ (**8**)

$Ph_3P{=}CHP(O)(OR)_2$ (**9**)

$(RO)_2P(O)\bar{C}HP(O)(OR')_2$ (**10**)

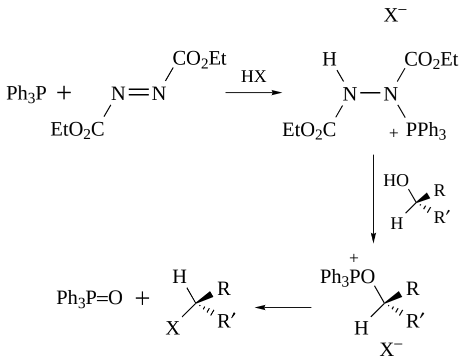
Species of the type (**9**) have been used for the construction of phosphonic acid analogues of natural nucleotides, such as (**11**).[61]

Quasiphosphonium intermediate species are found to be involved in the transition metal–catalyzed reaction of haloaromatics[62–67] and vinylic halides[68,69] with trivalent phosphorus-containing esters. These reactions, while giving products that appear to be from a Michaelis–Arbuzov type reaction, actually involve addition–elimination reactions.



(**11**)

A further synthetically useful reaction is worthy of note here as it involves a pair of quasiphosphonium ion intermediates. Commonly referred to as the Mitsunobu reaction,[70] a variety of phosphorus reagents, including trialkyl or triaryl esters of phosphorous acid, may be used in this reaction to replace the hydroxyl of an alcohol with a halide and inversion of configuration about the carbinol carbon site. Triphenylphosphine is the most commonly used trivalent phosphorus reagent for this conversion, reacting with the diester of an azodicarboxylic acid in the presence of an acid to form the quasiphosphonium ion bearing a nitrogen atom bound to the positive phosphorus site. This intermediate then undergoes reaction with the selected alcohol generating a new quasiphosphonium species bearing a phosphorus–oxygen bond. Finally, as with the Michaelis–Arbuzov reaction and the tetrahalomethane reactions noted previously, the associated anion performs a nucleophilic substitution reaction at the original carbinol carbon site yielding the product with inversion of configuration about the carbinol carbon (equation 24).



(24)

Using [31]P NMR, the intermediacy of the quasiphosphonium ion bearing the phosphorus–oxygen linkage has been demonstrated experimentally. In the absence of added acid, the same product formation occurs, but the intermediate quasiphosphonium species has not been detected experimentally. However, evidence of an intermediate oxyphosphorane (see Section 5.3) has been demonstrated under these conditions, as it has under acidic conditions, and such an intermediate has independently been shown to provide the usual products of the reaction. Evidence is available in other systems for the equilibrium of oxyphosphoranes with oxygen-containing quasiphosphonium salts.

5 PENTAVALENT ORGANOPHOSPHORUS COMPOUNDS

5.1 Overview

Numerous categories of pentavalent organophosphorus compounds are known that differ quite significantly in their structures and reactivities. We will consider a number of these general categories here, starting with species that, while pentavalent, are tetracoordinated at phosphorus. These include the oxidized forms of phosphines (phosphine oxides, phosphine sulfides, and related materials) as well as phosphonic and phosphinic acids and their derivatives. Pentacoordinated pentavalent organophosphorus compounds that are considered here include the phosphoranes, the oxyphosphoranes, and polyhalogen phosphorus compounds.

5.2 Phosphine Oxides, Sulfides, and Related Compounds

Tertiary phosphines readily undergo oxidative addition reactions to form phosphine oxides (**12**) when challenged with a variety of oxidizing agents, including nitric acid, manganese dioxide, permanganate ion, dichromate ion, hydrogen peroxide, and even molecular oxygen as present in air. Similarly, sulfur or selenium may be added readily to generate the corresponding phosphine sulfides (**13**) or phosphine selenides (**14**).

$R_3P{=}O$ (**12**) $R_3P{=}S$ (**13**) $R_3P{=}Se$ (**14**)

Tertiary phosphine oxides are also produced as significant by-products in several of the reactions of phosphines that have been noted previously, including the Wittig olefination and the conversions of alcohols to haloalkanes with triphenylphosphine as an adjunct reagent. The tertiary phosphine oxides produced in such reactions present a problem in chemical economics, as they themselves possess little chemical utility. The phosphine may be regenerated, but several steps are required, as previously noted with preparations of phosphines by reduction (see Section 3.2).

Tertiary phosphine oxides and sulfides are also produced by way of the Michaelis–Arbuzov reaction beginning with phosphonous esters [R_2POR'] and thiophosphonous esters [R_2PSR'], when used in reaction with haloalkanes (see Section 3.5). Similarly, phosphine oxides are formed from trivalent phosphorus reagents in the Michaelis–Becker reaction as well as the conjugate addition reactions of phosphinous acid derivatives with α, β-unsaturated compounds (see Section 3.5).

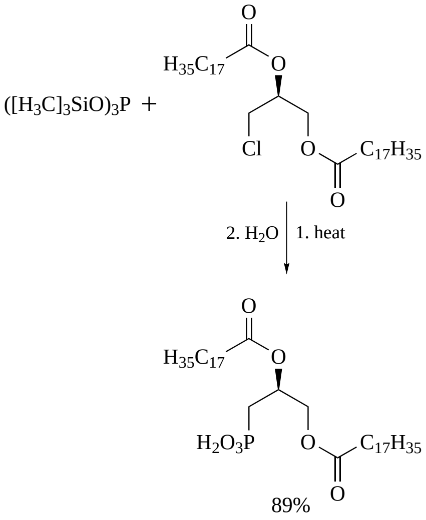
A direct approach for the preparation of phosphine oxides in reasonable yield involves the treatment of elemental phosphorus (either white or red) with primary haloalkanes in a basic (KOH) medium of water/dioxane with the presence of a phase-transfer catalyst.[9,10]

The structurally related phosphinamines (aza-Wittig reagents; see Section 4.3) are formally in this category as phosphorus is singly bound to each of three alkyl (or aryl) groups and doubly bound to an electronegative atom (nitrogen). A most interesting mode of preparation of such materials is by the reaction of a tertiary phosphine with an alkyl azide (equation 25).

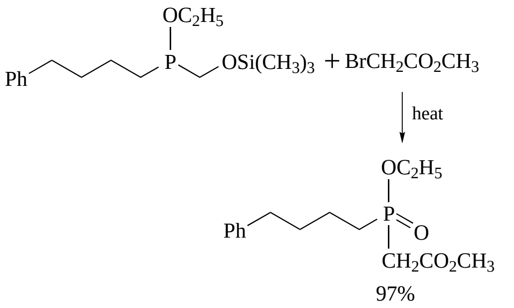
$$R_3P + N_3R' \longrightarrow N_2 + R_3P{=}NR' \qquad (25)$$

As may be noted, major advances in the development of preparative routes for tetracoordinated quinquevalent organophosphorus compounds occurred in the late nineteenth and early twentieth centuries. In more recent times, owing to increased applications and potential applications for derivatives of phosphonic and phosphinic acids, including biomedical regulation, pest control, flame retardation, and biochemical mechanistic exploration, among others, increased attention has been given to approaches for the preparation of such materials.

As previously discussed, the Michaelis–Arbuzov reaction is the best-known method for the preparation of phosphonic and phosphinic acids and their derivatives. However, the original approach has numerous drawbacks, not the least of which are the reaction yields, which usually are only moderate, and the stringent heating conditions usually required. A significant development for the fundamental reaction in relatively recent years has been the use of silyl esters of the trivalent phosphorus-containing acid rather than alkyl or aryl esters.[71] The advantage of using silyl esters is twofold: first, less stringent conditions are generally required to cleave the ester linkages and generate the free phosphorus-containing acid target (equation 26), and, second, there is great selectivity observed in the displacement step of the overall process with the silyl ester being displaced preferentially to ordinary alkyl ester linkages (equation 27).

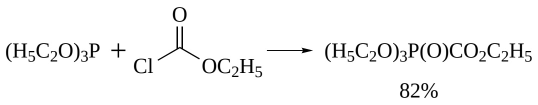


(26)



(27)

The reaction is also facile (no external heating) and proceeds in high yield when the substrate is an acyl halide or related material. Such reactions, producing acylphosphonate derivatives (equation 28), are of use for the preparation of compounds for a variety of practical applications.[72]



(28)

The closely related Michaelis–Becker reaction also is attendant with difficulties. There are particular problems with solubility of the reagents that hinder facile reaction. Some advance in overcoming this type of problem is accomplished in some instances using amines as the base, and even Mannich-type bases for which the base serves not only as the deprotonating agent, but also as a masked substrate for reaction.

The cleavage of carbon–phosphorus bonds in phosphoryl compounds is another matter for consideration. Once a carbon–phosphorus bond is generated, usually it is extremely difficult to cleave it without major damage to the remainder of the molecule. However, phosphonate and phosphinate esters, as well as phosphine oxides, in which a hydroxyl or carbonyl group is present at the carbon directly attached to phosphorus are subject to facile cleavage of the carbon–phosphorus bond.

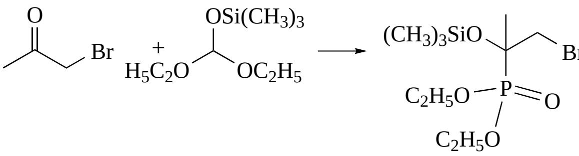
For example, acylphosphonate esters (as produced in equation 28 above) easily undergo cleavage of the carbon–phosphorus bond in aqueous and other basic media. (With the free acid, conversion to the conjugate base of the parent acid renders the carbon–phosphorus bond resistant to cleavage.)[73] Synthetic targets here involve not only organophosphorus compounds, but others derived from the parent organophosphorus compound such as amides (equation 29). In addition to such carbonyl linkages, a hydroxyl substituent located off the carbon directly bound to phosphorus in such systems also renders the carbon–phosphorus bond labile under basic conditions, as long as a free phosphorus acid site is not present.[74] With this in mind, the use of α-hydroxyphosphoryl compounds holds significant promise as *umpolung* reagents for organic syntheses.[75] The susceptibility of such carbon–phosphorus bonds to selective cleavage holds great potential for synthetic utility that has only begun to be

exploited.[76]

$$PhC(O)P(O)(OC_2H_5)_2 + PhCH_2CH_2NH_2 \longrightarrow PhC(O)NHCH_2CH_2Ph \quad (29)$$
82%

Approaches are being developed that will introduce oxygen substituents to otherwise unsubstituted carbon directly attached to phosphorus and thus allow facile cleavage of the carbon–phosphorus bond.[77]

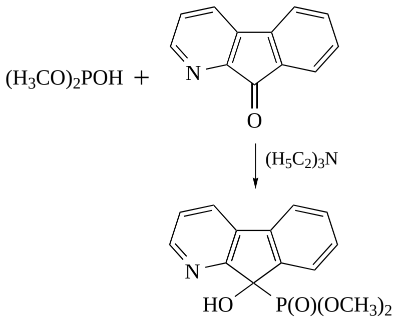
The preparation of species such as α-hydroxyphosphonates has been alluded to only briefly here (see Section 3.5). We would note two direct approaches that are available for the preparation of these materials, both involving nucleophilic addition to carbonyl carbon.[7] One of these is referred to as the Abramov reaction that involves the addition of a fully esterified trivalent phosphorus acid to a carbonyl carbon followed by a dealkylation of the phosphorus ester site. This preparation is quite inefficient when ordinary ester linkages are used, but the use of silyl esters overcomes most of these difficulties and allows facile isolation of the target compounds (equation 30). Note that reaction occurs preferentially at the carbonyl carbon and not by displacement of halogen at carbon. Addition occurs preferentially at carbonyl carbon compared to displacement at a carbon–halogen linkage, and provides product *if removal of the ester linkage is facile*.



(30)

89%

An alternative approach that avoids many of the difficulties of the Abramov reaction uses a trivalent phosphorus component with at least one acidic site on phosphorus. The Pudovik reaction uses a base for the removal of the acidic proton and facilitates attack by the electron-rich phosphorus anionic site on the carbonyl carbon. A variety of bases have been used for this purpose, as have phosphorus reagents with differing numbers of acidic sites on the phosphorus component. High yields of adducts are possible under very mild conditions using this approach (equation 31). The



(31)

90%

facile cleavage of α-hydroxyphosphonate esters and related compounds is not surprising in light of their preparation by this reaction as it is fundamentally an 'aldol' type process that is truly reversible under basic conditions.

The corresponding reactions using imines as substrates have advanced recently as the demand for analogues of amino acids has grown. As with the reactions involving the simple carbonyl compounds, addition of trivalent phosphorus reagents at imino carbon occurs in a facile manner under a wide range of conditions.[7] This procedure (for example, equation 32) has allowed the investigation of numerous biological processes using the carbon–phosphorus analogues of the natural materials.

$$PhCH_2CH{=}NH + (H_5C_2O)_2POH \xrightarrow[\text{work-up}]{H_3O^+} PhCH_2CH(NH_2)PO_3H_2 \quad (32)$$
71%

Phosphoryl compounds may also be generated by the addition of trivalent phosphorus reagents in a conjugate addition mode to a variety of α,β-unsaturated substrates. This constitutes another approach for the generation of new carbon–phosphorus bonds. Most often these reactions have been used for the preparation of esters of phosphonic acids, although other types of phosphoryl compound may easily be generated by this method. The reaction conditions used vary greatly, generally being divided into categories roughly analogous to those used for the Abramov and Pudovik reactions respectively (*vide supra*). Examples of both approaches are shown (equations 33 and 34). In general, higher product yields are obtained using the neutral (nonbasic) conditions with silyl ester reagents.

$$(H_5C_2O)_2POSi(CH_3)_3 + H_2C{=}CHCO_2C_4H_9 \longrightarrow (H_5C_2O)_2P(O)CH_2CH_2CO_2C_4H_9 \quad (33)$$
82%

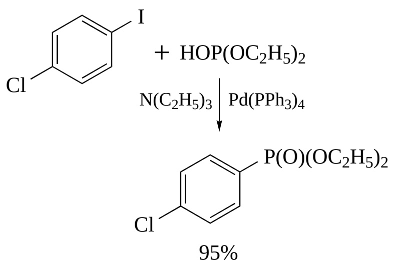
$$(H_5C_2O)_2POH + PhCH{=}CHCONH_2 \xrightarrow{NaOC_2H_5} (H_5C_2O)_2P(O)CH(Ph)CH_2CONH_2 \quad (34)$$
74%

In complete analogy with procedures noted for the preparation of phosphines (see Section 3.2), carbon–phosphorus bonds may be generated directly from P(V) halide species using organometallic reagents (equation 35).

$$HC{\equiv}CMgCl + H_3CP(O)(Cl)OCH_3 \longrightarrow HC{\equiv}CP(O)(CH_3)OCH_3 \quad (35)$$
50%

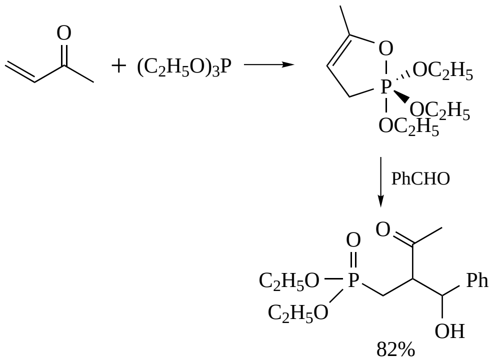
For the generation of phosphoryl compounds with an *aromatic* group attached directly to phosphorus, numerous reaction systems have been devised using catalytic agents (equation 36).[78–82] Overall, these reactions appear to be similar to the Michaelis–Arbuzov and Michaelis–Becker

reactions discussed previously. However, the mode of formation of the carbon–phosphorus bond is actually rather different, involving addition–elimination processes. In similar manner are formed phosphoryl compounds with a vinylic carbon–phosphorus bond (see Section 4.4).



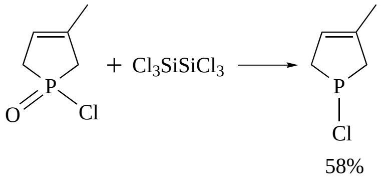
(36)

An intriguing approach to phosphonates (and potentially phosphinates and phosphine oxides) substituted at the 2-position relative to phosphorus has been reported.[83] This approach involves the conjugate addition reaction of a trivalent phosphorus reagent (*vide supra* - see equation 34) with an α,β-unsaturated carbonyl-type substrate. However, under the reaction conditions used, an intermediate pentacoordinated species (an oxyphosphorane; see Section 5.3) is isolated that can be treated with a variety of electrophilic reagents to produce the phosphonate with the electrophilic reagent substituted at the 2-position. An example is shown in equation (37).



(37)

As was noted in Section 3.2, phosphine oxides and phosphine sulfides can be reduced by a range of reagents to produce the trivalent phosphorus species related to them. In some instances, more than simple reduction occurs. For example, lithium aluminum hydride often effects the reduction of the full range of pentavalent and tetracoordinated phosphorus to the parent phosphines, removing all groups attached to phosphorus other than carbon, and replacing them with hydrogen. In certain instances (using THF as reaction medium and with careful control of the temperature), the degree of reduction can be limited. Heterogeneous reactions using sodium borohydride in ether solvents have been found to permit isolation of phosphorus products in higher oxidation states than the phosphine. Similarly, halosilane reducing agents can be used to allow isolation of such trivalent phosphorus compounds in oxidation states higher than the phosphine, starting with halogen derivatives of phosphonous and phosphinous acids.[20] An example of such a reduction is shown in equation (38).



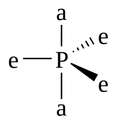
(38)

5.3 Phosphoranes and Related Compounds

The term phosphorane refers to compounds bearing a pentavalent pentadirectional phosphorus site. Our discussion here will give particular attention to organophosphoranes, compounds that have at least one of the five bonds from phosphorus to carbon, and will include classical phosphoranes in which all five bonds to phosphorus are directly from carbon atoms, as well as the oxyphosphoranes wherein one or more of the five bonds is to oxygen.

Before considering the chemical reactions involving such species, it is important to review the stereochemical aspects associated with a pentacoordinated phosphorus site. Coordination of five ligands about a single atomic center (phosphorus) could be imagined to assume either a trigonal-bipyramidal (tbp) or a square-planar (sp) configuration. If fact, the tbp structure is that which is commonly found in phosphoranes.[84]

A tbp configuration has intriguing consequences for stereochemical considerations.[85–88] Consider a phosphorane of the general structure PX_5, one with five identical ligands associated with the central phosphorus site. In the tbp array, two distinct types of positions exist for the ligands relative to the central phosphorus, as illustrated with (**15**). Herein, three of the ligands lie in a planar trigonal array about the central atom (equatorial positions) and two lie directly above and below that plane (apical positions). In general, the bond distances for the two types of ligands are not identical, but, even if equal in length, equatorial and apical ligands are in distinct positions owing to their different relationships with the remaining ligands.

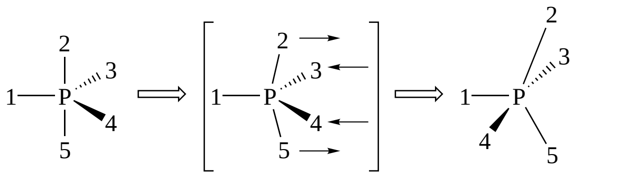


(**15**)

Given this array having two distinct types of positions about phosphorus, it might be anticipated that nominally identical ligands X would be distinguishable in apical and

equatorial positions under all conditions where dissociation is not occurring. In fact, it is a simple matter to prepare materials having five nominally identical ligands about phosphorus for which, without dissociation, the five are indistinguishable. That is, there is an exchange process for ligands about such a phosphorus center even in the absence of dissociation. This exchange of ligand sites occurs by a process referred to as *pseudorotation*,[89] as illustrated in Scheme 1. This process may be described as involving one of the equatorial ligands being retained 'static' (for the period of the particular pseudorotation cycle) in the equatorial position while the remaining four ligands undergo an 'umbrella-type' inversion process, exchanging equatorial and apical positions. In a subsequent pseudorotation cycle, some other equatorial ligand is retained in the equatorial position while the remaining four ligands exchange sites. Through the use of graphical methods,[85,89] it may be determined quickly that all ligands will occupy each type of position for equivalent periods of time when pseudorotation occurs rapidly (Figure 1).

The rapid exchange of sites by way of pseudorotation at ordinary temperatures renders indistinguishable those nominally identical ligands about phosphorus that would



Scheme 1

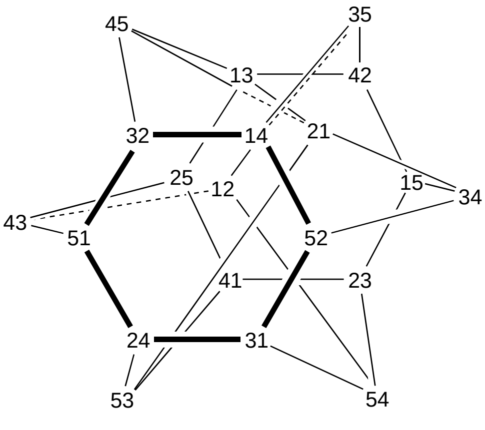


Figure 1 Each juncture of lines represents a configuration for which the pair of numbers indicates the ligands that are in the apical positions. Lines interconnecting number pairs represent cycles of pseudorotation; that ligand of the five not indicated by a number at either end of a given line is the 'static' equatorial ligand for that particular pseudorotation cycle. The interchange of numbers (as '15' '51') indicates a pair of enantiomers for the system Pabxyz

be distinguishable in the absence of site exchange. The process of pseudorotation also has significant consequences for phosphoranes bearing five nonidentical ligands. Consider the generalized structures Pabxyz wherein each of the ligands is unique. In the absence of pseudorotation (or dissociation and recombination), 10 diastereoisomeric racemic forms of such a formulation with a tbp array could possibly exist. A sequence of no more than five pseudorotation cycles, however, is all that is required for the interconversion of enantiomers and each pseudorotation cycle converts a given structure into one of its diastereoisomers.

In contrast with a tetrahedral center substituted as Cabxy for which the interchange of any two ligands generates the enantiomeric form, with a tbp structure of Pabxyz interchange of any two equatorial, or the two apical ligand sites generates the enantiomeric form and interchange of any apical with any equatorial site generates a diastereoisomeric form.

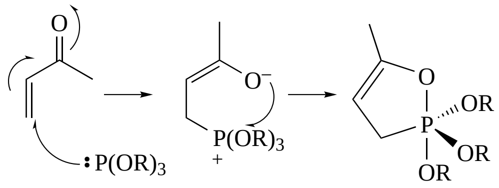
In some instances, particular pathways of pseudorotation are precluded by the presence several suitably substituted ring systems or other restrictive structural elements. In these instances, optically active phosphoranes should be capable of existence. This has, in fact, been accomplished with the preparation of the pentaarylphosphorane biphenylylene(4-methylbiphenylylene)biphenyl-2-ylphosphorane in the degradation of an optically active hexacoordinated phosphorus species (see Section 6).[90]

In most instances of organophosphorus compounds, the stereochemistry is significantly less complex than for the general Pabxyz situation. Particularly, the presence of ring structures joining two of the positions of the tbp structure eliminates the possibility of certain pseudorotation process occurring.

In addition to considering tbp structures centered about phosphorus for isolable molecules, transient, intermediates bearing pentavalent pentadirectional phosphorus occur in numerous organophosphorus reactions. The formation of a tbp array by the introduction of an additional ligand to a tetrahedral array about phosphorus is generally considered to occur by the addition of the incoming ligand to a tetrahedral face to generate a new apical ligand site. Further, loss of a ligand to regenerate a tetrahedral array occurs from an apical/tetrahedral face position. Within the tbp structure, the more electronegative ligands tend to occupy preferentially the apical positions. These factors, along with the process of pseudorotation (and the limitations placed on the pseudorotation process by the presence of rings), make certain reactions facile while it hinders others.

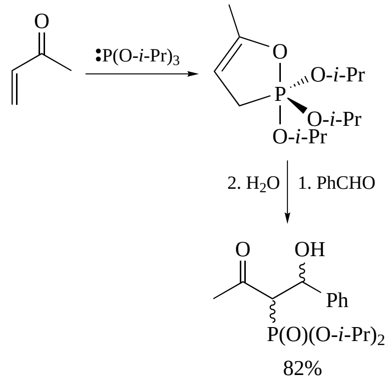
Organophosphoranes with only a single carbon–phosphorus linkage may be prepared in several ways. One important method, as illustrated in Scheme 2,[91] has been developed for the preparation of a wide range of other organophosphorus compounds.[92–96]

The formation of this oxyphosphorane occurs by initial attack of the electron-rich phosphorus at the β-position of the substrate forming a transient quasiphosphonium ion,



Scheme 2

followed by intramolecular addition of the electron-rich oxygen to a face of the quasiphosphonium ion tetrahedral structure placing the last-added oxygen in an apical position of the oxyphosphorane. Subsequently, the reaction of the oxyphosphorane with an electrophilic substrate involves the original α-carbon of the parent α, β-unsaturated species and cleavage of the phosphorus–oxygen linkage from an apical position. Only limited pseudorotation processes are possible with the oxyphosphorane intermediate species as shown in Scheme 2. An example of the use of this approach in a synthesis of a structurally more complex organophosphorus target molecule is exhibited in equation (39).[92]



(39)

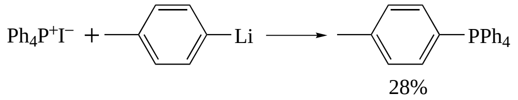
A category of phosphorane bearing a single carbon–phosphorus bond is produced from the phosphonous dihalides (see Section 3.5). Phosphonous dihalides, as do other trivalent phosphorus compounds, add halogen molecules to generate phosphoranes of the general type RPX_4, as shown in equation (40). Similar halogen adducts are formed with organophosphorus parents such as R_2PX and R_3P.

$$CF_3PF_2 + Cl_2 \longrightarrow \underset{79\%}{CF_3PF_2Cl_2} \qquad (40)$$

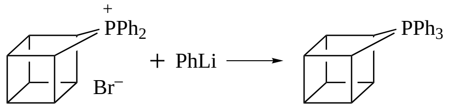
Phosphoranes bearing four carbon–phosphorus bonds and one to an oxygen atom can be generated by the addition of alcohols to ylides (see Section 4.3). In this reaction, the hydroxyl of the alcohol formally adds across the ylidic carbon–phosphorus linkage, as shown in equation (41).

$$PH_3P{=}CH_2 + H_3COH \longrightarrow \underset{60\%}{Ph_3P(CH_3)OCH_3} \qquad (41)$$

The general approach for the preparation of ylides bearing five carbon–phosphorus bonds was developed by Wittig.[97] Phosphonium salts bearing no hydrogens on carbon directly attached to phosphorus undergo addition reactions with organolithium reagents to generate the corresponding phosphorane. (If hydrogen is attached to even one of the carbons bound to phosphorus, ylide formation occurs rather than does addition.) Such addition reactions are thereby fundamentally limited to tetraarylphosphonium salts, as illustrated in equation (42). A notable exception occurs with the highly strained phosphonium salt, homocubyldiphenylphosphonium bromide, wherein two hydrogens are attached to carbon bound to phosphorus (equation 43). The facile formation of the phosphorane (as opposed to deprotonation) in this instance is attributed to the increased strain that would be involved with the formation of the ylide. Addition of the phenyl group (with phenyllithium, or a methyl group using methyllithium adding to homocubyldimethylphosphonium bromide) to phosphorus allows a C–P–C linkage to exist with an angle close to 90° (spanning an apical and an equatorial position of phosphorus) without adding strain to the system. The ^{1}H NMR spectra of these phosphoranes indicate that they undergo rapid pseudorotation at room temperature. In this process, the equatorial position bound within the ring system can never be the static position.

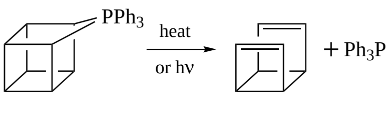


(42)

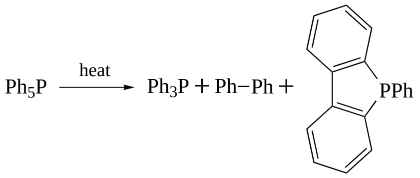


(43)

Phosphoranes bearing five phosphorus–carbon bonds are unreactive in many of the processes seen for oxyphosphoranes (such as completion of the Michaelis–Arbuzov reaction or the addition reactions as shown in equation 39). However, they are capable of undergoing thermal or photochemical cleavage of a carbon–phosphorus bond under particular circumstances. For example, the homocubyltriphenylphosphorane (equation 43) undergoes a cheleotropic fragmentation to generate triphenylphosphine and the tricyclic octadiene fragment as shown in equation (44). Other fragmentation reactions of phosphoranes under thermal or photochemical conditions have been observed that lead to triarylphosphines and hydrocarbons as fragments (equation 45).



(44)



(45)

Pentaarylphosphoranes also undergo cleavage of carbon−phosphorus bonds in aqueous acid or base, as well as halogenolysis. In the latter instance, a quaternary phosphonium salt is generated along with the haloaromatic product (equation 46).[98]

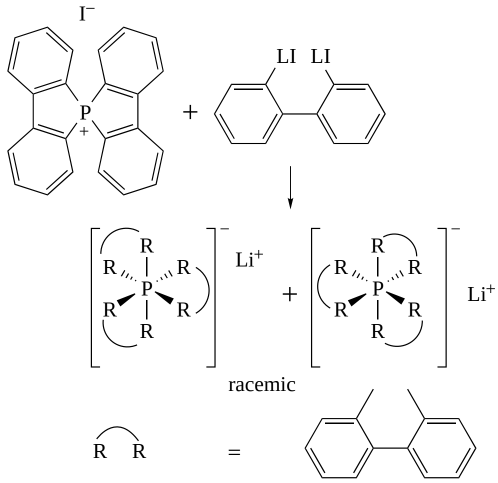
$$Ph_5P + Br_2 \longrightarrow Ph_4P^+Br^- + PhBr \qquad (46)$$

6 HEXAVALENT ORGANOPHOSPHORUS COMPOUNDS

Compounds in which six ligands are attached to a single phosphorus center generally bear a formal negative charge at that phosphorus. Several approaches to such compounds are available, depending on the degree of carbon substitution about the phosphorus center. For example, halophosphoranes add an anion to generate the hexacoordinated phosphorus site as illustrated in equation (47).

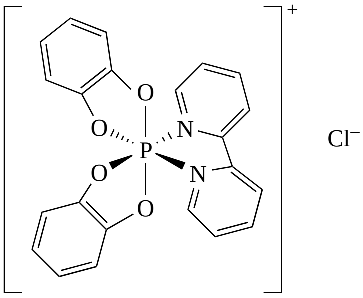
$$Ph_2PF_3 + CsF \longrightarrow Ph_2\bar{P}F_4\ Cs^+ \qquad (47)$$

Fully carbon-substituted hexacoordinated phosphorus can be produced by reaction of a quaternary phosphonium salt with suitable organolithium reagents.[99] Since such a site has an octahedral array of ligands, chiral hexacoordinated phosphorus should be possible with appropriate ligands. Optically active hexacoordinated phosphorus compounds of this type bearing bidentate organic ligands have been isolated. The racemic materials bearing the 2,2′-biphenylylene ligands have been constructed (equation 48) and resolved by classical means using brucine derivatives.



(48)

Hexacoordinated phosphorus species bearing a formal *positive* charge have been generated, albeit without a carbon−phosphorus bond. Rather, compounds of the type for which an example is shown as (**16**) have been prepared with four oxygen and two nitrogen ligands with an overall positive charge.[100]



(**16**)

7 ORGANOPHOSPHORUS NOMENCLATURE

There has been established a systematic nomenclature for organophosphorus compounds. In Table 1 is provided a summary of the standard English and German nomenclature for the variety of compounds noted in this article.

1 INTRODUCTION

The 10 years since the last edition of the Encyclopedia of Inorganic Chemistry have seen dramatic growth in inorganic and organometallic photochemistry. The routine use of photochemistry to effect molecular transformations continues unabated, and the application of new spectroscopic techniques has allowed the analysis of photochemical processes in exquisite detail. The very definition of what it means to carry out high speed studies has evolved from nanoseconds to femtoseconds in this period. For example, the photochemical C–H activation processes have been probed at increasingly high speeds permitting events from the moment of excitation, through carbonyl-loss, to oxidative addition to be examined. The use of nontraditional solvents ranging from noble gases to supercritical fluids has emerged and species with noble gases or alkanes within the solvation sphere are no longer regarded as unusual. Old and familiar compounds such as the family of metal bipyridinyl, or more generally diimine, derivatives have made the leap to bioinorganic chemistry as probes for electron transmission in proteins and DNA while others such as the venerable Roussin's salts and esters are attractive reagents for the delivery of nitrogen oxide in photopharmaceutical applications. Well understood reactions such as the photochemical cleavage of the Mo–Mo bond in $[Cp(CO)_3Mo]_2$ derivatives have allowed the phenomenon of radical cage recombination to be examined in great detail.

The challenge for this reviewer has thus not been one of finding enough to write about but dealing with hyperabundance and the necessity to compress and exclude. Early on in the process it was recognized that exciting topics such as solid-state photochemistry and nanomaterials with unique optical properties had to be left for another review. Some topics such as the photochemistry of $[Cp(CO)_2Fe]_2$ and the use of chromium carbene complexes in organic synthesis that have been recently reviewed are discussed only in broad outline with the reader urged to refer to the secondary literature. The literature has been reviewed through 2003. This reviewer regrets the omission of much good work and hopes that what remains is of some lasting use to the community.

2 REVIEWS AND BOOKS ON INORGANIC PHOTOCHEMISTRY

Photochemistry and Photophysics of Metal Complexes by Roundhill provides a comprehensive review of the literature of inorganic and organometallic photochemistry through 1993.[1] Of particular note are the chapters on the photochemistry, photophysics, and photoredox behavior of $Ru(bipy)_3{}^{2+}$ and the photochemistry of classical transition metal complexes. Additional reviews on the photochemistry of Fe(III)[2] and Cr(III)[3] species have appeared. Professor Arthur Adamson has provided a retrospective on inorganic photochemistry and his seminal contributions to this field.[4] Reviews of the photochemistry of chromium, manganese, and iron porphyrins,[5] the excited state properties of metal phosphine complexes,[6] and chemistry induced by MLCT excitations[7] have appeared. The photochemistry of several coordination compounds, notably $Fe(CN)_5L^{3-}$, with relevance to energy conversion,[8] and the thermal and light induced electron transfers from main group hydrides and organometallic complexes[9] have been reviewed.

As will be seen below, much of the progress in understanding the intimate details of photochemical processes have come about because of ultrahigh speed methods that have pushed photochemistry into the femtosecond time scale.[10] The award of the Nobel Prize to Professor Ahmed H. Zewail for his contributions to these studies is tribute to the importance of this field.[11] With the introduction of femtosecond spectroscopic techniques it is now possible to directly observe the excited

state species itself. In ultrafast time-resolved IR spectroscopy, this means that vibrationally hot species may be followed as they undergo dissociation, triplet formation, or relaxation to ground state.[12]

Several reviews have appeared describing the application of spectroscopic techniques to the study of photochemical reaction intermediates. Omberg *et al.*[13] and Ford[14] have described the use of time-resolved IR while several authors have described frozen matrix techniques and applications.[15] Tyler has reviewed the basic principles of organometallic photochemistry for chemical educators.[16]

High level ab initio and dft quantum mechanical calculations of both ground and excited states have emerged as strong supplements to photochemical studies, particularly those conducted at the femtosecond time scale. Some of these applications have been reviewed.[17]

Other reviews will be noted within the text as relevant.

3 SYNTHETIC AND MECHANISTIC PHOTOCHEMISTRY

3.1 Mononuclear Transition Metal Carbonyl Compounds

The photochemistry of simple metal carbonyl, cyclopentadienyl metal carbonyl, and arene metal carbonyl compounds continues to be examined for synthetic applications as well as insight into the fundamental photophysics of excited state processes. At the outset it is probably useful to recall that the energy necessary to break a typical metal carbonyl bond is ca. 190–210 kJ mol^{-1},[18] while the energy of a 325-nm laser is 370 kJ mol^{-1}. At least in principle, 570 nm light should be capable of initiating decarbonylation reactions. In practice, the extra energy in an excitation event in condensed phases is dissipated through intramolecular vibrations or through local solvent heating. In the gas phase, these processes are not available thus multiple carbonyl-loss is observed.[19]

Iron, nickel, and cobalt carbonyls were reported by Mond[20] in the early 1900s with the group VI carbonyls being reported by Job and Cassal in mid-1920s.[21] The photolysis of $Fe(CO)_5$ to yield $Fe_2(CO)_9$ was reported by Dewar almost coincident with the initial syntheses of the pentacarbonyl itself.[22] Photochemical exchange of carbonyl groups for a variety of ligands is well known having been first reported by Strohmeier in 1960.[23]

Gas matrices provided a medium for the first direct observation of the photochemical carbonyl-loss intermediates of the metal carbonyls. Beginning with the 1969 report by Rest and Turner of the formation of $Ni(CO)_3$ in Ar, Kr, and Xe matrices,[24] observation of the carbonyl-loss species of $Fe(CO)_5$,[25] $Ta(CO)_6$,[26] and the group VI metal carbonyls[27] followed shortly thereafter. Cyclopentadienyl and arene metal carbonyl compounds have also been examined in a variety of noble gas and alkane matrices. Thus the carbonyl-loss species of $CpV(CO)_4$,[28] $CpNb(CO)_4$,[29] $CpTa(CO)_4$,[29] $(C_6H_6)Cr(CO)_3$,[30] $CpMn(CO)_3$,[30,31] $CpRe(CO)_3$,[30b,32] $Ru(CO)_2(dppe)$,[33] $CpCo(CO)_2$,[34] $CpRh(CO)_2$,[34] and $CpIr(CO)_2$[34] have all been observed. For example, a difference IR spectrum for $CpNb(CO)_4$ in Nujol after photolysis is presented in Figure 1. Poliakoff and Turner reviewed the photochemistry, reaction chemistry, and spectroscopy of $Fe(CO)_4$ in both 1987[35] and 2001[36] and the photochemistry of $Fe(CO)_5$ itself has been reviewed through 1999.[37]

Gas-phase photochemistry of $Fe(CO)_5$ has been carried out at three wavelengths, 351, 248, and 193 nm. At 351 nm $Fe(CO)_4$ and $Fe(CO)_3$ are produced while at 248 nm $Fe(CO)_2$ is also observed. The gas-phase structures of these materials were determined by comparison of their IR spectra with those in condensed phases. At 193 nm, a new species believed

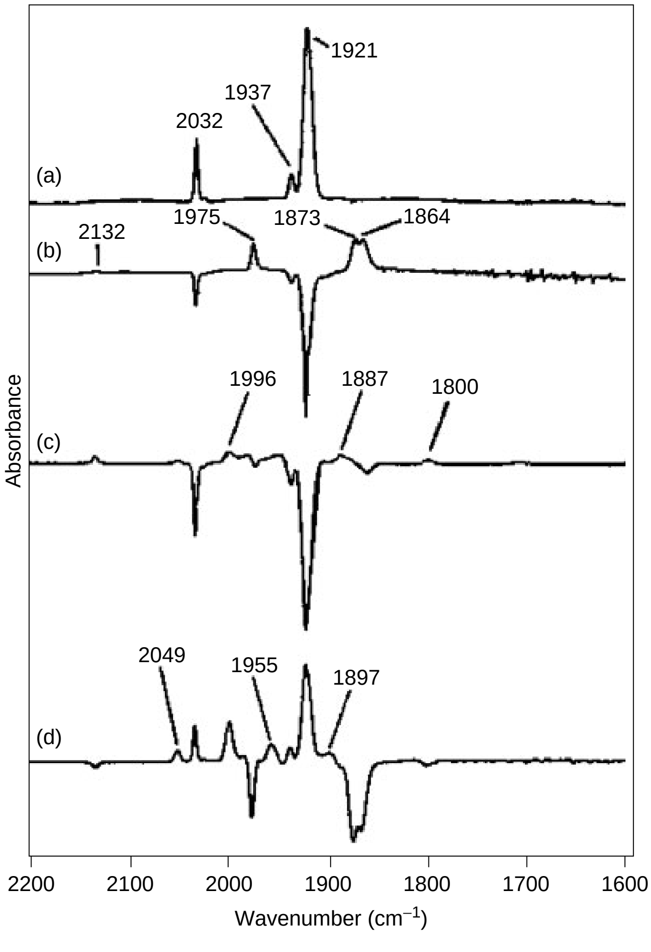

Figure 1 IR spectra with (η^5-C_9H_7)$Ta(CO)_4$ isolated in a Nujol matrix: (a) starting material, (b) subtraction spectrum, 60 min irradiation at $340 < \lambda < 620$ nm (100 min total at $\lambda > 340$ nm) minus starting material, (c) subtraction spectrum, 20 min irradiation at $\lambda < 285$ nm minus 100 min irradiation at $\lambda > 340$, (d) subtraction spectrum, anneal to 173 K minus 125 min total photolysis at $\lambda > 225$ nm. (Reprinted from Ref. 29. © 1998, with permission from Elsevier)

to be an excited state of $Fe(CO)_3$ was observed.[38] The photochemistry of $CpMn(CO)_3$ has been studied by time-resolved IR in the gas phase. Photolysis at 355 nm results in formation of $CpMn(CO)_2$ and CpMn(CO), while the latter predominates upon 266 nm photolysis. In contrast to the iron studies described above, the positions of the observed vibrational bands were not consistent with those observed in condensed phases.[39] Ultrafast gas-phase studies of $CpMn(CO)_3$ have established that loss of the first CO occurs in 66 fs.[40] Theoretical studies of the excited states of $CpMn(CO)_3$ predict two excited states, a weakly bonding state and a dissociative state that is responsible for the observed rapid loss of CO.[41] $(C_6H_6)Cr(CO)_2$ and $(C_6H_6)Cr(CO)$ been generated photochemically in the gas phase.[42] Gas-phase and solution studies of the photolysis of $CpCo(CO)_2$ have identified CpCo(CO) as the intermediate in reactions with ligands.[43]

Gas-phase photochemistry of $W(CO)_6$ at 355 nm yields $W(CO)_5$. The reactions of this species with NH_3, C_2H_6, CF_4, SF_6, and Xe were examined. NH_3 and C_2H_6 form stable species under these conditions while Xe formed an unstable species. Neither CF_4 nor SF_6 formed complexes.[44]

Femtosecond photochemistry (267 nm) of gas-phase $M(CO)_6$, M = Cr, Mo, W,[45] $Fe(CO)_5$,[46] and $Ni(CO)_4$,[47] has established multiple processes in the first 1000 fs after excitation. For example, $Fe(CO)_5$ undergoes five consecutive processes. The first four of which occur within 3300 fs and represent a continuous pathway from the Frank-Condon region down to the lowest singlet state of $Fe(CO)_4$. The fifth stage corresponds to loss of a second carbonyl group. A review of this work appeared in 2001.[48] In the case of $Fe(CO)_5$, CASSCF/MR-CCI calculations have been carried out on the excited states.[49]

Important theoretical insights are forcing revisions of long held views on the fundamental nature of photoprocesses in metal complexes. The dominant paradigm has been built upon an assumption that photodissociation of ligands arises from LF transitions.[50] For the case of the group VI metals this assignment was built upon the work of Gray and Beach[51] who assigned low-energy shoulders in the electronic spectra of these compounds to LF transitions. It should be noted that these authors expressed some hesitation with these assignments in that it required the ligand field splittings of all of the group VI metals to be the same. A typical qualitative MO level diagram of $Cr(CO)_6$ is presented in Figure 2.

Recent theoretical studies by several groups have determined that the LF transitions are at much higher energy than previously appreciated, and have determined that the observed low-energy shoulders are due to symmetry-forbidden MLCT excitations.[52] The observed dissociations arise from strongly avoided crossings of the CT and LF states as the M–CO bond elongates. The potential energy diagram for $Cr(CO)_6$ illustrating the effect of distance along the $(CO)_5Cr$–CO bond coordinate for singlet excited states is presented in Figure 3. State a^1T_{1u} in this diagram corresponds

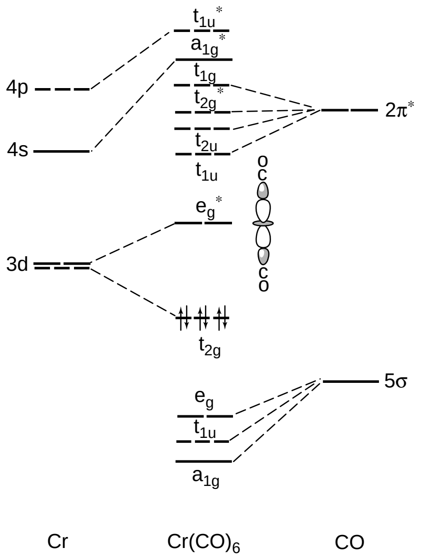

Figure 2 Typical qualitative MO diagram for a d^6 metal carbonyl complex. (Reprinted with permission from Ref. 52b. © 1997 American Chemical Society)

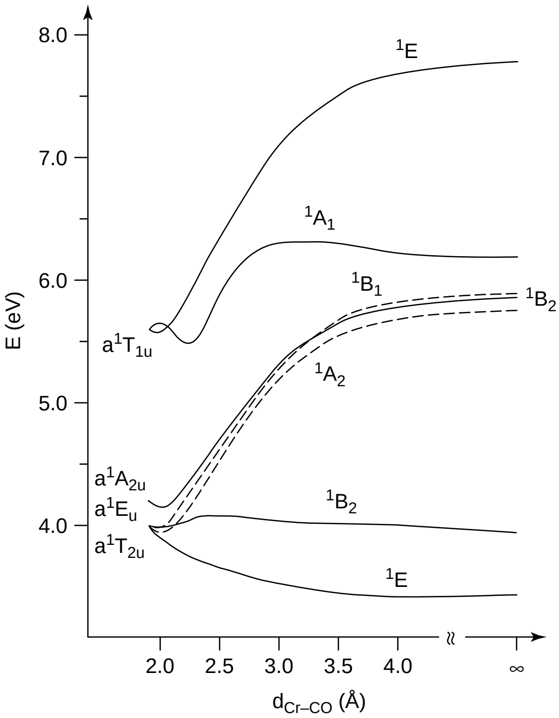

Figure 3 Potential energy curve along the Cr–CO dissociation coordinate for singlet states (in C_{4v} symmetry) arising from the lowest excited configuration. (Reprinted with permission from Ref. 52b. © 1997 American Chemical Society)

to the LF transition, while a^1T_{2u}, a^1E_u, and a^1A_{2u} are CT transitions. States a^1T_{2u} and a^1E_u give rise to $^1B_2$ and

^1E in the C_{4v} point group. Combined with studies on the photoprocesses of $Mn(CO)_5Cl$, and $Mn_2(CO)_{10}$,[53] as well as diimine compounds to be discussed below, these new interpretations have far reaching impact. It should be noted that in this article we shall retain the spectral assignment notation of the original authors although it is assumed that these may be subject to reexamination.

Photolyses in frozen N_2 matrices result in the substitution of N_2 for CO yielding $M(CO)_{n-x}(N_2)_x$,[54] $CpM(CO)_{n-x}(N_2)_x$,[19,21,23,55] or $(C_6H_6)Cr(CO)_{n-x}(N_2)_x$[21] photoproducts. N_2 species can also be observed by photolysis of metal carbonyls impregnated in polyethylene films followed by exposure of the films to N_2.[56] Similar routes to H_2 species will be described below. $Fe(CO)_4(N_2)$, $CpMn(CO)_2(N_2)$ and $(C_6H_6)Cr(CO)_2(N_2)$ have been observed by time-resolved IR spectroscopy in the gas phase.[57]

Observations by Perutz and Turner that the electronic absorptions and IR stretching frequencies of $Cr(CO)_5$ in frozen gas matrices were sensitive to the nature of the matrix prompted the suggestion that the organometallic species are best regarded as '$Cr(CO)_5S$' in which the matrix molecules serve as weak ligands.[58] Subsequent studies on a range of organometallic photointermediates confirmed this hypothesis. Noble gas complexes have been observed in liquid noble gases,[59] as well as in the gas phase[60] and supercritical phases.[61] Time-resolved IR spectra of $W(CO)_6$ in Ar, Kr, and Xe are presented in Figure 4. Curiously, although CpRh(CO) forms solvated species with both Kr and Xe, CpCo(CO) and Cp*Co(CO) do not appear to interact with either solvent.[62] As will be discussed below, these differences have been associated with the spin state of the photointermediates. Quantum mechanical ab initio calculations at the MP2 and CCSD(T) level of theory have been carried out for the group VI metal derivatives, $M(CO)_5$ Ng, where Ng = Ar, Kr, Xe.[63] Transition metal-noble gas compounds have been reviewed to 2001[64] and more generally, organometallic photochemistry in liquefied and supercritical noble gases has been reviewed through 1995.[65]

Supercritical carbon dioxide is increasingly important as a solvent for Green chemical applications, including organometallic photochemistry, yet few studies have been conducted to directly observe CO_2 bound species. Time-resolved IR studies of the photolysis of the group VI carbonyls in supercritical noble gases or CO_2 resulted in direct observation of a series of complexes including $W(CO)_5Ar$, $M(CO)_5Kr$, $M(CO)_5Xe$, and $M(CO)_5(CO_2)$, where M = Cr, Mo, and W.[66] $W(CO)_5(CO_2)$ has also been observed by time-resolved IR of the flash photolysis of $W(CO)_6$ and CO_2 in the gas phase.[67] It was observed that Xe and CO_2 have similar strengths of interaction (ca. $33\,kJ\,mol^{-1}$) with the electron-deficient metal species.

The relative rates of exchange of noble gas solvated species, $M(CO)_5S$ and $CpRe(CO)_2S$, with CO was shown to be Xe < Kr < Ar, and Re ≪ W < Mo ≈ Cr.[61b] Comparison of the rates of reaction of CpM(CO)2S, where M = Mn or Re

and S = Kr, Xe, *n*-heptane, with CO under pseudo first-order conditions established the relative order Xe ≈ *n*-heptane < Kr, and Re ≪ Mn.[68]

The reactivity of a number of alkane complexes has been examined and this field has been reviewed through 1996 by Hall and Perutz.[69] Flash photolysis of $Cr(CO)_6$ in cyclohexane showed that solvation occurs within the first picosecond after photolysis, a fact that appears to rule out spin crossing as an important component in the dissociation of CO from $Cr(CO)_6$.[70] The stability of $CpRe(CO)_2$(alkane) is particularly striking. Comparison of the rate constants for heptane solvated metal complexes with CO, Table 1, reveals that the rate constant for $CpRe(CO)_2$(heptane) is five orders of magnitude slower than that of $CpV(CO)_3$(heptane). In fact, the stability of the $CpRe(CO)_2$(alkane) complexes is so high that it has been possible to carry out low-temperature NMR on the cyclopentane complex generated by continuous photolysis of

the sample in the NMR probe.[71] The 500 MHz 1D 1H NMR spectra of $CpRe(CO)_3$ in cyclopentane and its isotopomers is presented in Figure 5.

Rates of reaction of CO with (arene)$Mo(CO)_2$(alkane) and $M(CO)_5$(alkane), where M = Cr, Mo, W, have demonstrated that the reaction with $Cr(CO)_5$(alkane) involves an interchange mechanism while for Mo and W the mechanism is more associative.[72] These results are consistent with the known ability of the higher homologs to expand beyond a coordination number of 6. Flash photolysis and ultra high speed detection (0.4 ps, 4 cm^{-1} resolution) have allowed direct observation (Figure 6) of the vibrational cooling of CpCo(CO)(*n*-hexane), CpCo(CO)(*n*-hexene),[73] and the group VI carbonyls.[74]

Photoacoustic calorimetry has been used to establish the enthalpies of M–CO bond dissociation from the group VI carbonyls in a series of hydrocarbons. From these studies, the bond strength of Cr, Mo, and W to heptane were calculated to be 42, 38, and 54 kJ mol^{-1}, respectively.[75] The enthalpies and volumes of reaction for the substitution of CO in $Mo(CO)_6$ by alkane and the subsequent displacement of the alkane by THF have been determined by photoacoustic calorimetry. Enthalpies of substitution for CO by alkane and alkane by THF were found to be 520 and −250 kJ mol^{-1}, respectively. The volumes of reaction were determined to be 18 and −1 mL mol^{-1}. Utilizing known Mo–CO bond energies, Mo–alkane and Mo–THF bond energies were calculated to be 190 and 440 kJ mol^{-1}, respectively.[76] Similar studies involving reaction of piperidine with $Mo(CO)_6$ in heptane yielded Mo–heptane and Mo–piperidine bond dissociation energies of 300 and 590 kJ mol^{-1}, respectively.[77] In contrast to earlier studies, the quantum yield for substitution of CO by alkane was found to be independent of the length of the alkane chain suggesting that the product determining step does not involve coordination of solvent. Recently, laser-induced optoacoustic spectroscopy was used to determine the enthalpies and volumes of reaction of tetrahydrothiophene, THT, with $Mo(CO)_6$ in alkanes. The resulting bond energies for Mo–alkane and Mo–THT were found to be 55 and 155 kJ mol^{-1}, respectively.[78]

Photochemical reactions continue to be utilized for the introduction of ligands to metal carbonyl compounds. The following examples are drawn from a very large number of reactions in the literature. In contrast to the

thermal exchange of carbonyl for phosphines observed for $CpTa(CO)_4$,[79] $Cp^*Ta(CO)_4$ ligand exchange requires photochemical conditions.[80] Photolysis of $CpNb(CO)_4$ in supercritical ethene yields $CpNb(CO)_3(C_2H_4)$ and the thermal reverse of this reaction follows clean second order kinetics.[81] The photolysis of $Cp'Tc(CO)_3$, where $Cp' = Cp$ or Cp*, and $Tp^*Tc(CO)_3$ with PPh_3 yields the expected monophosphine products.[82] Photolysis of $(C_6H_6)Cr(CO)_3$ and $(C_5H_{5-n}Me)Mn(CO)_3$, where $n = 0$, 1, with nitrogen ligands such as pyridine and pyrazine yielded seemingly conventional mono and binuclear derivatives, respectively. However, upon examination these derivatives proved to be paramagnetic and photolabile. The magnetic moments of the complexes were found to decrease with decreasing temperature suggesting that the paramagnetism arises from low lying ligand field states that may be populated thermally or photochemically at room temperature.[83]

In condensed phases, it is generally observed that one carbonyl group is lost following single photon excitation since excess energy in the molecule is quickly dissipated to solvent. For $Fe(CO)_5$, however, disubstitution has been observed with PPh_3,[84] $AsPh_3$, and $P(OMe)_3$.[85] Of particular importance was the observation based on flash photolysis studies that both $Fe(CO)_4(PPh_3)$ and $Fe(CO)_3(PPh_3)_2$ were primary photolysis products.[86] Subsequent studies have established that $Fe(CO)_4$ exists as a triplet and that reaction of $^3Fe(CO)_4$ with ligands can proceed by two routes, one involving immediate spin crossover to $Fe(CO)_4L$, while the second involves spin conservation and displacement of a CO to give $^3Fe(CO)_3L$, which subsequently reacts with a second ligand to yield $Fe(CO)_3L_2$.[87] Similar reactions of 17 electron intermediates are commonly used to explain the rapid ligand exchange of organometallic radicals.[88]

The triplet nature of $Fe(CO)_4$ has consequences on the rate of reactions of simple ligands such as CO,[89] N_2,[90] and H_2. In these cases, the rates of reaction of $^3Fe(CO)_4$ in the gas phase are substantially lower (three orders of magnitude in the case of H_2) than its homologs, $Ru(CO)_4$[91] and $Os(CO)_4$,[92] supporting the proposal that ligand addition requires a crossing from a triplet to a singlet potential energy surface during the course of the reaction.[93]

Oxidative addition of H_2, alkanes, and silanes to electron-deficient metal species has attracted considerable attention. A continuum exists between nonclassical, or σ, complexes such as η^2-H_2 or the solvated alkane complexes described above and the classical, or fully oxidatively added, species such as dihydrides. Photochemistry represents a major, and in many cases only, source of the reactive intermediates central to this chemistry. As such, detailed studies have been conducted of the reactions of photointermediates with these reagents in a variety of media and phases. The chemistry of dihydrogen and σ bonded complexes has been extensively reviewed by Heinekey and Oldham,[94] Sweany,[95] and Kubas.[96]

In the early 1980s, Sweany carried out studies of $Fe(CO)_5$ and $HCo(CO)_4$ in H_2 doped Ar matrices and established the ability of H_2 to oxidatively add to photochemically generated electron-deficient metal species to form $H_2Fe(CO)_4$ and $H_3Co(CO)_4$ under these conditions. At about the same time careful examination of the products formed when group VI carbonyls were photolyzed in H_2 doped Ar matrices suggested that the species were not the oxidative addition product, $H_2Cr(CO)_5$, but rather a complex of molecular hydrogen, $Cr(CO)_5(H_2)$.[97] The significant feature in the analysis was the decrease in carbonyl stretching frequency of the reaction product, opposite to the effect observed for oxidative addition. After the publication by Kubas[98] of the synthesis, neutron diffraction, and X-ray structure of $W(CO)_3(PCy_3)(H_2)$ clearly containing an intact H_2 ligand, Sweany published a detailed report of his matrix studies for $Cr(CO)_6$.[99]

The spectrum of $Cr(CO)_6$ in H_2 doped Ar as reported by Sweany is presented in Figure 7 for both its historical significance and to illustrate a frequently observed feature of frozen matrix photochemistry. Photolysis of $Cr(CO)_6$ results in CO-loss and formation of $Cr(CO)_5$ and perhaps some $Cr(CO)_4$. As we have already noted, these are best described as solvated species, $Cr(CO)_5Ar$, and $Cr(CO)_4Ar_2$. In the H_2 doped matrix, these species react to form small amounts of $Cr(CO)_5(H_2)$, $Cr(CO)_4(H_2)_2$, and $Cr(CO)_4(H_2)$. Long wavelength photolysis is frequently observed to result in reversal of high energy photolyses owing to photodissociation of the weakly bound solvent species.[100] In these H_2 doped matrices, the H_2 is more mobile than CO, thus the coordinatively unsaturated species formed on long wavelength photolysis are captured by H_2 as illustrated by the dramatic growth of the band for $Cr(CO)_5(H_2)$.

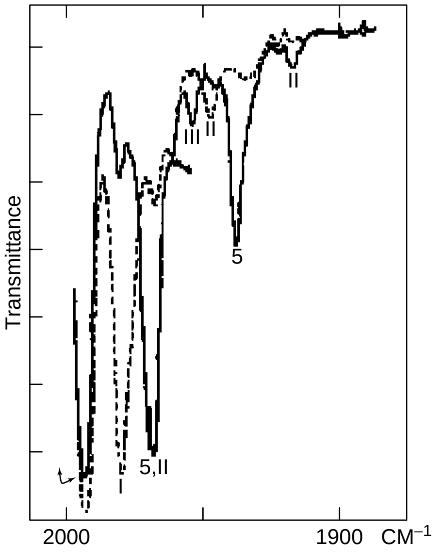

Figure 7 Ar matrix of $Cr(CO)_6$ doped with H_2. Solid lines represent spectrum after broad band irradiation followed by irradiation through cobalt glass. Dashed lines represent the spectrum of the same matrix after 90 min irradiation with the visible light from a Nernst glower. Band assignments: I, $Cr(CO)_5(H_2)$; II, $Cr(CO)_4(H_2)_2$; III, $Cr(CO)_4(H_2)$; 6, $Cr(CO)_6$; 5, $Cr(CO)_5$. (Reprinted with permission from Ref. 99. © 1985 American Chemical Society)

Liquid and supercritical noble gases are ideal media for studying H_2 species since H_2 is completely miscible under these conditions. The group VI metal carbonyl hydrides, $M(CO)_5(H_2)$, and cis-$Cr(CO)_4(H_2)_2$ were formed photochemically in liquid Xe/H_2 mixtures.[101] H_2 and N_2 complexes of a number of half-sandwich compounds were formed in supercritical Xe. These included $(C_nR_n)M(CO)_2Y$, where R = H, Me, M = Mn, Re (n = 5), Cr (n = 6), and $(C_4H_4)Fe(CO)_2Y$, where Y = H_2 or N_2. In all cases except Re, nonclassical H_2 complexes were formed.[102]

Room temperature, time-resolved IR studies of $LM(CO)_4$, where L = Cp or Ind, M = Nb or Ta, in heptane saturated with H_2 have been carried out. $CpNb(CO)_4$ gives rise to both classical, $CpNb(CO)_3(H)_2$, and nonclassical, $CpNb(CO)_3(\eta^2\text{-}H_2)$ species. In contrast, $CpTa(CO)_4$ yields the classical product, $CpTa(CO)_3(H)_2$ while $IndTa(CO)_4$ gives rise to the nonclassical, $IndTa(CO)_3(\eta^2\text{-}H_2)$ product indicating a delicate electronic and possibly steric balance between the two forms.[103]

Photoacoustic calorimetry and time-resolved IR have been used to study the photochemical reaction of $CpV(CO)_4$ with H_2 and N_2. By combining the data from these techniques, bond dissociation energies of V-H_2 and V-N_2 could be calculated to be $91 \pm 20\,\text{kJ mol}^{-1}$, and $120 \pm 9\,\text{kJ mol}^{-1}$, respectively.[104] Similar studies on $(C_6H_6)Cr(CO)_3$ permitted the Cr–H_2 and Cr–N_2 bond dissociation energies to be determined as $60 \pm 4\,\text{kJ mol}^{-1}$ and $66 \pm 4\,\text{kJ mol}^{-1}$, respectively.[105] The gas-phase photochemistry of $CpMn(CO)_3$ and $(C_6H_6)Cr(CO)_3$ with H_2 and N_2 have been examined. The products $CpMn(CO)_2Y$ and $(C_6H_6)Cr(CO)_2Y$, where Y = H_2, N_2, were observed directly, but the addition products of CpMn(CO) and $(C_6H_6)Cr(CO)$ were thought to be obscured by overlap with other absorptions.[106]

A photochemical flow reactor (Figure 8) utilizing supercritical fluids or hydrogen saturated solvents has been developed for the preparation of gram scale quantities of labile dihydrogen and alkene complexes. Thus, $Cr(CO)_5$(alkene),[107,108] $CpMn(CO)_2$(propene),[42] and $CpMn(CO)_2(H_2)$[109] have been prepared in good yield. A series of phosphine substituted manganese compounds, $(C_5H_4CH_3)Mn(CO)_2L$, where L = $PMe_{3-n}Ph_n$, have been photolyzed with N_2 in supercritical Xe and CO_2. Little difference was found in the effectiveness of the two solvents.[110] The use of supercritical fluids as Green solvents in thermal and photochemical applications has been reviewed.[111]

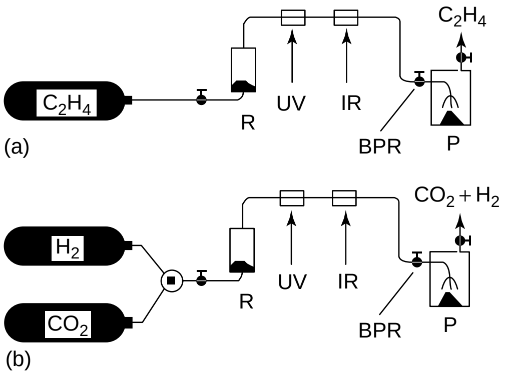

Figure 8 Schematic diagram of flow reactor for photochemical synthesis in supercritical fluids. (Reproduced by permission of Ref. 108)

Photochemical reductive elimination of H_2 from dihydrides serves as a route to generating reactive intermediates. Photolysis of $Ru(PPh_3)_3(CO)H_2$ in benzene yields $Ru(PPh_3)_3CO$. Ultrafast measurements found that hydride loss and $Ru(PPh_3)_3CO$ formation is complete in 6 ps.[112] Photolysis of both $Ru(CO)_2(PPh_2)_2H_2$ and $Ru(CO)_3(PPh_3)_2$ in gas matrices resulted in the formation of the same $Ru(CO)_2(PPh_3)_2$ intermediate.[113]

New high-yield routes to *trans*-Cp*$Re(CO)_2H_2$ have permitted a detailed examination of the photochemistry of this species (Scheme 1). Noble gas matrix and solution photolyses in cyclohexane and Xe establish the primary photoprocess of *trans*-Cp*$Re(CO)_2H_2$ to be unimolecular, nondissociative isomerization to the cis isomer. In solution, slow cis to trans isomerization is observed. Reductive elimination of H_2 is only observed from the cis isomer.[114]

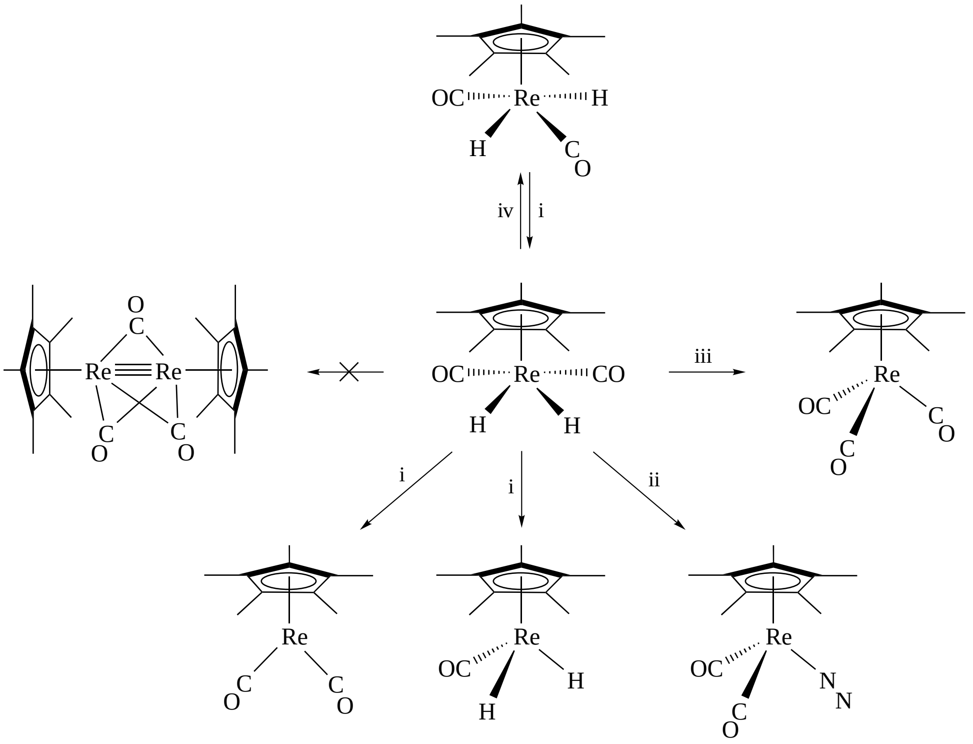
The field of photochemical dihydride reductive elimination has been reviewed by Perutz[115] and Bergamini *et al.*[116]

Dihydride photochemistry is not limited to reductive elimination. $CpRe(PPh_3)_2H_2$ is known to photochemically catalyze H/D exchange between C_6D_6 and other arenes or alkanes.[117] Photochemical studies of the mechanism of this process have ruled out loss of phosphines and instead postulate photochemical transfer of one or both hydrides to the cyclopentadienyl ligand yielding a 14-e intermediate, $(\eta^3\text{-}C_5H_7)Re(PPh_3)_2$, as a likely intermediate.[118]

Sigma complexes of Si–H bonds were first reported by Graham[119] in 1969 although the nonclassical nature of the bonding was not recognized until after the first reports on H_2 complexes. The early history of this field has been reviewed by Graham[120] and Schubert,[121] and the literature through 2001 has been reviewed by Kubas.[96]

The rates of oxidative addition of Et_3SiH, Et_2MeSiH, $EtMe_2SiH$, and Et_2SiH_2 to photochemically generated $Cp'Mn(CO)_2$, where Cp′ = Cp, CpMe, and Cp*, have been determined in both neat silane and a 50/50 mixture of silane and methylcyclohexane.[122]

Examination of the reactions of several organometallic species with silanes has established that the spin state of the photointermediate is important in rates of reaction. In general, triplet intermediates do not form strong agostic bonds to alkanes or alkyl groups, thus tend to go directly to Si–H oxidative addition. In contrast, singlet photointermediates may form relatively stable adducts that must undergo rearrangement prior to Si–H oxidative addition. Femtosecond UV pump/IR probe experiments have established that species known to have triplet states such as $CpV(CO)_3$, CpCo(CO), and $Fe(CO)_4$ are stable, unsolvated species in



Scheme 1 Photochemistry of $CpRe(CO)_2(H)_2$ in Nujol. (i) Photolysis processes in Nujol, 12 K; (ii) secondary process in N_2 matrix; (iii) secondary process in CO matrix, (iv) thermal reversal in Nujol, 298 K. Ref. 114

alkanes while triplet $CpMn(CO)_2$ rapidly relaxed to its solvated singlet in ca.120 ps.[123,124] In contrast to their long-term stability in alkanes, the triplet species, $CpV(CO)_3$, CpCo(CO), and $Fe(CO)_4$, undergo fast spin crossover and Si–H oxidative addition. Singlet intermediates such as CpRh(CO) or $CpRe(CO)_2$ react rapidly to form either Si–H oxidative addition products or solvated species. In the case of rhodium, the $CpRh(CO)\cdot Et_3SiH$ species requires almost 370 µs to transform to $CpRh(CO)(H)(Et_3Si)$ while in the case of $CpRe(CO)_2\cdot Et_3SiH$ about 6.8 µs are required for rearrangement to the oxidative addition product.[125] The proposed mechanism for $CpRe(CO)_3$ is presented in Figure 9. The more complicated mechanism of $CpMn(CO)_3$ in which both singlet and triplet species are observed is shown in Figure 10. The rearrangement of $CpMn(CO)_2(Et_3SiH)$ to $CpMn(CO)_2(HSiEt_3)$ has been observed using photoacoustic calorimetry.[126] Harris has reviewed these results as well as parallel results (discussed below) relating to C–H activation.[127]

C–H activation has been extensively examined since the virtually simultaneous discovery by Graham[128] and Bergman[129] that photochemically generated, electron-deficient organometallic species could insert into the C–H bond of an alkane. Numerous recent reviews and books have appeared describing both photochemical and thermal strategies for generating the critical electron-deficient intermediates. Because of the sheer magnitude of this field, we shall focus here on studies directed toward understanding the mechanism of these reactions based on the photochemical generation of active species.

An excellent short review of C–H bond activation including both thermal and photochemical mechanisms has been provided by Labinger and Bercaw.[130] Lees has reviewed the photochemical and photophysical features of these reactions.[131] Bergman has described the contributions of his group toward the understanding of the mechanisms of C–H activation up to 1992,[132] and within the context of physical organic chemical methods.[133] Schneider has examined the similarities between Si–H and C–H activation.[134] Shilov and Shul'pin have provided extensive reviews of C–H activation.[135] As with Si–H oxidative addition, the spin state of the photochemical intermediate plays a major role in the probability of insertion. This has been reviewed for the specific case of methane activation.[136]

Photolysis of $Cp^*M(CO)_2$, M = Rh or Ir, and $CpIr(CO)_2$ in methane matrices afforded the first direct observation of C–H activation from a photointermediate.[137] Similarly, photolysis of $Cp^*Ir(CO)(H)_2$ in methane matrices yielded $Cp^*Ir(CO)(H)(CH_3)$.[138] The rate of oxidative addition of alkanes to a CpRh(CO) photointermediate in the gas phase has been measured.[139]

A detailed stepwise mechanism for C–H activation emerged from the flash photolysis of $Cp^*Rh(CO)_2$ and neopentane in liquid Kr. Cp*Rh(CO)Kr was shown to be in equilibrium

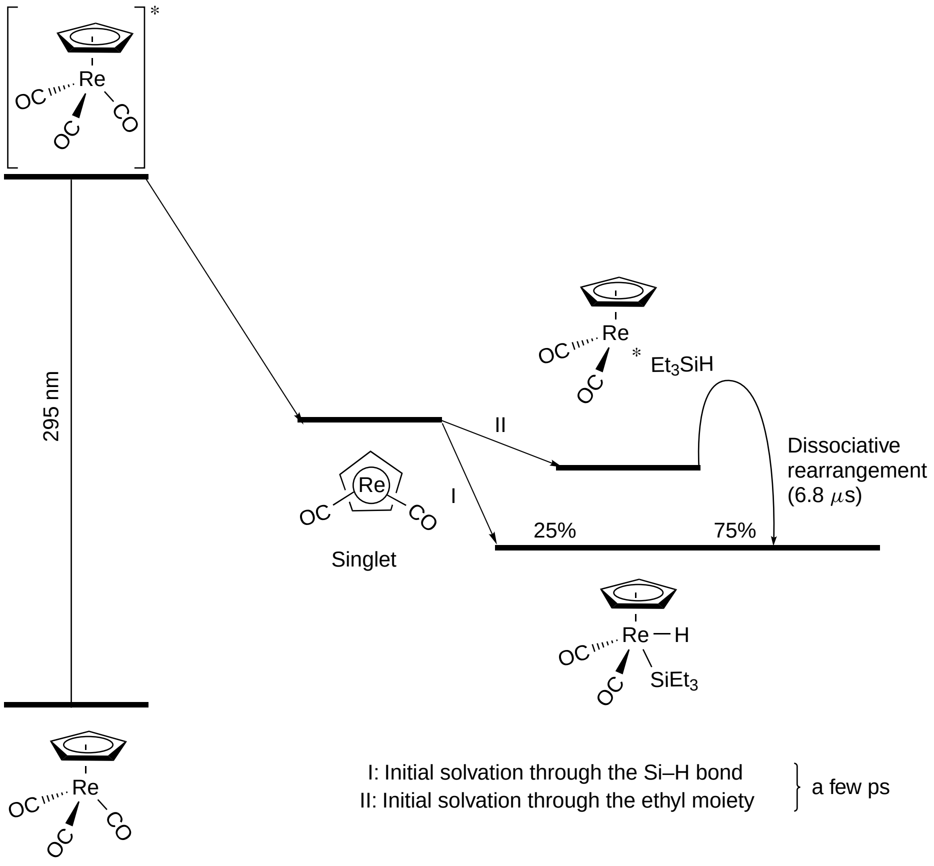


Figure 9 Proposed reaction mechanism of Si–H bond activation by $CpRe(CO)_3$. (Reprinted with permission from Ref. 127. © 1999 American Chemical Society)

with $Cp^*Rh(CO)(\sigma\text{-}C_5H_{12})$. The latter thermally converts to $Cp^*Rh(CO)(H)(C_5H_{11})$with a rate of 4.08×10^4 sec^{-1}. The use of d^{12}-neopentane made it possible to observe both the Kr and neopentane species.[140] Similar experiments had been performed earlier with cyclohexane in Kr, but it had not been possible to directly observe the σ-cyclohexane complex.[141] More recent studies of $Cp^*Rh(CO)_2$ in Kr with a series of alkanes has established an alkane structural effect on the rate of C–H oxidative addition. It was found that the equilibrium between the Kr and σ-alkane complexes shifts toward the alkane complex as alkane size increases. This is attributed to the relative polarizabilities of the alkane ligands. The rate of conversion from σ-alkane to oxidative addition product follows a reverse trend. It is proposed that the transition states for oxidative addition of the various alkanes lie closer together in energy than do the energies of the σ-alkane precursors. Thus differences in activation energy, and hence rate of oxidative addition, directly reflect the stability of the σ-alkane complex.[142] Deuterium isotope effects for this reaction have been examined. A large normal isotope effect ($k_H/k_D = 10$) was observed for the C–H activation step, while a negative isotope effect ($k_H/k_D = 0.1$) was observed for the preequilibrium. The authors attribute this negative isotope effect to greater stabilization of the σ-deutero alkane complex.[143]

Picosecond transient absorption spectroscopy of $Cp^*M(CO)_2$, where M = Rh and Ir, establish a biexponential decay of the excited state species that have been assigned to a fast nondissociative relaxation from the excited state and a slow dissociative step. The low quantum yields observed upon preparative photolysis are attributed to the fast nondissociative decay.[144] Building upon wavelength dependence and quantum yield studies by Lees,[145] a theoretical model of the excited states of $CpM(CO)_2$, where M = Rh and Ir, suggests that two excited states are strongly mixed. These excited states correspond to a MLCT state that is responsible for the observed photochemistry and a ligand Cp to metal and CO charge transfer excitation that quickly relaxes without initiating photochemistry.[146] Subpicosecond IR studies of the photolysis of $CpRh(CO)_2$ in cyclohexane have observed a species consistent with $(\eta^5\text{-}C_5H_5)Rh(CO)(C_6H_{12})$ ruling out a haptotropic $(\eta^3\text{-}C_5H_5)Rh(CO)(C_6H_{12})$ species in the reaction.[147] Somewhat unexpectedly, the photochemical ligand exchange of $Cp'Rh(CO)_2$, where Cp′ = Cp and Cp*, with PPh_3 appears to proceed through an associative mechanism involving an η^3-Cp′ ring.[148]

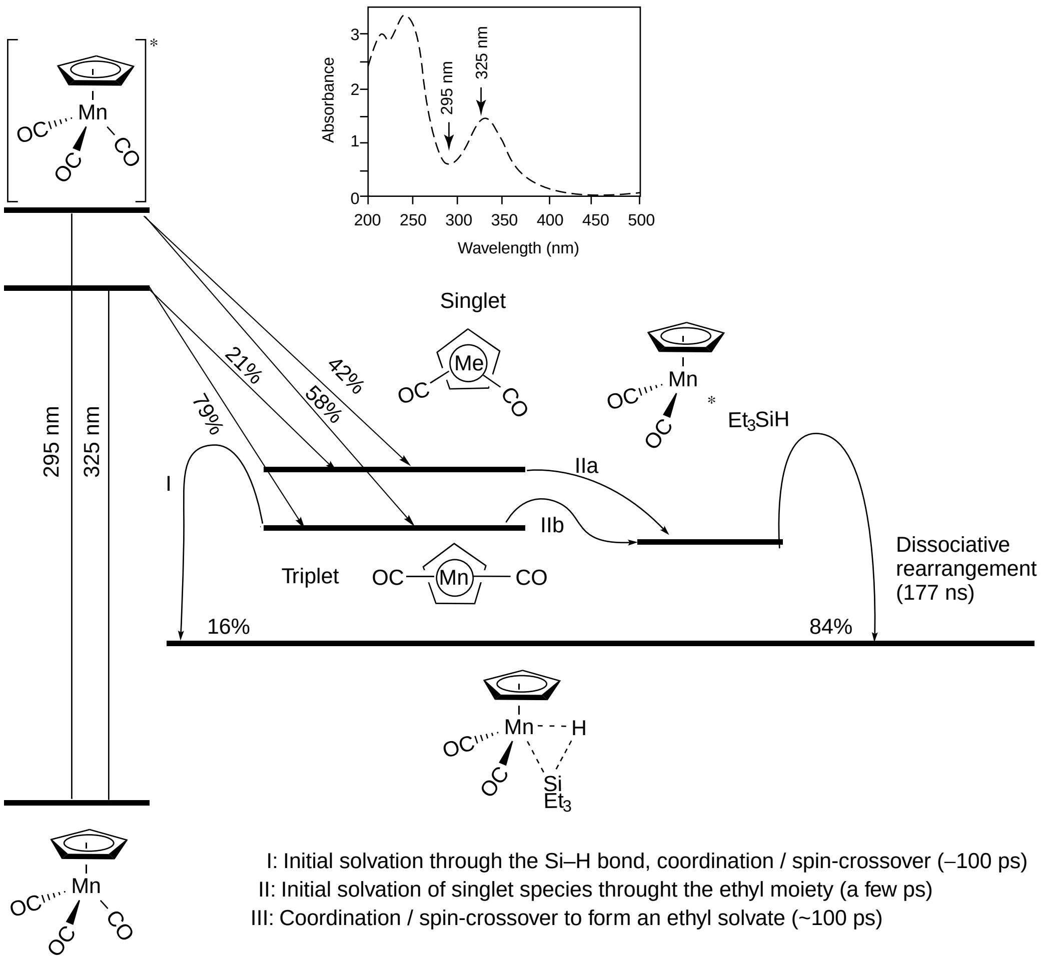

Figure 10 Proposed mechanism of Si–H activation by $CpMn(CO)_3$. Inset: UV–vis spectrum of $CpMn(CO)_3$ in neat Et_3SiH under experimental conditions. (Reprinted with permission from Ref. 127. © 1999 American Chemical Society)

The photochemical transformation of $CpIr(CO)(\eta^2\text{-}C_2H_4)$ to $CpIr(CO)(H)(C_2H_3)$ in an Ar matrix is presented in Figure 11(a). The oxidative addition is reflected in the increase of the carbonyl stretching frequency reflecting the formal transformation from Ir(I) to Ir(III). In a methane matrix (Figure 11(b)), a second species is observed corresponding to $CpIr(CO)(H)(CH_3)$ arising from the dissociation of ethane. Interestingly, a pronounced wavelength dependence was observed for the photolyses in methane matrices. Upon low-energy irradiation ($\lambda > 365$ nm) $CpIr(CO)(H)(C_2H_3)$ was formed exclusively, but with increasing energy of the incident radiation methane activation was found to compete with ethane activation.[149] It seems likely that higher energies introduce a dissociative component to the reactions not present at lower energies.

Reaction of CH_4, C_2H_4, and C_2H_6 with $Cp^*Ir(CO)_2$ in supercritical CO_2, Xe, and CHF_3 has been examined. H_2 addition is unaffected in sc CHF_3, but oxidative addition of ethane is almost completely suppressed, perhaps owing to hydrogen bonding by the solvent. 'Solvent free' photolysis has also been carried out in supercritical methane, ethane, and ethene.[150]

Density functional theory modeling of the group IX CpM(CO) intermediates correlates the activation barrier to oxidative addition of a C–H bond to the singlet-triplet splitting, ΔE_{st}, of the 16 electron intermediate. Smaller values of ΔE_{st} are observed with the lower transition metals in agreement with the ease of oxidative addition.[151]

While examining analogs for $CpRh(CO)_2$, Ghosh and Graham prepared $Tp^*Rh(CO)_2$ and found that this species activated aromatic and alkane C–H bonds with great efficiency under daylight or tungsten illumination.[152] Gas matrix studies established that both CO dissociation and Tp* ligand dechelation occurred upon photolysis.[153] Extensive studies by Lees[154] and Bergman[155] have established a detailed mechanism for these reactions (Scheme 2). Consistent with the matrix studies, photolysis may lead to dechelation of the κ^3-Tp* ligand or CO-loss with dechelation dominating at longer wavelengths while CO-loss is more significant at shorter wavelengths. Dechelation is inconsequential with

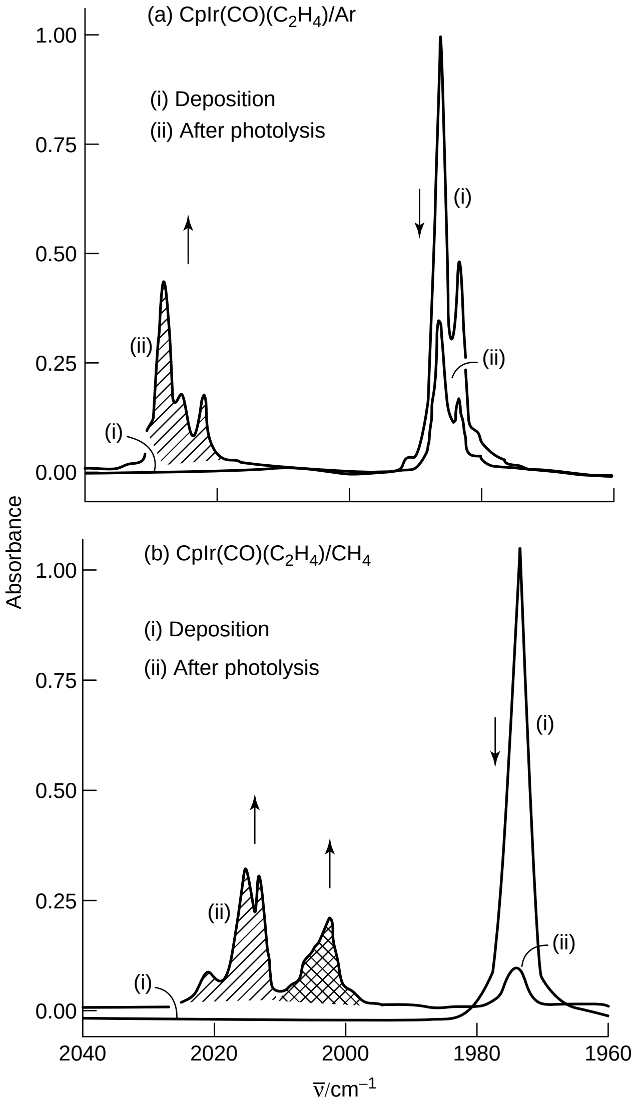

Figure 11 IR spectrum of $CpIr(CO)(\eta^2\text{-}C_2H_4)$ in (a) Ar showing $CpIr(CO)(H)(C_2H_3)$ and (b) CH_4 matrices showing both $CpIr(CO)(H)(C_2H_3)$ and $CpIr(CO)(H)(CH_3)$. Spectra (i) are as deposited, while (ii) are photolyzed samples. (Reprinted with permission from Ref. 149. © 1993 American Chemical Society)

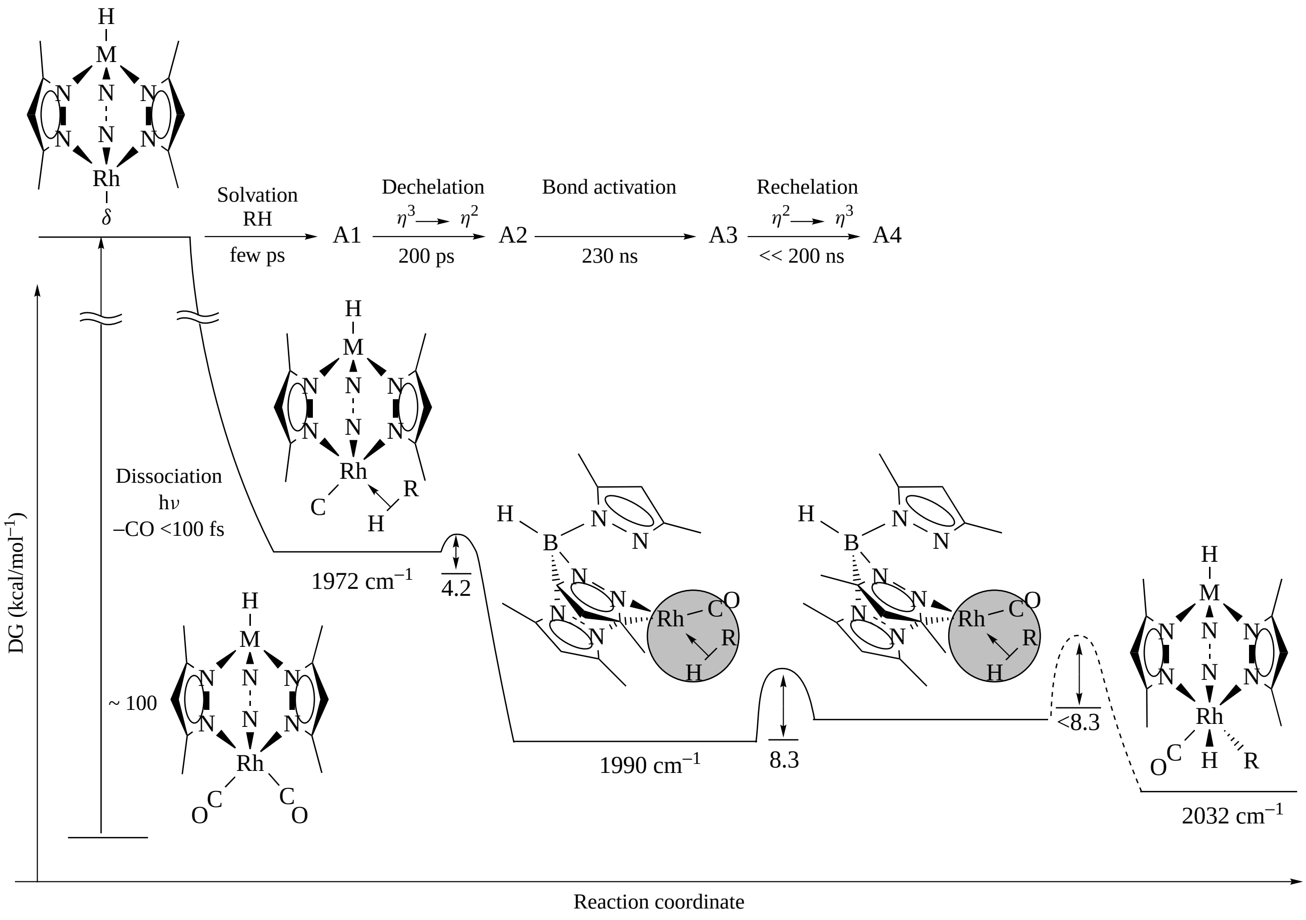
respect to C–H activations since the dangling pyrazolyl ligand rapidly recombines with the metal. Solvation of the CO-loss species occurs within a few ps and is followed by dechelation of the κ^3-Tp* ligand giving rise to κ^2-Tp*Rh(CO)(RH). This species undergoes C–H bond activation to give κ^2-Tp*Rh(CO)(H)(R) followed by reattachment of the pyrazolyl ligand to yield the product, κ^3-Tp*Rh(CO)(H)(R).

One of the significant challenges in synthetic chemistry is to follow a C–H activation step with further bond making or breaking transformations. In the processes described above, the C–H oxidative addition product is the thermodynamic sink of the reaction. Three processes that have transcended this difficulty are carbonylation, dehydration, and borylation.

In the course of examining the photochemistry of benzene solutions of $H_3Ir(CO)(dppe)$ under CO, Fischer and Eisenberg observed formation of benzaldehyde. The actual catalytic species was determined to be HIr(CO)(dppe).[156] Examination of related metal complexes, notably $Rh(CO)L_2Cl$, where L = PPh_3 or PMe_3, established that both aromatic and saturated hydrocarbons could serve as substrates for photochemical carbonylation.[157] The significance of this reaction is perhaps reflected in issuance of several patents.[158] An examination of a range of phosphorus ligands established that the order of reactivity was $PMe_3 \approx$ 1,3,4-trimethylphospholane $\approx$ 1,3,4-trimethylphospholene $>$ $P(CH_2O)_3CMe > PEt_3 > P(CHMe_2)_3 \approx PPh_3 \approx P(OMe)_3 >$ dppe.[159] A catalytic mixture consisting of $Rh_2(CO)_4Cl_2$ and PMe_3 was found to catalyze pentane carbonylation at a rate ca. 20 times that of $Rh(CO)(PMe_3)_2Cl$.[160] The effect of CO pressure on the dehydration and carbonylation of pentane established that increasing CO pressure suppresses dehydration, while increasing CO pressure to 600 mm reportedly displaced a phosphine from rhodium creating a more active catalyst.[161] A wavelength dependence on the regioselectivity of the reaction has been reported.[162] Photodehydrogenation,[163] C-Si[164] and C–C bond forming reactions[165] have been observed in the absence of CO. Evidence for the intermediacy of the CO-loss species, $Rh(PMe_3)_2Cl$, in dehydrogenation reactions has been reported.[166] The carbonylation of propane in liquid propane,[167] ethane in both supercritical ethane and supercritical CO_2,[168] and methane in supercritical CO_2 have been reported.[169] Several reviews of these reactions have been published.[170]

The mechanism of the $Rh(CO)(PMe_3)_2Cl$ catalyzed carbonylation has come under scrutiny. In the absence of CO, benzene is found to react photochemically with the catalyst to form two isomers of $Rh(CO)(PMe_3)_2(H)(Ph)Cl$ and $Rh(CO)(PMe_3)_2Ph$ arising from HCl loss from the Rh(III) species.[171] Closely related to this is the oxidative addition of benzene to $Rh(PMe_3)_3Cl$ to give $Rh(PMe_3)_3(H)(Ph)Cl$. This species could be isolated and a molecular structure was obtained confirming the cis orientation of the phenyl and hydride ligands.[172] $Rh(CO)(PMe_3)_2(H)(Ph)Cl$ undergoes secondary photolysis resulting in reductive elimination of benzaldehyde. Although benzene does oxidatively add to the CO-loss species, $Rh(PMe_3)_2Cl$, this did not appear to be the primary route to carbonylation. Instead, oxidative addition to an intact, excited state catalyst appears to be the precursor to the Rh(III) species.[173] Time-resolved optical and IR studies of the photolysis of $Rh(CO)L_2Cl$, L = PMe_3, PPh_3, P(*p*-toluyl)$_3$, in a variety of solvents has established that an initial excited state species is formed (<30 ps) and that this species decays to $RhL_2(sol)Cl$ over 40 to 560 ps depending upon L and solvent. The solvated species undergo oxidative addition to form Rh(III) species. CO suppresses the formation of the solvated species. It was confirmed that some fraction of the excited state species react directly with solvent without CO-loss to form Rh(III) species.[174] Nujol matrix photolysis of $Rh(CO)L_2Cl$, where L = PMe_3 and PBu_3, resulted in the formation of a new



Scheme 2 Reaction mechanism for photochemical C–H activation by $Tp^*Rh(CO)_2$. Ref. 155d

carbonyl-containing species (Figure 12), believed on the basis of dft calculations to be a nonplanar triplet.[175] A very recent

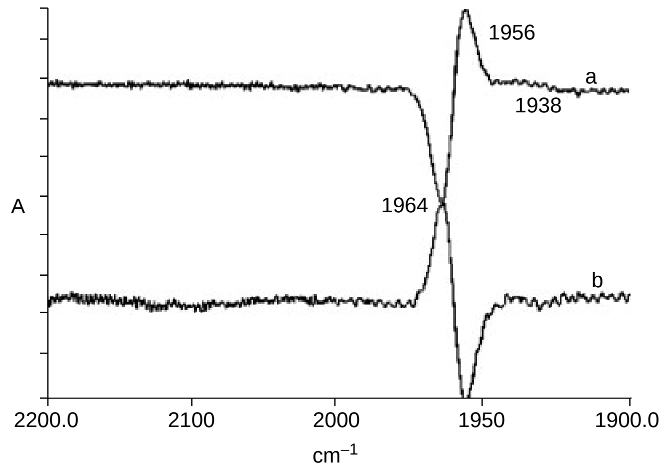


Figure 12 Photolysis of $Rh(CO)(PMe_3)_2Cl$ in Nujol matrix at ca. 90 K. (a) 4 h photolysis ($\lambda > 400$ nm). (b) Sample annealed to 153 K. (Reprinted from Ref. 175. © 2002, with permission from Elsevier)

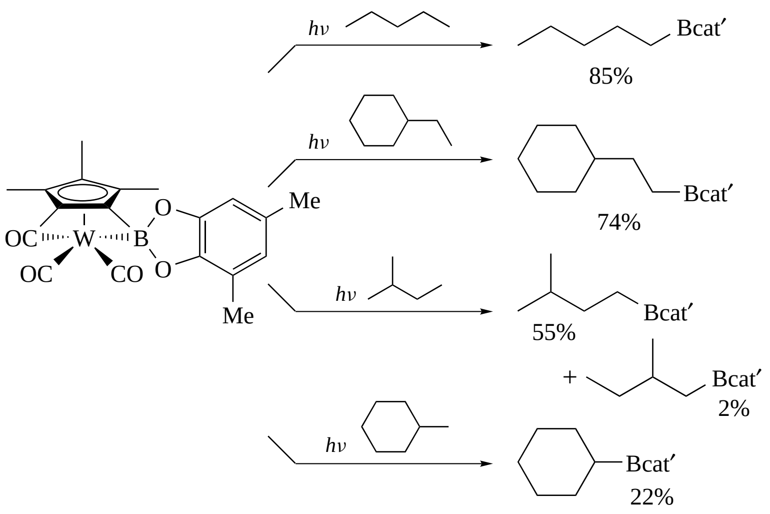
flash photolysis study of $Ir(CO)(PPh_3)_2Cl$ has been interpreted in terms of the formation of a long-lived electronically excited state of the iridium complex having an IR carbonyl stretch very close to that of the ground-state molecule.[176] Whether this is related to the species observed upon Nujol matrix photolysis is not yet known.

Thermal and photochemical borylation of alkanes and arenes via C–H activation provide a strategy for functionalizing hydrocarbon feedstocks.[177] Photolysis of a series of transition metal boryl compounds, $Cp^*M(CO)_nB(OR)_2$, where M = Fe($n = 2$), Ru ($n = 2$), or W ($n = 3$), R = B-1, 3, $O_2C_6H_2$-3, 5-Me_2, in the presence of benzene, alkanes, or alkenes results in the formation of alkyl boronate esters and the corresponding transition metal hydride.[178] $M(CO)_5B(OR)_2$, where M = Mn and Re, reacted with benzene to yield phenyl boronate ester and the corresponding metal hydride (Scheme 3).[179] Yields were as high as 85% with the tungsten compound. A strong preference was found for substitution at primary carbons of the alkanes. Photolyses in the presence of PMe_3 provided strong evidence of photochemical CO-loss as the initiating step in these reactions and, indeed, the CO-loss species of $Cp^*W(CO)_3B$(catechol) has been observed



Scheme 3 Photolysis reactions of $CpW(CO)_3Bcat'$ with yields of products. Ref. 178b

directly in frozen Nujol matrices.[180] The iron complex shows a strong preference for arene functionalization over alkane while the tungsten complex is equally effective at both. Dft modeling finds that reactions of $CpFe(CO)BO_2C_2H_4$ favor a one step, σ-bond metathesis involving a four-center transition state, while $CpW(CO)_2BO_2C_2H_4$ favors a two step process in which oxidative addition proceeds reductive elimination of $RBO_2C_2H_4$. arene addition to the iron intermediate is stabilized by interaction between the 'empty' boron p orbital and the π orbitals of the benzene.[181]

Photolysis of $Cp'M(CO)_3$, where M = Mn or Re, Cp′ = Cp or Cp*, in the presence of pentane and 4, 4, 4′, 4′, 5, 5, 5′, 5′-octamethyl-2, 2′ = bi-1, 3, 2-dioxaborolane (B_2Pin_2) resulted in formation of primary pentylboronate ester in yields as high as 95% for the Cp* derivatives. Photolysis of *trans*-$Cp^*Re(CO)_2(Bpin)_2$ in pentane produced pentylboronate ester in 100% yields suggesting that $Cp'M(CO)_2(Bpin)_2$ species are likely intermediates in these syntheses.[182] The analogous oxidative addition of a B–B bond has been observed upon photolysis of Cp_2WH_2 and CatBBCat (Cat = 4-tert-butylcatechol) in benzene yielding $Cp_2W(Bcat)_2$.[183]

In an interesting footnote to these alkane and aromatic borylation reactions, photolysis of $Cp^*M(CO)_3Me$, M = Mo or W, and H_3BPMe_3 resulted in the formation of methane and $Cp^*M(CO)_3BH_2PMe_3$.[184]

4 $Fe(DMPM)_2H_2$ AND RELATED COMPOUNDS

In the late 1970s, DuPont workers demonstrated that $Fe(dmpe)_2(H)$(Napthyl) undergoes reactions with a variety of R–H groups to give oxidative addition products, $Fe(dmpe)_2(H)(R)$ with the assumption that a 16-electron intermediate, $Fe(dmpe)_2$, was responsible for the chemistry.[185] Subsequent work in Australia[186] and Italy[187] demonstrated that $M(dmpe)_2H_2$, where M = Fe, Ru, Os, could undergo photochemical loss of H_2 to generate the same reactive intermediate. Oxidative addition of alkanes (including methane in supercritical Xe[188]), alkene, arene, and acetylenic C–H bonds to these intermediates has been studied.[189] A patent has been issued for the use of $Fe(dmpe)_2H_2$ for photochemical dehydrogenation of alkanes.[190] Thiophenes react with $Fe(dmpe)_2$ to insert both C–H and C–S bonds.[191] Photolysis of $Fe(dmpe)_2H_2$ in Ar matrices permitted direct UV detection of $Fe(dmpe)_2$. In solution, time-resolved spectra established that H_2 loss occurs within 30 ns. Rates of reaction between $Fe(dmpe)_2$ and a variety of substrates were measured. The order of decreasing rate was found to be: $CO \gg H_2 > C_2H_4 > N_2 >$ cyclopentene $> Et_3SiH$.[192] A dft analysis has been carried out on $M(PH_3)_4$, where M = Fe, Ru, as models of the dmpe complexes. Singlet $Ru(PH_3)_4$ was calculated to have a D_{2d} geometry while the corresponding singlet iron species was found to have a C_{2v} geometry. Triplet $M(PH_3)_4$ for both Fe and Ru were found to have C_{2v} geometries. Interestingly, the singlet ruthenium species was calculated to be 11.7 kcal $^{-1}$ mol more stable than the triplet, while the singlet iron species was found to be 8.0 kcal mol^{-1} less stable than its triplet.[193]

Matrix photolysis of the series $Ru(P2)_2H_2$, where P_2 = depe, $Et_2PC_2H_4Pet_2$, dppe, $Ph_2PC_2H_4PPh_2$, dfepe, $(C_2F_5)_2PC_2H_4P(C_2F_5)_2$ established that in all cases H_2 loss yields $Ru(P_2)_2$. The rates of reaction of the various photointermediates with H_2 and CO established a rate order of $Ru(dfepe)_2 < Ru(dppe)_2 < Ru(depe)_2$.[194]

$PtLH_2$, where L = $(t\text{-}Bu_2P)_2C_2H_4$,[195] undergoes photolysis to yield PtL that has been found to effect arene C–H activation but not alkane.[196] The concerted elimination of H_2 has been confirmed in that an equimolar solution of $PtLH_2$ and $PtLD_2$ gave only H_2 and D_2 as products. A qualitative bonding model assigns the HOMO to a $\sigma(x^2\text{-}y^2)$ and the LUMO

to the corresponding $\sigma^*(x^2 - y^2)$. Excitation is expected to result in loss of H_2. This is consistent with parahydrogen studies in which H_2 adds in a concerted, pairwise manner to $Pt(Ph_2PCH_2CHMeOPPh_2)$.[197]

5 LIGAND EXCHANGE, BOND HOMOLYSIS, AND HETEROLYSIS

Photochemical homolysis of metal–ligand bonds has been observed with a number of simple organometallic derivatives. For example, photolysis of $CpFe(CO)_2R$, where R = Bz,[198] $C(Ph)(H)(OSiMe_3)$,[199] in the presence of excellent ligands such as CO or phosphines result in homolysis of the Fe–C bonds. Subsequent recapture of the carbon radical by exocyclic attack on the Cp ring of the intermediate $CpFe(CO)_2L$, yields *exo*-$C_5H_5RFe(CO)_2L$.

The photochemical generation of methyl radicals has been applied to studies of DNA cleavage. The photochemical generation of methyl radicals from $Co(cyclam)Me(H_2O)(ClO_4)_2$ has been known for some time.[200] Photolysis of $Co(cyclam)Me(H_2O)(ClO_4)_2$ in the presence of plasmid DNA results in the conversion of supercoiled DNA to the nicked circular form. The likely mode of DNA damage is hydrogen atom abstraction by pathways very similar to those of hydroxyl radicals.[201] group VI $CpM(CO)_3R$, $CpFe(CO)_2R$, where R = Me, Ph, and $[CpFe(CO)_2]_2C_6H_4$ compounds have also been used in studies of DNA double strand scission.[202] Of particular interest were cyclopentadienyl complexes bearing DNA recognition elements on their rings. These species form bioconjugate complexes with DNA placing the photoactive species immediately adjacent to the DNA strand.[203]

Photochemical bond heterolysis is a much less common, or at least much less studied, phenomenon than ligand dissociation or bond heterolysis. $CpFe(CO)_2X$, where X = halide, are well known to undergo CO-loss upon photolysis,[204] and the CpFe(CO)Cl species has been observed in gas matrices.[205] In the presence of nitrogen bases such as pyrrole,[206] cyclic imides,[207] nucleobases,[208] and nucleosides, LH, $CpFe(CO)_2I$ undergoes photolysis to form $CpFe(CO)_2L$. Quantum yields of the heterolysis reaction have been recorded in the range of 488–647 nm. The most effective photoconversions were found to occur at long wavelength ($\phi = 0.38 \pm 0.02$, $\lambda = 647$ nm) and have been attributed to a LF transition.[209]

6 BIMETALLIC CARBONYL AND CYCLOPENTADIENYL CARBONYL COMPOUNDS

The photochemistry of bimetallic carbonyl and cyclopentadienyl carbonyl compounds is characterized by both carbonyl-loss and metal–metal bond homolysis.[210] Like the mononuclear carbonyls, carbonyl-loss species may react with a variety of ligands, or may undergo internal reorganization such as the formation of semibridging, bridging, or 4-electron bridging carbonyl groups to maximize bonding. Metal–metal bond homolysis produces radical species that may react with ligands to substitute carbonyl groups or may initiate hydride or halide abstraction reactions.

The photolysis of $Mn_2(CO)_{10}$ is representative of the behavior of many bimetallic carbonyl compounds. In solution[211] and in the gas phase[212] strongly wavelength dependent photochemistry has been observed. At low energy, Mn–Mn bond homolysis predominates while at high energy CO-loss is observed.

Photolysis of $Mn_2(CO)_{10}$ in 3-methylpentane glass or Ar matrix resulted in loss of a carbonyl ligand and formation of a species with a bridging carbonyl.[213] The low IR stretching frequency of the bridging carbonyl, ca. 1760 cm^{-1}, requires that it be assigned as a 4-electron bridging carbonyl, μ-η^1:η^2-CO. The difference spectrum illustrating the formation of the CO-loss species in 3MP is shown in Figure 13. Under these matrix conditions $Mn(CO)_5$ radicals are not observed owing to rapid recombination within the solvent cage. UV flash photolysis with UV[214] and IR[215] detection of $Mn_2(CO)_{10}$ in cyclohexane solution directly observed the radical (Figure 14) and CO-loss (Figure 15) channels. The excited state species dissociates with an upper limit of 2–3 ps. The vibrationally hot $Mn_2(CO)_9$ species cools through two distinct channels in 15 and 170 ps, respectively. Although these channels were initially associated with formation of the bridging carbonyl intermediate, later work in 3-methylpentane glass provided strong evidence for formation of a solvated species, $Mn_2(CO)_9$(sol) that then decays to the bridged form.[216] Photolysis at 400 nm rather than in the UV permitted the $Mn(CO)_5$ radical formation and cooling to be observed without interference by the CO-loss product.[217] The EPR spectrum of $Mn(CO)_5$ radicals was recorded by trapping the gas

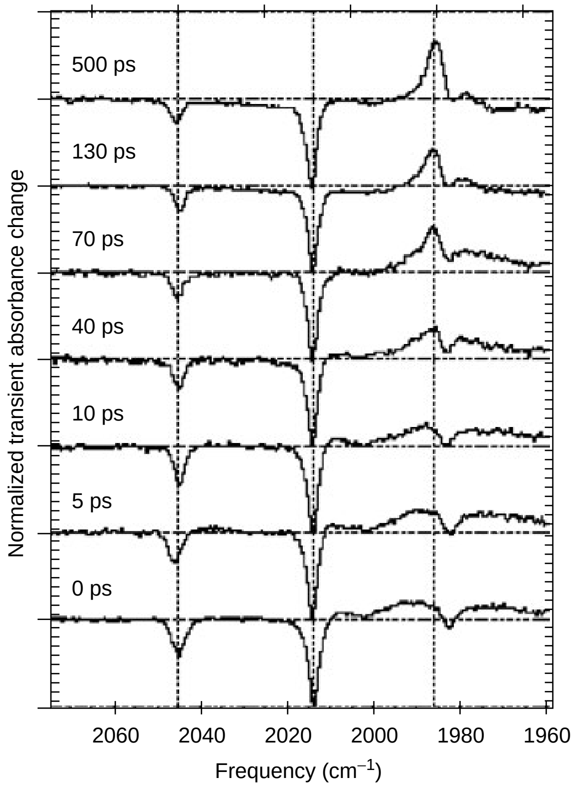

Figure 14 Normalized time-resolved IR spectra of 400 nm photodissociation of $Mn_2(CO)_{10}$ in cyclohexane for several pump probe delay times. Vibrational cooling of the $Mn(CO)_5$ radical can be observed to be complete by 70 ps. (Reprinted from Ref. 217. © 2002, with permission from Elsevier)

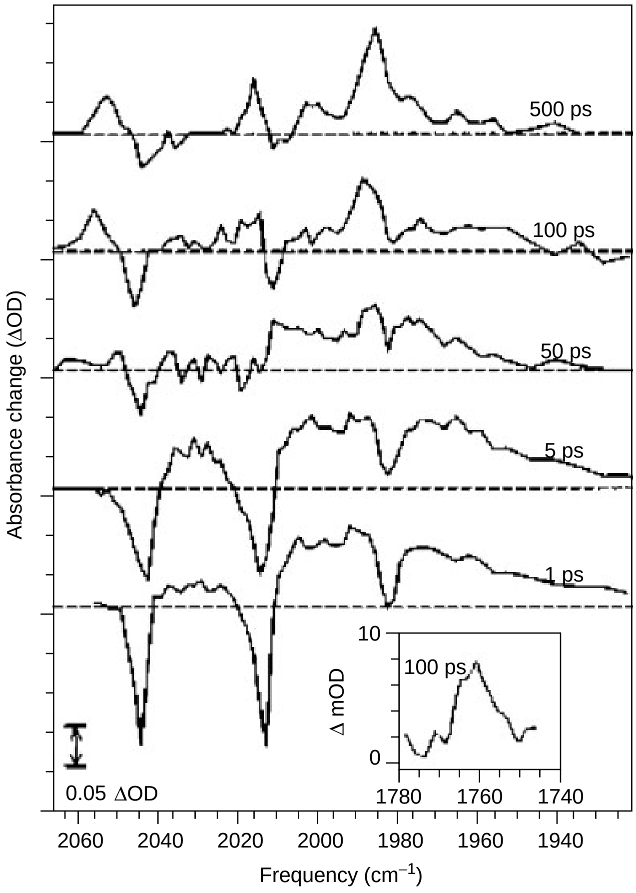

Figure 15 Transient IR spectra of 310 nm photodissociation of $Mn_2(CO)_{10}$ in cyclohexane at several time delays. Insert is bridging carbonyl region at 100-ps delay. Both $Mn(CO)_5$ radical and $Mn_2(CO)_8(\mu\text{-}\eta^1, \eta^2\text{-CO})$ are observed. (Reprinted with permission from Ref. 215. © 1996 American Chemical Society)

phase photochemically generated radicals in an adamantane matrix.[218]

Several theoretical studies of the ground and excited states of $Mn_2(CO)_{10}$ have been reported.[220]

Extended photolysis of $Mn_2(CO)_{10}$ in 3-methylpentane glass gives rise to $Mn_2(CO)_8$ resulting from double CO-loss and an isomer of $Mn_2(CO)_9$ with a semibridging carbonyl.[221] Dft calculations have been used to probe possible structures of the $Mn_2(CO)_8$ species.[222]

Examination of the photochemical products of the series $Mn_2(CO)_{10}$, $MnRe(CO)_{10}$, $Re_2(CO)_{10}$ allows a comparison of the tendency of the various species to form solvated or bridging carbonyl complexes upon CO-loss. As noted above, $Mn_2(CO)_9$ forms a solvated species that readily converts to a bridged carbonyl intermediate. In contrast, $MnRe(CO)_9$ forms a stable solvated species that requires visible light to transform it into an analogous bridging carbonyl species. $Re_2(CO)_9$, consistent with the reluctance of third row transition metals to form carbonyl bridges, forms only a solvated species.[219]

When $Mn_2(CO)_{10}$ and PR_3 are photolyzed in 3-methylpentane at 90 K only CO-loss is observed. Warming solutions containing $Mn_2(CO)_8(\mu\text{-}\eta^1{:}\eta^2\text{-CO})$ and PBu_3 results in formation of equatorial $Mn_2(CO)_9(PBu_3)$ that rearranges to its axial isomer. When photolyses are carried out at 213 K the solvent is fluid, thus both CO-loss and radical channels are accessible. It is believed that the rate of reaction between $Mn(CO)_5$ radicals and PBu_3 are high leading to effective formation of $Mn(CO)_4(PBu_3)$ radicals that recombine to initially give axial, equatorial, and, equatorial isomers of $Mn_2(CO)_8(PBu_3)_2$. These isomers transform over time to the more stable axial, axial isomer.[223]

Substantial progress has been made in understanding the photochemistry of the group VI and group VIII cyclopentadienyl metal carbonyl compounds, $Cp_2M_2(CO)_6$, where M = Cr, Mo, W, and $Cp_2M_2(CO)_4$, where M = Fe, Ru, Os. The photochemistry of these compounds has been recently reviewed[224] thus only the highlights of these studies will be described here. As described for $Mn_2(CO)_{10}$, these metal–metal bonded compounds possess two, wavelength dependent, photochemical reaction channels, M–M bond homolysis and CO-loss. In rigid media such as low-temperature matrices only the first of these processes is observed, while in solution both pathways are available.

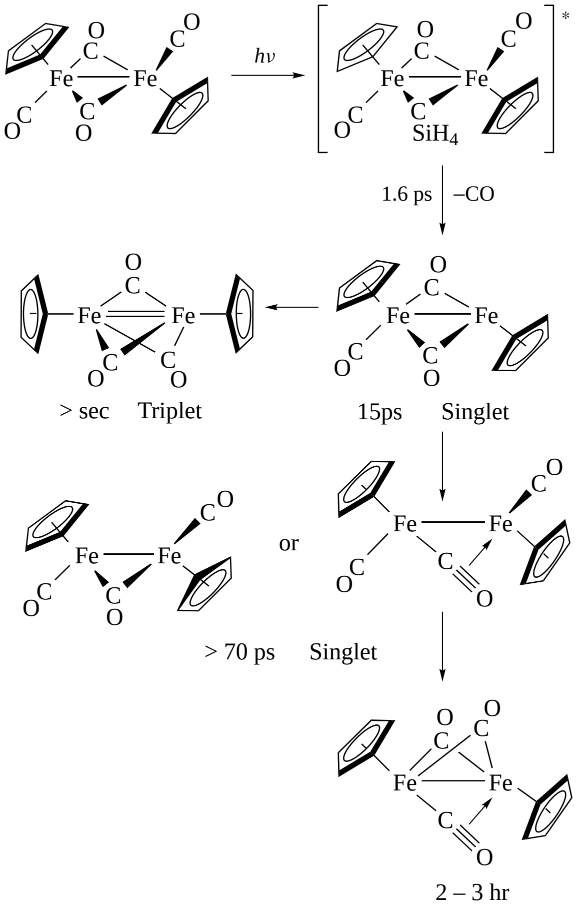
Photolysis of $Cp_2M_2(CO)_6$, where M = Mo and W, in frozen matrices yields a pentacarbonyl species with both semibridging and 4-electron bridging carbonyl groups.[225] For Mo, this species is stable in solution when formed (λ_{irr} = 308 nm) at 200 K, but decays at 240 K to $Cp_2Mo_2(CO)_6$ and $Cp_2Mo_2(CO)_4$. Photolysis of $Cp_2Mo_2(CO)_6$ at visible wavelengths results in radical formation. The recombination of these $CpMo(CO)_3$ radicals gives both gauche and trans forms. The rapid isomerization of the gauche to the more stable trans form has been followed by time-resolved IR.[226] Photolysis of $Cp^*_2Cr_2(CO)_4$ in solution results in the formation of $Cp^*_2Cr_2(\mu\text{-}CO)_3$. This species reacts with CO about 1000 times faster than $Cp_2Fe_2(\mu\text{-}CO)_3$.[227]

Photolysis of $Cp_2M_2(CO)_4$, where M = Fe, Ru, Os, in frozen matrices gives rise to CO-loss and formation of species characterized by a M=M double bond and three bridging carbonyl groups.[228] CO-loss has also been observed for $Cp^*_2Ru_2(CO)_4$ in 3-MP with formation of $Cp^*_2Ru_2(\mu\text{-}CO)_3$. Extended photolysis ejects a second CO with formation of $Cp^*_2Ru_2(\mu\text{-}CO)_2$.[229] For $Cp^*_2Fe_2(\mu\text{-}CO)_3$, a molecular structure has confirmed the core geometry.[230] In solution, both CO-loss and M–M bond homolysis are observed.

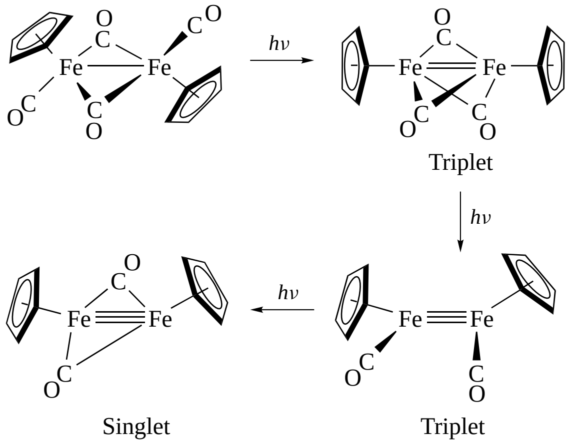
For $Cp_2Fe_2(CO)_4$, the seemingly simple CO-loss photochemistry becomes quite complex when examined using high speed methods. As summarized in Reference 224b (Fe review), excitation of the doubly bridged isomer, $Cp_2Fe_2(CO)_2(\mu\text{-}CO)_2$, gives an excited state species that decays with CO-loss in ca. 1.6 ps to singlet $Cp_2Fe_2(CO)(\mu\text{-}CO)_2$, or more likely, $Cp_2Fe_2(CO)_2(\mu\text{-}CO)(sol)$.[231] Spin crossover gives rise to the triply bridged, triplet, $Cp_2Fe_2(\mu\text{-}CO)_3$,[232] while a second channel gives a short-lived (>70 ps) singlet species corresponding to either $Cp_2Fe_2(CO)_2(\mu\text{-}CO)$ or $Cp_2Fe_2(CO)_2(\mu\text{-}\eta^1{:}\eta^2\text{-}CO)$ that relaxes to a very long-lived species $Cp_2Fe_2(\mu\text{-}CO)_2(\mu\text{-}\eta^1{:}\eta^2\text{-}CO)$. These processes are summarized in Scheme 4.

At long photolysis times (Scheme 5), the triplet $Cp_2Fe_2(\mu\text{-}CO)_3$ loses a CO to give the triplet $Cp_2Fe_2(CO)_2$. Further photolysis converts this triplet to a doubly bridged singlet, $Cp_2Fe_2(\mu\text{-}CO)_2$. These dicarbonyl species are characterized by iron–iron triple bonds.[233]

Introduction of a bridging alkylidene group suppresses radical formation and favors formation of species with bridging carbonyl groups. For example, detailed studies of the photochemistry of $Cp_2Fe_2(\mu\text{-}CO)_3(\mu\text{-}CHCH_3)$ ruled out metal–metal homolysis as a reaction pathway.[234] Photolysis of $Cp^*_2Fe_2(CO)_2(\mu\text{-}CO)(\mu\text{-}CH_2)$ in 3-MP matrices results in loss of CO to give $Cp^*_2Fe_2(\mu\text{-}CO)_2(\mu\text{-}CH_2)$. Extended photolysis results in the loss of a second CO to give $Cp^*_2Fe_2(\mu,\eta^{1:2}\text{-}CO)(\mu CH_2)$.[235] These processes are summarized in Scheme 6. Similarly, photolysis of $Cp_2Co_2(CO)_2(\mu\text{-}CH_2)$ in 3-MP matrices results in loss of CO to give $Cp_2Co_2(\mu\text{-}CO)(\mu\text{-}CH_2)$, while extended photolysis results in loss of the remaining CO to give an unseen species believed to be $Cp_2Co_2(\mu\text{-}CH_2)$ with a formal bond order of 3 between the cobalt atoms.[236]

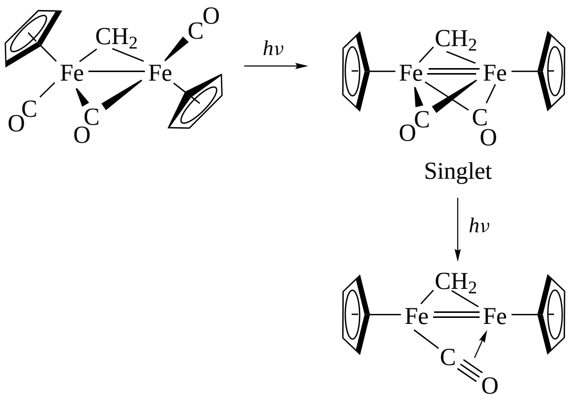


Scheme 4 Proposed overall mechanism for CO-loss process of $Cp_2Fe_2(CO)_4$. Ref. 224b

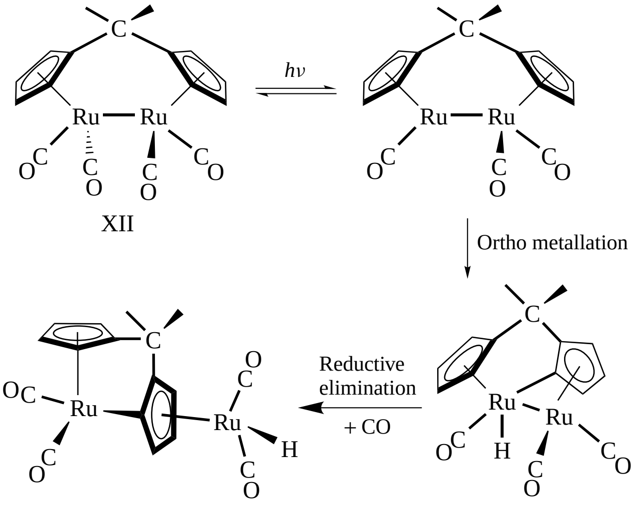


Scheme 5 Photoproducts from extended photolysis of $Cp_2Fe_2(CO)_4$. Ref. 233

Coupling of rings, for example, $(\mu\text{-}Cp\text{-}Q\text{-}Cp)M_2(CO)_n$, where Q = CH_2, CMe_2, C_2H_4, $SiMe_2$, M = Mo, W (n = 6),



Scheme 6 Photoproducts from the extended photolysis of $Cp_2Fe_2(CO)_2(\mu\text{-}CO)(\mu\text{-}CH_2)$. Ref. 235



Scheme 7 Proposed mechanism of 'twist' reaction of $(\mu\text{-}\eta^5, \eta^5\text{-}Cp\text{-}CR_2\text{-}Cp)Ru_2(CO)_4$. Ref. 237b

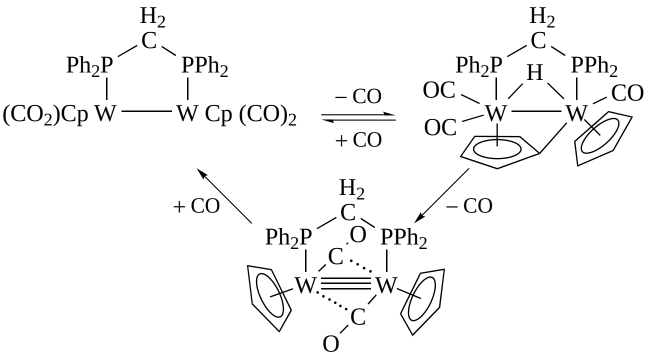
Fe, Ru ($n = 4$), also suppresses radical formation upon photolysis and leads to CO-loss species with a mixture of bridging and semibridging carbonyl groups.[237] Since the coupled bridges also preclude formation of linear species stabilized by multiple bridging COs, these compounds tend to undergo simple ligand exchange reactions.[238] In the absence of potential ligands, Mo, W, and Ru compounds undergo an internal C–H activation, twist reaction, with formation of a metal-to-ring sigma bond and transfer of the ring hydrogen to the second metal atom to form a hydride (Scheme 7). In the presence of chlorine-containing solvents, the corresponding chloride compounds can be isolated. The kinetics of the back reaction from the twist hydride, $(\mu, \eta^5\text{:}\eta^{5:1}\text{-}C_5H_4\text{-}CMe_2\text{-}C_5H_3)[Ru(CO)_2][Ru(CO)_2)H]$ are cleanly first order, but the kinetics of the formation of the twist hydride itself are more complex.[239] A very similar photochemistry has been observed with the heterobimetallic compounds $(\mu\text{-}Cp\text{-}CR_2\text{-}Cp)RuM(CO)_5$, where R = H, Me, M = Mo, W.[240]

Photolysis of Cp_2 $W_2(CO)_4(\mu\text{-dppm})$ in which the metals are tethered with a bidentate dppm ligand leads to C–H oxidative addition reactions analogous to the twist reactions described above (Scheme 8). The product in this case, $(\mu\text{-}\eta^{5:1}\text{-}C_5H_4)(\eta^5\text{-}C_5H_5)W_2(CO)_3(\mu\text{-}H)(\mu\text{-dppm})$, undergoes additional decarbonylation to yield $(\eta^5\text{-}C_5H_5)_2(\mu\text{-}CO)_2(\mu\text{-dppm})$ in which the oxidative addition is reversed.[241] The mixed W, Mo analog undergoes CO-loss to give $(\mu\text{-}\eta^{5:1}\text{-}C_5H_4)(\eta^5\text{-}C_5H_5)MoW(CO)_3(\mu\text{-}H)(\mu\text{-dppm})$ in which C_5H_4 is η^5 bonded to the tungsten and η^1 bonded to molybdenum.[242]

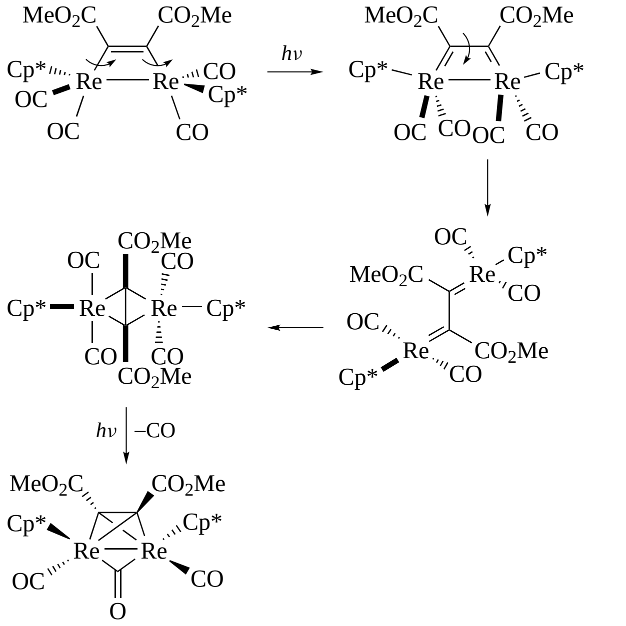
Photolysis of Re–Re bonded $Cp^*_2Re_2(CO)_4(\mu\text{-}\eta^1, \eta^1\text{-}MeO_2CC_2CO_2Me)$ with fluorescent light results in the clean rearrangement to $Cp^*_2Re_2(CO)_4(\mu\text{-}\eta^2, \eta^2\text{-}MeO_2CC_2CO_2Me)$. Further photolysis with UV light yields $Cp^*_2Re_2(CO)_2(\mu\text{-}CO)(\mu\text{-}\eta^2, \eta^2\text{-}MeO_2CC_2CO_2Me)$.[243] Time-resolved IR studies indicate that an intermediate is formed within <150 ns of irradiation. This intermediate transforms cleanly to $Cp^*_2Re_2(CO)_4(\mu\text{-}\eta^2, \eta^2\text{-}MeO_2CC_2CO_2Me)$ over a period of several ps. It is proposed that photolysis results in Re–Re bond homolysis and that the resulting acetylene bridged diradical rearranges to a bis(metallacarbene), or 1, 4-dimetallabutadiene (Scheme 9).[244]

Photolysis of $[\mu\text{-}\eta^5,\eta^5\text{-}(C_5R_4)_2SiMe_2]Ru_2(CO)_4$, R = H, Me, results in a dramatic molecular rearrangement with formation of $(\mu\text{-}\eta^{5:1}\text{-}C_5R_4)(\mu\text{-}\eta^5\text{-}C_5R_4SiMe_2)[Ru(CO)_2]_2$ in which the Ru–Ru bond and one Cp–Si bond are broken (Scheme 10).[237b,245] Similarly, photolysis of $(\mu\text{-}\eta^5, \eta^5\text{-}C_5H_4C_5H_4)Ru_2(CO)_4$ breaks both the Ru–Ru and Cp–Cp bonds resulting in the thermally reversible formation of $(\mu\text{-}\eta^5\text{-}C_5H_4)_2[Ru(CO)_2]_2$ (Scheme 11).[246] In both cases, these appear to be internal transformations.

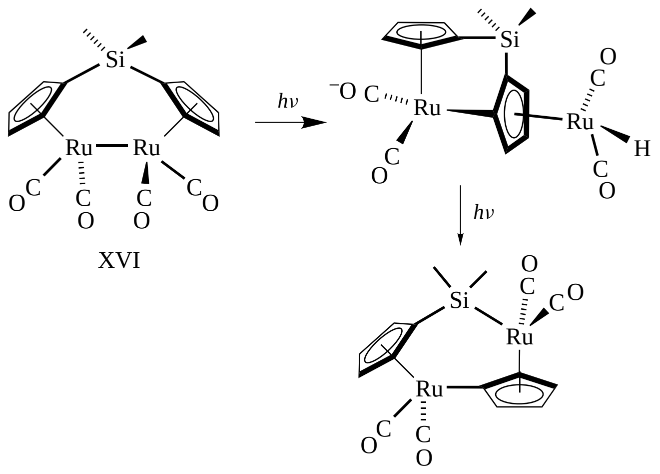
Photolysis of $Cp_2M_2(CO)_6$, M = Mo and W, or $Cp_2Fe_2(CO)_4$ under H_2 pressure gives rise to the corresponding metal hydrides, $CpM(CO)_nH$, by a mechanism that involves oxidative addition to the CO-loss species followed by reductive elimination to give $CpM(CO)_nH$ and $CpM(CO)_{n-1}H$



Scheme 8 Cp-H oxidative addition upon photolysis of $Cp_2Mo_2(CO)_4(\mu\text{-dppm})$. Ref. 241a



Scheme 9 Photochemical rearrangement of $Cp^*{}_2Re_2(CO)_4(\mu\text{-}MeO_2CC_2CO_2Me)$ via dimetallabutadiene intermediate. Ref. 244



Scheme 10 Sequential photolysis mechanism of (μ-η^5, η^5-Cp-SiMe$_2$-Cp)Ru$_2$(CO)$_4$ resulting in Si–Cp bond breaking (Ref. 237b)

(Scheme 12). Subsequent CO capture by this latter species gives a second mole of product.[247] It has been independently shown that CpM(CO)$_n$H, where M = Ru, Os, species lose CO upon photolysis in frozen matrices[228d] (see my Ru, Os paper).

Flash photolysis of the heterobinuclear compound, Cp(CO)$_3$Mo-Co(CO)$_4$, in 3MP glass results in loss of CO to form a solvated species with all terminal carbonyl groups. This species rearranges to give a product with a bridging carbonyl group. Comparison of the carbonyl bands of the solvated species with a number of derivatives of CpMo(CO)$_3$

and Co(CO)$_4$ led to the proposal that the initial CO-loss occurs only from the Mo. Photolysis of Cp(CO)$_3$Mo-Co(CO)$_3$L and Cp(CO)$_2$LMo-Co(CO)$_3$L, where L = PBu$_3$, generates a complex set of CO-loss intermediates.[248] In solution,

photolysis homolysis of the Mo–Co bond gives rise to radicals.[249]

7 REACTIONS OF PHOTOCHEMICALLY GENERATED RADICALS

The well known formation of radicals by M–M bonded bimetallic compounds has been exploited by Tyler and his group in the study of radical cage effects in a variety of media. Initial studies by this group on photodegradable polymers containing $Cp_2Mo_2(CO)_6$ or $Cp_2Fe_2(CO)_4$ units in the polymer backbone[250] led to a recognition that various ring substituted $Cp'_2Mo_2(CO)_6$ compounds could serve as probes of cage effects in solvents. A photochemical cage-efficiency factor, F_{cP}, defined as kcP/(kcP + kdP), where kcP is the rate constant for cage recombination of a photochemically generated radical cage pair and kdP is the rate constant for cage escape, is measured by determining the quantum yield of $Cp'Mo(CO)_3Cl$ formation as a function of viscosity in a solution consisting of two solvents of different viscosity and CCl_4 as a radical trap.[251] It is assumed that at sufficiently high concentrations of CCl_4, all radicals that escape the solvent cage will be trapped, thus it would be expected that formation of $Cp'Mo(CO)_3Cl$ should increase as solvent viscosity decreases as is observed. Alternatively, as the mass of the $Cp'Mo(CO)_3$ radical increases with the introduction of ring substituents the F_{cP} should increase.

A femtosecond photolysis study of $Re_2(CO)_{10}$ in CCl_4 and hexane has been interpreted in terms of the solvent acting as a viscous medium for $Re(CO)_5$ radicals.[252] Those $Re(CO)_5$ radicals that do diffuse out of the solvent cage may react with the chlorinated solvent to form $Re(CO)_5Cl$. The absence of IR bands for intermediates other than the $Re(CO)_5$ radical rule out the possibility of a 19-e intermediate, and support a mechanism in which involves only C–Cl bond activation.[253]

Photochemically generated radicals may also abstract halide ligands from other metal complexes. The reaction between $CpW(CO)_3$ radicals and $ClRh(dmgH)_2PPh_3$ yields $CpW(CO)_3Cl$ and $[Rh(dmgH)_2PPh_3]_2$. Kinetic studies confirm that the reaction proceeds by simple halide abstraction followed by dimerization of the $[Rh(dmgH)_2PPh_3]$ radical.[254]

8 METAL TO LIGAND CHARGE TRANSFER PROPERTIES

A substantial literature exists describing the photochemistry and photophysics of $Ru(bipy)_3^{2+}$ and related compounds, and progress on the study of these and related compounds has continued unabated since the first edition of the Encyclopedia of Inorganic Chemistry. Some properties of these compounds, such as their ability to transfer electrons, have been exploited by Gray, Barton, and others to explore the electron transmission through proteins and DNA, while a second thrust of research has been directed toward injecting electrons into the conduction band of wide band gap semiconductors such as TiO_2. These applications will be discussed below. As we have seen above, the availability of new ultrafast spectroscopic detection methods have pushed the examination of charge transfer processes into the femtosecond range. Driven partially by the availability of time-resolved IR and resonance Raman methods mixed carbonyl/diimine compounds have been extensively examined.

$Ru(bipy)_3^{2+}$ is the prototype of a very large family of MLCT species. In the standard model of the photoprocesses of this compound, a photon excites the molecule to an initial Frank-Condon singlet state, ^{1}MLCT, that rapidly transforms to a triplet, ^{3}MLCT, with a quantum yield of near unity.[255] Femtosecond pump probe experiments have established a half-life of about 100 fs for the formation of the triplet state.[256] Recent studies utilizing femtosecond time-resolved fluorescence emission spectroscopy has observed fluorescence emission from the Frank-Condon state itself and the lifetime of this state has been estimated to be 40 ± 15 fs.[257]

A long standing question concerning the degree of charge delocalization in the initially formed ^{3}MLCT state has been resolved. It has been known for some time that the long-lived ^{3}MLCT state of $Ru(bipy)_3^{2+}$ has a dipole of ca. 14 D,[258] requiring that the charge be localized on one of the bipyridinyl ligands. Time-resolved IR studies have unambiguously established the charge localization nature of the excited state species on the 100-ns time scale.[259] Absorption,[260] transient circular dichroism,[261] Raman[262] and electroabsorption (Stark effect)[263] experiments suggested the direct formation of a localized excited state, while emission spectral studies[264] lent support for an initially formed delocalized state that rapidly evolves to a localized state. Very recent ultrafast absorption anisotropy measurements provide strong evidence for a delocalized intermediate that decays to a localized intermediate in 50–173 fs depending upon the solvent. It was suggested that the charge localization is coupled to or controlled by the inertial solvent dynamics occurring in response to the photo-induced charge transfer.[265] Variable-temperature emission studies have been used to probe the coupling between solvent dynamics and solute structure.[266]

A large number of studies have been directed toward understanding the excited state behavior of metal complexes containing both carbonyl and diimine ligands. The presence of the carbonyl chromophore serves as a reporter ligand for electronic changes taking place within the molecule. In general, MLCT transitions increase the positive charge at the metal thus reducing the extent of back bonding and causing metal carbonyl vibrations to shift to higher frequencies. Interligand transitions such as IL$\pi\pi*$ states often result in a modest increase in electron density at the metal and hence a shift of the carbonyl frequencies to lower values. Ligand field transitions that were once

believed to play a significant role in the photophysics of these species have been shown by calculation to be far too large to meaningfully participate. Instead, M → CO MLCT transitions appear to be more energetically favorable than previously believed. We noted above in the context of metal carbonyl complexes the radical transformation this necessitates in our understanding of events such as photochemical carbonyl-loss. The dominant ligands examined in these studies have been bipyridinyl, phenanthroline, and their many derivatives, and bulky alkyl derivatives of 1, 4-diazabutadiene (DAB). Some representative examples of compounds studied include: $M(CO)_4$(diimine), where M = Cr, Mo, W, $M(CO)_3X$(diimine), M = Mn, Re, X = H, halide, alkyl, and $Ru(CO)_2(X)(R)$(diimine), where X = halide.

The group VI compounds $M(CO)_4$(DAB) were first prepared by Tom Dieck and his coworkers in the 1960s[267] and their strong solvatochromism arising from the antiparallel dipole of the excited state was reported shortly thereafter.[268] Resonance Raman studies established the relationship between the MLCT absorption and several molecular vibrations, most notably the carbonyl stretching frequencies.[269] The resonance Raman spectra of this class of compounds has been reviewed.[270] Vlček has published a detailed review of the photophysics and photochemistry of the group VI diimine compounds.[271]

As noted above, strong bands in the visible spectra of $M(CO)_4$(diimine) complexes are associated with a MLCT transition that is sensitive to the character of the ligand as well as the solvent environment. In the light of high level TD-DFT[272] and CASSCF/CASPT2[273] calculations, a weaker band or shoulder in the 400–370 nm region that had been associated with ligand field transitions[274] has now been reassigned to an M → CO MLCT transition. The high molar absorptivity of the bands at ca. 400 nm in $M(CO)_4$(diimine) and $M(CO)_4$(en) (for which there are no accessible ethylenediamine π^* states for MLCT) lend further support to this reassignment.

The photochemical loss of CO from $M(CO)_4$(diimine) complexes continues to be exploited for synthetic purposes,[275] and as a probe for the photophysics of the excited states. Photosubstitution quantum yields depend upon the wavelength of irradiation, nature of the diimine ligand, the metal, and the incoming ligand. Dissociative ligand field excitations have been observed while the mechanism of substitution upon MLCT excitation depends upon the nature of the metal and incoming ligand.[276] A long standing belief that ligand field dissociations were attributable to ^{3}LF states have been challenged with observations on $W(CO)_4$(en),[277] $Cr(CO)_4$(bipy)[278] and $W(CO)_5L$, L = 4-cyanopyridine, 4-formylpyridine[279] that suggest that photodissociation occurs directly from the singlet state prior to intersystem crossing to form the triplet. In light of the discussion above concerning the reassignment of LF transitions to M → CO MLCT transitions, it is likely that the M → CO MLCT singlet may be the actual reactive state.

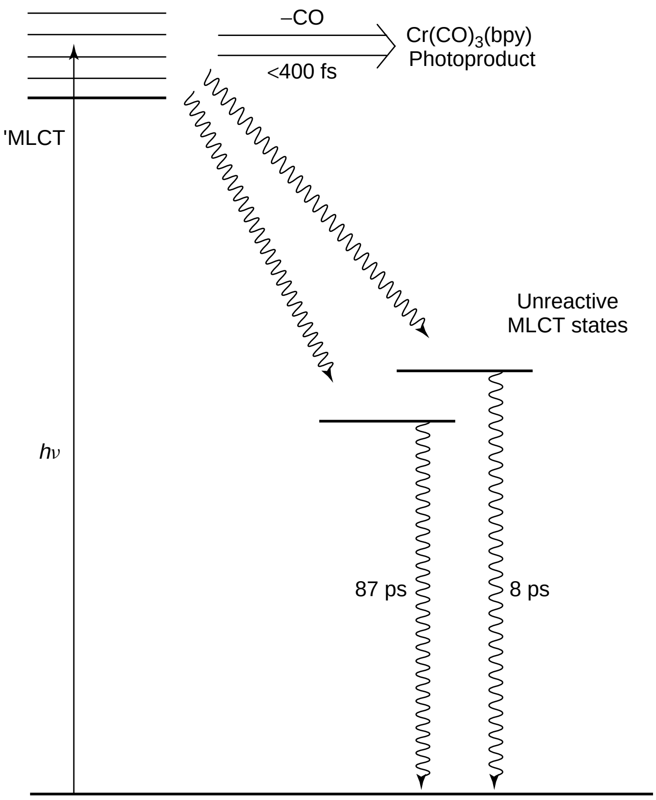

Figure 16 Excited state dynamics of $Cr(CO)_4$(bipy). (Reprinted with permission from Ref. 280b. © 1999 American Chemical Society)

The role of singlet and triplet MLCT states has also been brought into question. In the case of $Cr(CO)_4$(bipy) excitation into the MLCT band gives rise to an excited singlet Frank-Condon species that decays in less than 400 fs either through a prompt loss of an axial CO, or relaxation to two triplet states that decay independently (8 and 87 ps, respectively) to the ground state.[280] The excited state dynamics of $Cr(CO)_4$(bipy) is illustrated in Figure 16.

The group VII diimine compounds, $M(CO)_3X$(diimine), where X = halide, H, Me, Et, Bz, or metal fragments such as $Mn(CO)_5$, or $M(CO)_4L$(diimine), where L = nitrogen base, have been extensively studied. Notably, excited states of the rhenium compounds are better reducing and oxidizing agents than the ground-state species,[281] lending themselves to processes such as CO_2 reduction.[282] $\{Re(CO)_3[P(OEt)_3]bipy\}^{1+}$ has been shown to be a particularly efficient catalyst for the reduction of CO_2.[283]

Examination of the emission behavior of $Re(CO)_3X$(diimine), X = Cl, Br, I, diimine = bipy, *i*Pr-DAB, established that variation in halogen alters both the energy of the emission and the character of the lowest emitting state itself. For chloride, the lowest energy excited state is MLCT, while for iodide the excited state gains more halide character and is better described as an X → π^*(diimine) XLCT excitation.[284]

A qualitative MO scheme comparing the chloride and iodide complexes is presented in Figure 17. The XLCT states are characterized by longer lifetimes and are better luminophores because of higher emission quantum yields.[285] MO calculations on the manganese analogs show a mixing of metal and halide contributions to the excited states.[286] The photodissociation and electronic spectroscopy of the hypothetical $Mn(CO)_3H(H\text{-}DAB)$ has been modeled using wave packet propagations on CASSCF/MR-CCI potentials. Relevant to the nature of the excited states, a low lying, visible absorption band was found to correspond to a $3d_{xz} \rightarrow \pi^*$(DAB) MLCT excitation, while a UV band had

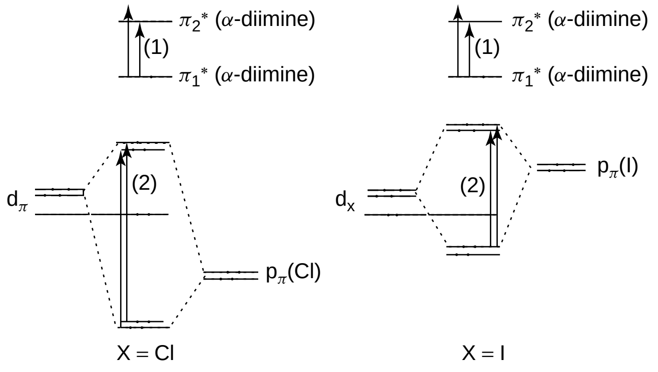

Figure 17 Qualitative MO scheme for $Re(CO)_3Cl$(diimine) and $Re(CO)_3I$(diimine). (Reprinted with permission from Ref. 285b. © 1996 American Chemical Society)

components of both $3d_{yz} \rightarrow 3d_{xy}$ and $\sigma_{Mn-H} \rightarrow \pi^*$(DAB) excitations.[287]

The shifts in excited state character described above arises from the relative energies of the d orbitals and either the sigma bond to X or the p(π) electrons on X. This effect is clearly seen with the alkyl series: Me, Et, and Bz. Photolysis of $Re(CO)_3R$(*i*-Pr-DAB) results in efficient homolysis for Et and Bz, but not for Me. These observations were rationalized by comparing the relative energies of the MLCT and σ_b(Re–R)π^* states.[288] Photoelectron spectra of the methyl derivative demonstrated that the ionization energy of the σ_b (Re–Me) orbital is higher than that of the d_π(Re) orbitals. While the photoelectron spectrum of the ethyl complex could not be recorded, photoelectron spectra of analogous $(CO)_5MM(CO)_3$(*i*-Pr-DAB), where M and M′ = Mn or Re, were recorded. In the metal–metal bonded compounds the σ_b orbitals were found to have ionization energies below those of the d_π(Re) orbitals.[289] These metal–metal bonded species are known to undergo homolysis upon photolysis.[290] The excited state of $Re(CO)_3Bz$(*i*-Pr-DAB) has been directly observed by time-resolved electronic and IR spectroscopies. The relatively long lifetime of the excited state species (ca 250 ns) and the relatively small positive shift of the carbonyl frequencies both are indicative of a $\sigma\pi^*$ MLCT excited state rather than a Re → DAB MLCT state.[291] Both the methyl and benzyl derivatives of $Re(CO)_3R$(bipy) undergo homolysis upon UV photolysis.[292]

Very recent ultrafast dynamics studies have demonstrated that the Frank-Condon ^{1}MLCT state of $Re(CO)_3R$(dmb), dmb = 4,4′-dimethyl-2,2′-bipyridine, undergoes rapid ($\leq$400 fs for Me, ca. 800 fs for Et) branching into two channels, a homolysis channel via a ^{3}SBLCT (triplet σ-bond to ligand charge transfer) or to a ^{3}MLCT state. For the methyl derivative, the ^{3}MLCT state is lower in energy than the ^{3}SBLCT state. The ^{3}MLCT state decays with a 35 ns lifetime to the ground state. Methyl homolysis occurs with a quantum efficiency of 0.4 (293 K). In contrast, the ^{3}MLCT state of the ethyl derivative lies above that of the ^{3}SBLCT state and can decay into it with a lifetime of 213 ps (in CH_2Cl_2). The homolysis quantum yield of the ethyl derivative is unity with both prompt and delayed channels to homolysis.[293] These pathways are illustrated in Figure 18. Chemically induced dynamic electron polarization pattern (CIDNEP) studies of the photochemically generated alkyl radicals support a triplet assignment to the dissociative state.[294] CASSCF/MR-CCI calculations on $M(CO)_3(H)$(H-DAB), where M = Mn, Re, complexes underscore the significance of the relative energies of the MLCT and SBLCT states in directing the progress of these homolysis reactions.[295]

The photochemical behavior of the $Mn(CO)_3X$(diimine) compounds differs from that of the rhenium compounds in that CO-loss becomes a significant competitive process. For example, $Mn(CO)_3X$(bipy), where X = Cl, Br, I, and $Mn(CO)_3X$(*i*-Pr-DAB), where X = Cl, Br, and Me, have all been shown to lose CO as a primary photochemical step.[296] The differences in photochemistry between the rhenium and manganese compounds have been attributed to the differing M–CO bond strengths.[297] For $Mn(CO)_3Bz$(*i*-Pr-DAB) and the metal–metal bonded derivatives,[298] $(CO)_5Mn\text{-}Mn(CO)_3$(diimine), where diimine = bipy, *p*-tol-DAB, radical formation is observed. Perhaps the most interesting case (Scheme 13) is that of *fac*-$Mn(CO)_3X$(bipy) for which initial photolysis results in loss of CO from an equatorial position followed by a rapid shift of the halide to the open position creating an axial vacancy.[299] Recapture of CO yields *mer*-$Mn(CO)_3X$(bipy). Surprisingly, the *mer* isomer undergoes photolysis with homolysis of the Mn–X bond.[300] A DFT analysis has provided an explanation of both the initial equatorial CO-loss and halide shift events.[301]

Charge-transfer-to-solvent reactions are a special class of MLCT processes. Commonly a halogenated solvent serves as the acceptor with formation of a halide ion and a radical. Subsequent reaction chemistry between the oxidized metal species and either the halide ion or radical may take place.[302] For example, photolysis of $Fe(et_2dtc)_2(CO)_2$ in $CHCl_3$ results in formation of $Fe(et_2dtc)_2Cl$ via electron transfer to solvent from a MLCT excited state.[303] Similarly, photolysis of $(Cp\text{-}CH_2\text{-}Cp)Fe_2(\mu\text{-}CO)_2(\mu\text{-}dppm)$ in $CHCl_3$

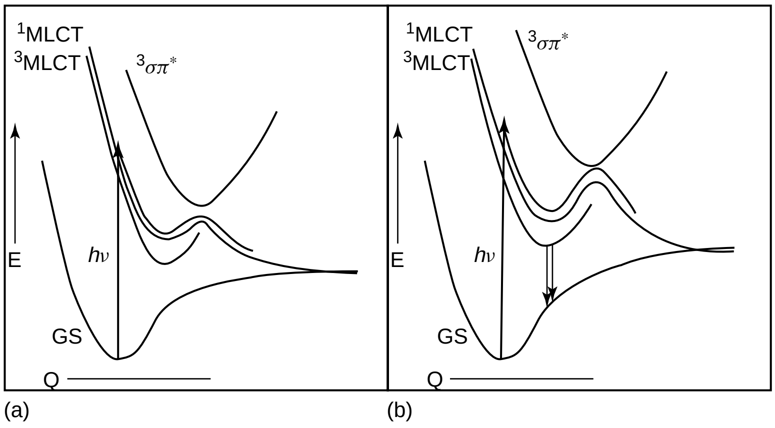

Figure 18 Schematic representation of the potential energy curves of the ground, ^{3}MLCT, ^{1}MLCT, and $^3\sigma\pi^*$ states of $Re(CO)_3R(dmb)$ with R = Et, Bz, and *i*-Pr (a) and R = CH_3 and CD_3 (b). Note that the barrier to dissociation for CH_3/CD_3 is substantially larger than that of Et, Bz, and *i*-Pr accounting for the differences in radical quantum yield. (Ref. 293a. Reproduced by permission of Wiley-VCH)

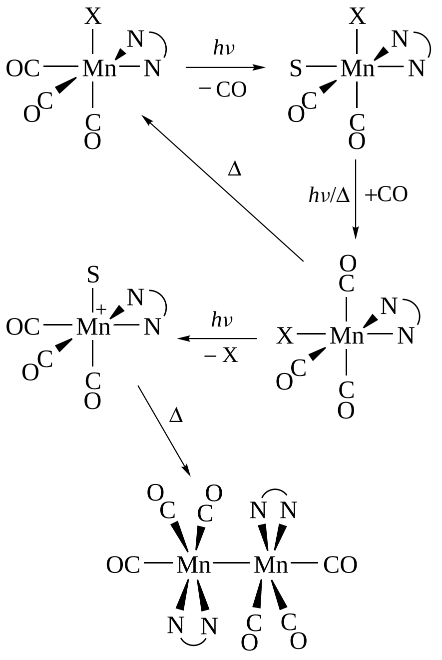

Scheme 13 Mechanism of *fac*-$Mn(CO)_3X$(diimine) to *mer*-$Mn(CO)_3X$(diimine) and subsequent loss of X radical. Ref. 300a

results, after workup, in the isolation of (CHOCp-CH_2-Cp)Fe_2(μ-CO)$_2$(μ-dppm) arising from the reaction of a $CHCl_2$ radical with the radical cation of (Cp-CH_2-Cp)Fe_2(μ-CO)$_2$(μ-dppm) followed by transformation to the aldehyde.[304] Photolysis of $CpL_2M{\equiv}CR$, where M = Mo, W, L = CO, P(OMe)$_3$, R = Ph, Me, cyclopropyl in halogenated solvents results in oxidation of the complex. Electron transfer from the MLCT excited state of the carbene to solvent is the likely cause of oxidation.[305]

9 APPLICATIONS OF CHARGE TRANSFER EXCITATION

As noted above, photochemical MLCT excited state species can be better electron acceptors and donors than their ground-state species. The photochemical reduction of CO_2 was noted in which the excited state of photostable $Re(CO)_3X$(diimine) complexes interact with a sacrificial electron donor to give $[Re(CO)_3X(diimine)]^{1-}$.

Direct transfer of an electron from the excited state to the conduction band of semiconductors has been extensively explored.[306] Of particular interest is the development of low cost alternatives to silicon based photovoltaic devices.[307] Efficient electron transfer is achieved when an excited state of sensitizer species is matched to the conduction band energies of a semiconductor. For example, the Frank-Condon states of $Ru(bipy)_2X_2$, where X = SCN, CN, or $Ru(CO)_3Cl$(bipy) and related species are compatible with the conduction bands of TiO_2, ZnO, and SnO_2 (Figure 19). Direct measurement of the rate of electron injection has been achieved by nano- or femtosecond mid-IR measurements[308] of a broad feature (1600–1800 cm^{-1}) assigned to electrons in the conduction band of TiO_2.[309] The rates of injection have been found to be dependent upon the nature of the sensitizer, the semiconductor, and the nature of their interaction. For $Ru(bipy)_2(SCN)_2$ type sensitizers, the rate of electron injection into TiO_2, SnO_2, and ZnO were found to be ~50 fs, ~4 ps, and ~100 ps, respectively. The differences were attributed to a d orbital based conduction band in TiO_2 and s orbital based conduction band in SnO_2 and ZnO. Alternately this can be described as a difference in the density of states in the conduction band. A detailed study of the electron transfer revealed two channels. A fast (fs) injection is attributed to electron transfer from the singlet Frank-Condon excited state,[310] while slower (ps) transfer arises from a long-lived triplet MLCT state.[311] The sensitivity of the electron injection rates to wavelength and to

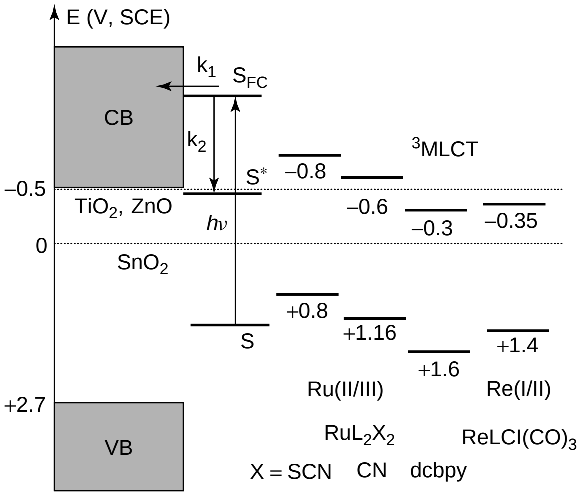

Figure 19 Schematic diagram of electron injection and energetics of sensitizers and semiconductors. (Reprinted with permission from Ref. 313. © 2001 American Chemical Society)

the redox potential of the sensitizer species provides further support for this model.[312] It is suggested that the interligand electron transfer processes may play a role in determining the rates from the triplet state. Lian and his coworkers have presented a comprehensive review of these studies.[313]

The length of the spacer connecting a sensitizer to the surface has also been shown to be significant with the rate of electron transfer decreasing with increasing spacer length.[314] For carboxylate functionalized sensitizer molecules, the number of carboxylate groups, that is, the number of possible points of attachment with the metal oxide surface, determines the efficiency of electron transfer.[315] Comparisons of electron injection kinetics for TiO_2 sensitized with Ru(4,4′-dicarboxy-2,2′-bipyridyl)$_2$(SCN)$_2$, and its tetrabutyl ammonium salt provide evidence for a role for coadsorbed protons in the electron injection process.[316]

As noted above, MLCT excited states of diimine metal complexes are both better reductants and oxidants than the ground-state species. This property has been exploited by Gray, Barton, and others for the study of proteins, DNA, and other biological molecules. Flash/quench experiments were first developed to provide a high driving force method to measure rates of electron transfer in proteins.[317] In these experiments an excited diimine complex, typically a member of the Ru(bipy)$_2$(diimine)$^{2+}$ family of complexes, is oxidatively quenched with $Ru(NH_3)_6{}^{3+}$, $Co(NH_3)_5Cl^{2+}$, or methyl viologen, or reductively quenched with *p*-methoxy-*N*,*N*-dimethylaniline to yield a highly active redox species.

Barton has carried out extensive studies into the transport of charge through DNA utilizing the flash/quench method to inject charge.[318] In the absence of imperfections to the DNA stack, electron transport to sites 200 Å away from the point of charge injection have been observed.[319] These studies, which have been extensively reviewed,[320] forced a significant paradigm shift[321] in understanding of the mechanism of charge transport through the overlapping π-stack of the base pairs in DNA. Indeed, disruption of charge transport is diagnostic of base bulges,[322] mismatches,[323] or the presence of nonaromatic residues[324] in the DNA π-stack. The importance of intercalation of the metal sensitizer has been established through comparisons of intercalating and nonintercalating species covalently bound to the terminus of an oligonucleotide sequence.[325] In these studies, the 5′-G of a 5′-GG-3′ guanine doublet served as a measure of charge transport as this doublet has been shown to be particularly sensitive to oxidative damage.[326]

Studies of the rate of electron transport through the DNA using acceptors and donors that were intercalated but not covalently bound to the DNA established very high rates of ground-state recombination on the order of 10^{10} sec^{-1}, but ambiguities as to the relative spacing of the intercalated species complicated the interpretation.[327] To fully clarify the ability of the DNA stack to transport charge, a series of metal modified DNA duplex assemblies were prepared in which donor and acceptor species were covalently bound to the ends of the assembly (Figure 20). Using 15 base pair assemblies donor/acceptor distances on the order of 41 Å could be achieved and a lower limit of 3×10^9 sec^{-1} was measured.[328]

The broad field of photoreactions between Ru and Os complexes and DNA has been reviewed with an emphasis on tuning the excited state properties of the organic ligands so as to optimize electron transfer as opposed to ligand substitution.[329]

Gray and his coworkers have examined electron transport through proteins utilizing flash/quench techniques.[330] Recent studies have employed Ru(bipy)$_3{}^{2+}$ bound to an alkyl or aryl chain terminated with imidazole, adamantly or ethylbenzene functions. The chains thread themselves down channels in proteins placing the functionality within the pocket of a metalloenzyme active site where they effectively transfer charge from the ruthenium complex to the interior of the protein.[331] The P450 conjugate with ethylbenzene terminated Ru(bipy)$_3{}^{2+}$ is illustrated in Figure 21. Very high speed charge transfer using these materials permits the creation of reaction intermediates that do not accumulate in significant quantities using natural reductants.

Electron transport between cubane [Fe_4S_4] clusters,[332] cytochrome *c*,[333] or Cu^{1+} centers in blue copper proteins[334] and the periphery of the proteins has been examined by complexing ruthenium species to surface histidines. In the case of the iron sulfur cubane in *Chromatium vinosum*, four surface histidines served as points of ruthenium attachment. The rates of electron transport from the Fe_4S_4 core to ruthenium varied over two orders of magnitude and were used to diagnose the preferred channel for electron transport. Cysteine and lysine residues have also been used as binding sites in studies of cytochrome *c*[335,336] and cytochrome P450 cam[337] proteins.

The photochemical electron transfer triggering of folding of proteins such as cytochrome *c* has been examined.[338]

10 LIGAND REACTIONS AND REARRANGEMENTS

Time-resolved optical and time-resolved IR methods have been employed by Ford and his coworkers to probe the intermediates involved in the migratory insertion of methyl groups to carbonyl groups utilizing the principle of microscopic reversibility. Photolysis of metal-acyl derivatives, $M(CO)_nC(O)Me$ typically results in loss of CO. For $Mn(CO)_5C(O)Me$, a long-lived, transient species was observed whose spectrum showed only modest sensitivity to solvent.[339] These results were interpreted in terms of an η^2-acyl intermediate similar to that observed for $Co(CO)_3C(O)Me$ in argon matrices.[340] In contrast, room temperature, time-resolved IR studies of $CpFe(CO)_2C(O)Me$ and $IndFe(CO)_2C(O)Me$ suggest that a solvento species is the more likely intermediate in all solvents studied.[341] Figure 22 presents a 3-D stack plot of the absorbance changes in the carbonyl region for $CpFe(CO)_2(C(O)CD_3)$. In low-temperature (195 K) MCH, an unusually large frequency shift of the intermediate compared to the unphotolyzed species was taken as evidence of an η^2-acyl intermediate. It was suggested that there may be a strong temperature dependence of the solvated and η^2-acyl forms in weakly coordinating solvents. These studies have been reviewed.[342]

Aqueous solutions of $MeReO_3$ have been found to be very light sensitive. Analysis of the reaction products established methane and ReO_3 as products. In chlorinated solvents, CH_3Cl formed pointing to C–Re bond homolysis as a likely mechanism. Molecular orbital diagrams of $MeReO_3$ suggest that the HOMO is the Re-CH_3 bond with an e* LUMO that is antibonding toward the Re=O bonds. LMCT transitions would be expected to result in the observed bond homolysis (Figure 23).[343] In Ar matrices, photolysis of $MeReO_3$ gives rise to $CH_2{=}ReO_2OH$. It is proposed (Scheme 14) that the primary photochemical event is Re–C bond homolysis, and

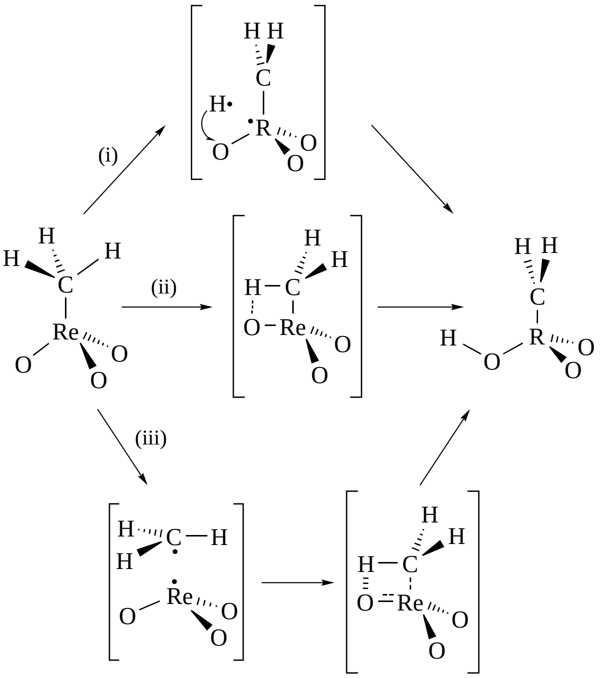
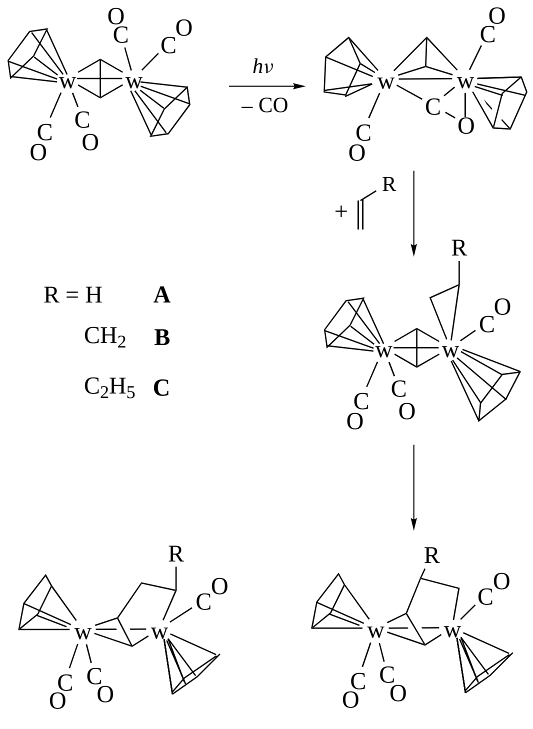


Scheme 14 Possible mechanism for photoconversion of $Re(CH_3)O_3$ to $Re(CH_2)(OH)O_2$ in an Ar matrix at ca. 14 K. Ref. 344a

that the resulting methyl and rhenium radicals recombine with cleavage of a C–H bond.[344] The similarity of $CH_2{=}ReO_2OH$ to species that have been proposed as intermediates in olefin metathesis and isomerization reactions was noted.[345] Continued photolysis of $CH_2{=}ReO_2OH$ yields a species with a single CO group. By analogy to the photochemical rearrangement of siloxiranylidene to H2SiCO upon photolysis in Ar matrices[346] the rhenium product is tentatively assigned as $H_2Re(CO)(O)OH$.

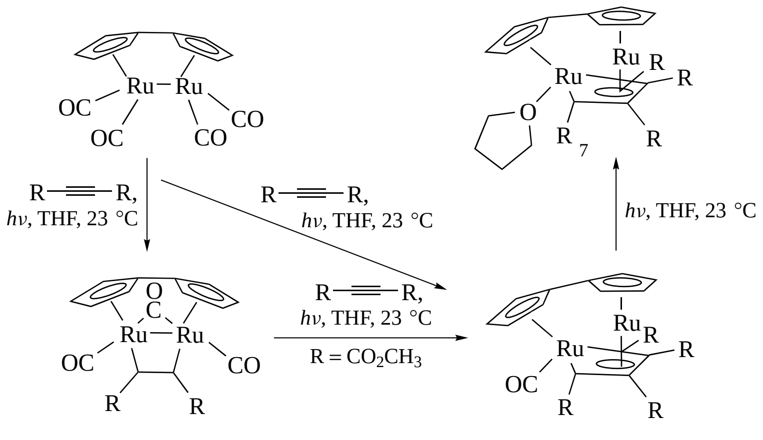
Me_3ReO_2[347] and Me_4ReO[348] have been examined in Ar matrices and found to undergo photolysis with loss of methane and formation of $CH_2{=}Re$ intermediates. Secondary photolysis of $CH_2{=}Re(CH_3)O_2$ results in formation of $(CH_2{=})_2Re(O)OH$. Me_3ReO_2 has recently been shown by gas electron diffraction to have a highly distorted trigonal bipyramidal geometry in which the two oxygen ligands occupy pseudoequatorial positions and the axial Me-Re-Me bond angle is 146°.[349]

Reactions of organic ligands within the coordination sphere of a metal result in carbon–carbon bond formation and has been recently exploited as a high-yield route to cycloaddition reactions. Photolysis of $Cp'_2M_2(CO)_4(\mu\text{-}\eta^{2:2}\text{-}C_2H_2)$, where $Cp' = C_5H_4C_4H_9$, has been shown by Nujol matrix photochemistry to eject a CO with formation of a species with a bridging or 4-electron bridging carbonyl.[350] This electron-deficient intermediate may react with any number of alkene or alkyne compounds to give a simple η^2-alkene or alkyne species that undergoes subsequent C–C bond formation joining the organic fragments (Scheme 15).[351] For example, reaction of $Cp_2Mo_2(CO)_4(\mu\text{-}\eta^{2:2}\text{-}C_2H_2)$ with ethene yields $Cp_2Mo_2(CO)_3(\mu\text{-}\eta^{1:4}\text{-}1$, 3-butadien-1-yl) and $Cp_2Mo_2(CO)_3(\eta^4$-butadiene) with the latter being the thermodynamically stable species.[352] Clearly significant reorganization of the ethyne, ethene complex must accompany formation of the butadiene species and possible mechanisms for these rearrangements are discussed by Kreiter.[353] Prior to Kreiter's photochemical studies, Knox *et al.* carried out thermal reactions of $Cp_2M_2(CO)_4(\mu\text{-}\eta^{2:2}$-alkyne) derivatives with alkynes and isolated analogous polyene 'flyover' derivatives.[354]



Scheme 15 Reaction mechanism for alkene addition to $Cp_2W_2(CO)_4(\mu\text{-}\eta^{2:2}$-alkyne). Ref. 353

Photolysis of the fulvalene derivative, $(\mu\text{-}\eta^5\text{-}\eta^5\text{-}C_5H_4C_5H_4)Ru_2(CO)_4$, with trans-2-butene yields mono and disubstituted species, $(\mu\text{-}\eta^5\text{-}\eta^5\text{-}C_5H_4C_5H_4)Ru_2(CO)_3L$ and $(\mu\text{-}\eta^5\text{-}\eta^5\text{-}C_5H_4C_5H_4)Ru_2(CO)_2L_2$, where L = 2-butene. Some rearrangement of the trans-2-butene to cis-2-butene was observed. In contrast, photolysis of $(\mu\text{-}\eta^5\text{-}\eta^5\text{-}C_5H_4C_5H_4)Ru_2(CO)_4$ with $MeO_2CC_2CO_2Me$ gives $(\mu\text{-}\eta^5\text{-}\eta^5\text{-}C_5H_4C_5H_4)Ru_2(CO)_2(\mu\text{-}\eta^1, \eta^1\text{-}MeO_2CC_2CO_2Me)$ in which

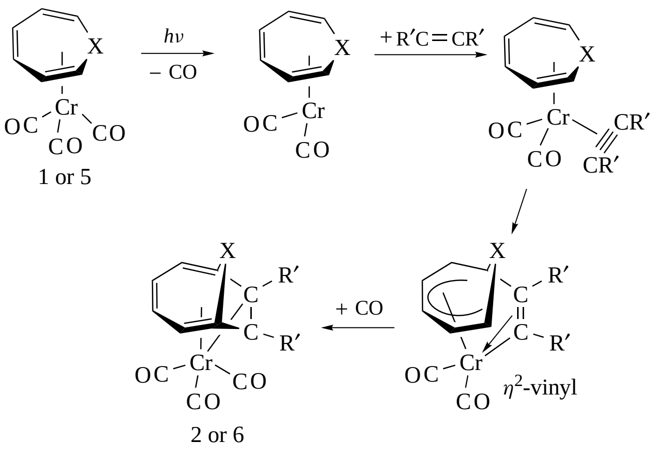


Scheme 16 Reaction products upon photolysis of $(\mu\text{-}\eta^5, \eta^5\text{-Cp-Cp})Ru_2(CO)_4$ and $MeO_2CC_2CO_2Me$ in THF. Ref. 355

the acetylene ligand bridges parallel to the Ru–Ru bond. Continued photolysis of this species in the presence of alkyne gives the metallacyclopentadienyl derivative, $(\mu\text{-}\eta^5\text{-}\eta^5\text{-}C_5H_4C_5H_4)Ru_2(CO)[\mu\text{-}\eta^2, \eta^4\text{-}C_4(CO_2Me)_4]$ (Scheme 16).[355]

Metal-mediated cycloaddition reactions serve to bring together organic fragments in pericyclic reactions beyond the range typically observed in classical organic chemistry. For example, the Diels-Alder reaction of a diene with a dienophile is described as a $[4+2]$ cycloaddition. So-called higher order metal promoted cycloaddition reactions include $[4+4]$, Ni(O),[356] $[5+4]$, Rh(I),[357] and $[5+2]$, Rh(I),[358] cycloadditions. These reactions have recently been reviewed.[359] Photolysis of chromium complexes containing η^6 ligands and manganese complexes containing η^5 ligands have expanded the range of cycloaddition reactions to include $[6+2]$, $[6+4]$, $[5+2]$, and $[5+4]$ cycloadditions. Photolysis of $(\eta^6\text{-}C_7H_8)Cr(CO)_3$,[360] $(\eta^6\text{-}C_8H_8)Cr(CO)_3$,[361] $(\eta^5\text{-}2,4\text{-}Me_2C_5H_5)Mn(CO)_3$,[362] or $(\eta^5\text{-}C_6H_7)Mn(CO)_3$[363] results in loss of CO to yield an electron-deficient species that may react with alkynes or alkenes to give bicyclo derivatives. Additions to $(\eta^6\text{-}C_8H_8)Cr(CO)_3$ are also known.[364] In those cases where a diene or alkyne is used with $(\eta^6\text{-}C_7H_8)Cr(CO)_3$ isolable $(\eta^{4:2}$-bicyclo[4.4.1]undeca-2,4,8-triene)$Cr(CO)_3$ or $(\eta^{4:2}$-bicyclo[4.2.1]nona-2,4,7-triene)$Cr(CO)_3$,[365] derivatives are formed. Reactions of alkynes with $(\eta^5\text{-}C_6H_7)Mn(CO)_3$ give $(\eta^{3:2}$-bicyclo[3.2.1]nona-2,6-dien-4-yl)$Mn(CO)_3$.[366] Where a substituted alkene is employed as a reactant, the resulting $(\eta^4$-bicyclo[4.2.1]nona-2,4-diene)$Cr(CO)_3$ is unstable to ligand loss. In the presence of excess cycloheptatriene these reactions can be catalytic. Heteroatom groups in the cycloheptatriene ring, C_6H_6X, have also been utilized,[367] as have cycloheptatriene ligands with pendant alkene and butadiene groups.[368] Isocyanates and ketenes add in a manner analogous to alkenes.[369] Chiral resolution of substituted cycloheptatriene chromium complexes permits the stereoselective addition of alkenes and alkynes yielding chiral bicyclic products.[370] A vast literature exists exploiting metal catalyzed higher order cycloaddition reactions for the synthesis of bi and tricyclo organic species and several reviews have been published.[371]

Mechanistic studies of the metal catalyzed cycloaddition reactions establish the intermediacy of a species bearing cyclopolyenyl or cyclopolyene ligand and a π -bound alkene or alkyne. Low-temperature solution studies established that coupling takes place in two steps, often with rearrangement of the alkene or alkyne fragments. This process is illustrated for alkyne addition to a cycloheptatriene ligand in Scheme 17.



Scheme 17 Proposed mechanism for $[6+2]$ cycloaddition. Ref. 366

The Pauson–Khand reaction typically involves the thermal reaction of a $Co_2(CO)_6(\mu\text{-}\eta^{2:2}$-alkyne) with alkene to form a substituted cyclopentenone. A photochemical version of this reaction has been reported.[372] Matrix studies of $Co_2(CO)_6(\mu\text{-}\eta^{2:2}$-alkyne) have established that CO-loss occurs from a single position, but that photochemical rearrangement of the $Co_2(CO)_5(\mu\text{-}\eta^{2:2}$-alkyne) photointermediate readily takes place.[373] Reaction of this intermediate with alkene is followed by coupling to form the cyclopentenone product.

The discovery of the synthesis of β-lactams by photolysis of chromium carbene complexes with imines[374] has led to an extensive application of group VI Fischer carbene photochemistry to organic synthesis. By analogy, intramolecular reactions of aldehydes give β-lactones.[375] In the presence of olefins, these reactions give rise to cyclobutanones,[376] while reactions with alcohols or amines yield carboxylic acid derivatives.[377] Examination of a series of derivatives, $(CO)_4LCrC(OEt)Me$, where L = CO, PPh_3, PBu_3, and $(CO)_3(dppe)CrC(OEt)Me$ established that increasing the σ-donor (or conversely decreasing the π-acceptor) ability of ligands suppresses the β-lactone formation in reactions with imines.[378] The ability of chromium carbenes to accommodate a range of heteroatom functions, $(CO)_5Cr{=}C(R)X$, where X = OR, NH_2, NHR, NR_2, SR, and PR_2, and their relative simplicity of preparation presents with organic chemist with a wide palette of choices in synthesis. The organic chemistry of the photochemical reactions has been extensively reviewed.[379]

The reactions described above appear to parallel known reactions of ketenes, thus most of the mechanistic interpretations have presumed an intermediate in which a ketene is stabilized by the metal center.[380] A good many studies have been directed toward understanding the photochemistry of Fischer carbenes, and observing the putative ketene intermediate. UV/visible spectroscopy of tungsten carbenes typically consist of three bands, a very weak band above 500 nm assigned to a spin-forbidden MLCT, a moderately intense band ca. 400 nm assigned as a spin-allowed MLCT, and a second moderately intense band ca. 350 nm assigned to a LF transition.[381] There is some evidence for an additional LF band masked by the MLCT band.[382] For the corresponding chromium species these band maxima are often shifted to higher energy. The MLCT bands are photochemically insensitive, while the LF bands are

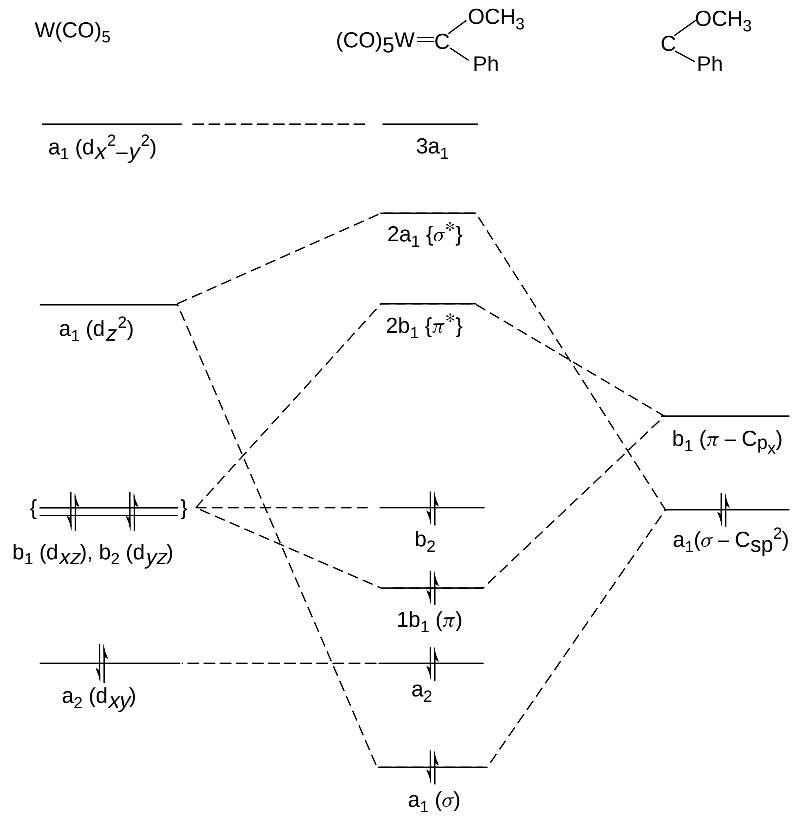


Figure 24 Simplified 1-electron energy level diagram for $(CO)_5WC(OMe)Ph$. (Reprinted with permission from Ref. 381. © 1983 American Chemical Society)

found to be responsible for the observed photoreactivity. It should perhaps be noted that almost all interpretations of the spectroscopy of these compounds have been based on an MO diagram (Figure 24) originally reported by Block, Fenske, and Casey[383] and subsequently modified by Geoffroy.[384] Recent MO studies based on dft methods offer new insight into the bonding of the Fischer carbenes and develop an orbital correlation diagram that is importantly nuanced from the more traditional view, Figure 25.[385] In particular, the recognition that the Cr-C-X π-interaction is a three-center, 4-electron bond reverses the order of the σ and π bonds between the metal and carbene fragments and redefines the HOMO to be one component of this bonding interaction. Significantly, these new results are in excellent agreement with PES studies of these carbene compounds.[386]

Ligand exchange studies on Fischer carbenes demonstrate that photolysis results in exclusive *cis* substitution.[387] Resonance Raman[388] and matrix studies[389] demonstrate that photolysis into the MLCT band of $(CO)_5MC(OMe)Ph$, where M = Cr, W, initiates an anti $\rightleftharpoons$ syn isomerization of the methoxy group. Time-resolved Raman studies have established that this transformation occurs in <10 ns.[390] Photolysis into the LF band causes both carbene isomerization and CO-loss.[391] Time-resolved resonance Raman studies demonstrated that photolysis of $(CO)_5WC(OMe)Ph$ in acetonitrile into the LF band results in CO-loss and formation of a solvated intermediate as well as a second intermediate in which the vacant site appears to be blocked by an agostic interaction between the methoxy methyl and the tungsten.[392] Very careful matrix studies have now effectively ruled out the formation of a metal-ketene species.[384] An interesting set of studies comparing a set of chromium carbene compounds known to undergo reaction with imines to form β-lactams with a second set that have low photochemical reactivity established that the former compounds underwent reaction with N_2 or ethene dopants while the second group did not. Solution flash studies showed that the rate of reaction between the CO-loss species and CO was solvent dependent while the latter group was not.[393] As of this writing, the identity, or even existence, of an intermediate that mimics metal-ketene behavior is still quite unsettled. It is likely that application of ultrarapid time-resolved IR methods will be necessary to resolve the current conundrum.

Interestingly, thermal reactions of olefins with Fischer carbenes give rise to cyclopropanation products.[394] Although relatively rare, photochemical cyclopropanations have been reported.[395]

11 PHOTOCRYSTALLOGRAPHY

Linkage isomerism is a well known phenomenon in inorganic chemistry[396] with the recognition that ligands such as nitrite might exist in both oxygen (nitrite) and nitrogen (nitro) bound forms dating back to the dawn of modern inorganic chemistry.[397] The recognition that linkage isomerism could be initiated by light is much more recent having been first reported for $Co(NH_3)_5(NO_2)^{2+}$ by Adell.[398] A group of significant new studies build upon photocrystallography, an important new technique pioneered by Coppens and his coworkers. The methodology

for photocrystallography has been reviewed.[399] In essence, photocrystallography is a low-temperature matrix method in which crystallographic data sets are compared before and after photolysis to produce a photodifference map from which the electron density and atomic positions of a metastable species may be calculated.

The first application of photocrystallography was directed toward resolving a long standing puzzle involving low temperature, photochemically generated, metastable states of nitroprusside that had first been observed in 1977.[400] Coppens' studies established the two metastable states to be the oxygen bound, isonitrosyl, and the side-on, η^2-NO, linkage isomers of the nitrosyl ligand (Figure 26).[401] This assignment has recently been confirmed by neutron scattering studies.[402] Matrix studies of the photochemistry of CpNi(NO) by Rest had demonstrated a photoproduct with an exceptionally low NO stretch the identity of which was left unresolved.[403] It has now been demonstrated by photocrystallography that the species is the η^2-NO linkage isomer, Figure 27.[404] Several additional examples of nitrosyl linkage isomerism have been identified.[405] Sulfur dioxide linkage isomerism has been observed in $[Ru(NH_3)_4(H_2O)(SO_2)]^{+2}$ has been observed[406] as has N_2 linkage isomerism in $[Os(NH_3)_5N_2]^{2+}$.[407]

In a remarkable extension of photocrystallography, the high intensity beam line at the National Synchrotron Light Source at the Brookhaven National Laboratory has been used in a stroboscopic diffraction experiment to determine the molecular structure (Figure 28) of the 50 µs lifetime, triplet excited state of $[Pt_2(pop)_4]^{4-}$.[408] In these studies, high intensity laser flashes are followed immediately by 33 µs X-ray pulses, Figure 29. The photochemistry of $[Pt_2(pop)_4]^{4-}$ has been extensively studied[409] and the ability of the excited state to abstract hydrogen atoms has been employed in the cleavage of duplex DNA by abstraction of both the 4′ and 5′-hydrogens from the 2′-deoxyribose groups.[410] Polarized electronic absorption measurements had predicted a Pt–Pt bond contraction upon excitation owing to a $5d\sigma^* \rightarrow 6p\sigma$ excitation.[411] These predictions have been confirmed by the

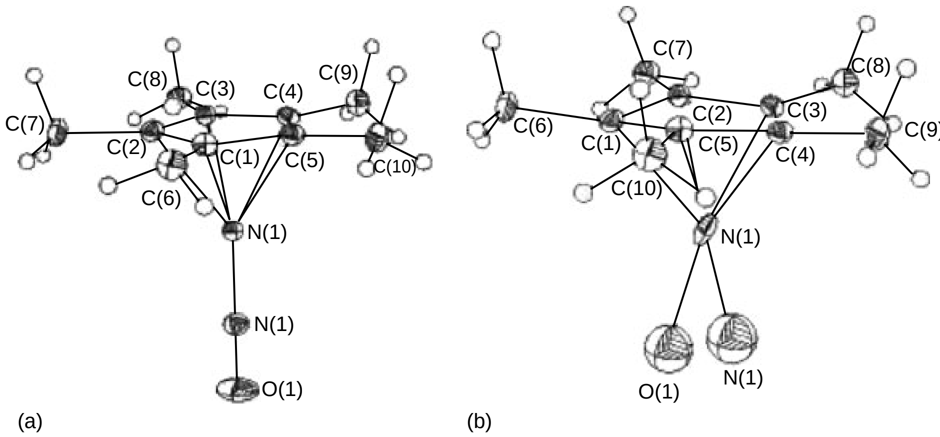

Figure 27 Ortep diagrams of CpNi(NO) (a), and its side-on, η^2-NO, (b) linkage isomer[404]

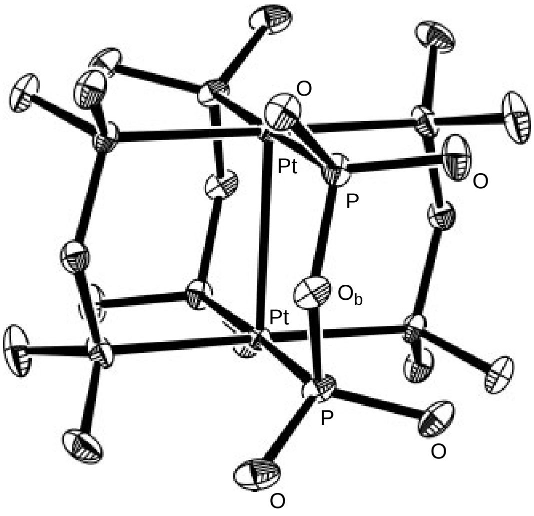

Figure 28 Ortep diagram of the $\{Pt_2(pop)_4\}^{4-}$ ion[408a]

photocrystallographic studies that demonstrate a contraction of the 2.9126(2) Å ground-state bond length by 0.28(9) Å in the excited state. These results are consistent with an estimate of a 0.225 Å change based on shifts in the Raman Pt–Pt stretching frequency,[412] and have been independently confirmed by a second time-resolved diffraction study.[413] Photocrystallographic methods for the investigation of molecular excited states have been reviewed.[414]

12 LINKAGE ISOMERISM AND LIGAND CONFORMATIONAL CHANGES

As noted above, photocrystallography has been used to identify nitrosyl linkage isomers in a variety of molecules. The unambiguous identification of these linkage isomers has permitted firm identification to be made in other cases where matrix studies indicated photochemical changes in nitrosyl environments. For example, rhenacarborane nitrosyl compounds, [1, 2-R_2-3, 3-$(CO)_2$-3-NO-*closo*-3, 1, 2-$ReC_2B_9H_9$], where R = H and Me, undergo photolysis to give both isonitrosyl and η^2-NO isomers depending upon the energy of the incident radiation.[415] $[CpM(CO)_2NO]^{1+}$, where M = Mn, Re, were studied in inert ionic matrices, NEt_3OctPF_6, and were found to undergo linkage isomerism upon photolysis.[416] In fact, continuing studies suggest that photochemical linkage isomerism may be the rule rather than the exception for this class of compounds.

The allyl ligand in $CpM(CO)_2(\eta^3\text{-}C_3H_7)$, where M = Mo, W, is known to assume both endo and exo orientations relative to the cyclopentadienyl ring.[417] Nujol and frozen gas matrix studies of the molybdenum compound have demonstrated that low-energy photolysis results in selective transformation of the endo form to the exo form.[418] The transformation is attributed to an excitation that populates the σ^* orbital of the bond responsible for fixing the geometry of the allyl ligand. Earlier observations on the tungsten compound were reinterpreted in light of these observations.[419]

13 APPLICATIONS OF PHOTOCHEMICAL REACTIONS

13.1 Catalysis

A number of strategies for the photochemical initiation of anion or cation catalyzed polymerization have been explored. For example, visible photolysis of the Reineckate anion, $[Cr(NH_3)_2(NCS)_4]^{1-}$, has long been known to release a thiocyanate ion.[420] Photolysis of the Reineckate anion in the presence of ethyl cyanoacrylate initiates polymerization.[421] The release of acac anions, and benzoylcyclopentadienyl

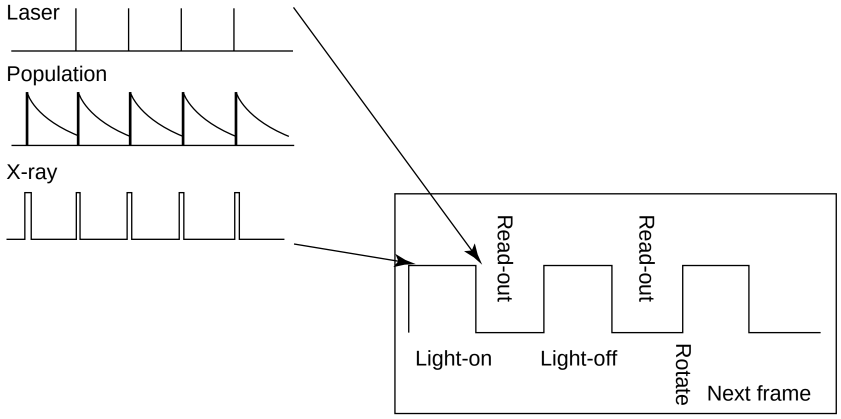

Figure 29 Time-structure and data collection sequence for stroboscopic diffraction experiments indicating the relationship between laser flash, photointermediate production, and X-ray data collection. (Ref. 414b. Reproduced by permission of Royal Society of Chemistry)

anions from $Pt(acac)_2$,[422] and 1,1′-dibenzoylferrocene,[423] respectively, have also been used as polymerization initiators. In the latter case resonance Raman studies have shown that the transition responsible for anion release has MLCT character.[424]

Photolysis of $(arene)_2M^{2+}$, where M = Fe, Ru, initiate arene loss by reduction of hapticity of the arene ligand followed by sequential introduction of solvent as the arene is fully displaced. In the case of $(arene)_2Ru^{2+}$ the relative wavelength insensitivity of quantum yields for arene loss, and the ability to initiate ligand loss by spin exchange from acetophenone argue for a triplet photoactive state.[425] In the case of the $(mes)_2Fe^{2+}$ complex, deligation occurs from both the MLCT and LF transitions.[426]

The photochemistry of $Cp(arene)Fe^{1+}$ complexes has been extensively examined since the discovery of photochemical arene loss by Nesmeyanov,[427] and this class of compounds has received considerable attention as a cationic photocatalyst for the polymerization of epoxides,[428] dicyanate esters,[429] and styrene[430] among others. As in the case of the bis(arene)metal complexes described above, photolysis is believed to initiate an $\eta^6 \rightarrow \eta^4$ transformation whereupon solvent enters the open site and thermally displaces the arene ligand. Consistent with this the quantum yields indicate a significant associative component in the ligand displacement.[431] Time-resolved studies indicate that the initial photochemical event occurs on the fs or ps scale.[432] There has been substantial confusion concerning the role of singlet and triplet excited states in the observed photochemistry. Sensitization studies established a reactive role for the triplet manifold, but did not exclude a role for the excited singlet states.[433] Recent detailed quantum yield studies at several wavelengths have established that arene loss occurs from both singlet and triplet excited states. It has been noted elsewhere in this review that singlet and triplet excited states differ considerably in their reactivity toward ligands, and it is proposed that these reactivity differences account for the quantum efficiency differences in the $Cp(arene)Fe^{1+}$ series.[434] A summary of the proposed excited states is presented in Figure 30.

The identity of the actual catalytic species in polymerization reactions has been obscured by the fact that the $CpFeS_3{}^{1+}$ species itself can undergo further decomposition to $FeS_6{}^{2+}$ and Cp_2Fe. In an elegant series of experiments, Kutal has utilized electrospray mass spectrometry to directly observe species generated within ms of photolysis. In these experiments, a solution containing catalyst in acetonitrile, ACN, or 1, 2-dichloroethane containing cyclohexene oxide, CHO, were photolyzed in the electrospray tip using an optical fiber coupled to a laser. By varying the distance of the fiber from the end of the spray tip the time delay from photolysis to observation of products could be changed. The arrangement of this apparatus is illustrated in Figure 31.These experiments confirmed the presence of $CpFe(ACN)_2{}^{1+}$, and $CpFe(ACN)_3{}^{1+}$ in the reaction mixture after photolysis. When CHO was present in solution, a suite of species, $CpFe(H_2O)(CHO)_n{}^{1+}$, where $n = 1{-}5$, were observed. It is speculated that some of the higher n species contain oligomers of CHO.[435]

Several reviews describing the use of metal complexes as photochemical polymerization initiators have appeared.[436]

14 PHOTOPHARMACEUTICAL APPLICATIONS

Nitrogen oxide is now known to play a broad role in biological processes including vasodilation, infection defense, and intercellular signaling. Considerable effort has been devoted to the design of compounds capable of delivering NO to a targeted site with one strategy being the photoliberation of NO.

Vasodilation studies of isolated rat tail arteries have demonstrated that $Fe_4(NO)_4(\mu_3\text{-}S)_4$ and $Fe_4(NO)_7(\mu_3\text{-}S)_3$, Roussin's black monoanion, thermally release NO in solution[437] and that this release is enhanced by visible light.[438] Roussin's black anion and red dianion, $Fe_2(NO)_4(\mu\text{-}S)_2$, are photoactive toward NO release, however, cell culture experiments have shown Roussin's black anion to be toxic making it an unlikely candidate for biological applications.[439] Chinese hamster cell cultures incubated with Roussin's red dianion showed a marked sensitization to γ-radiation cell death when simultaneously irradiated with visible light. Nitric oxide release by Roussin's black anion requires oxygen and results in formation of ferrous ions and ferric precipitates.[440] The red dianion produces the black anion upon photolysis. The so-called Roussin's esters, $Fe_2(NO)_4(\mu\text{-}SR)_2$ are attractive bases for pharmaceutical NO delivery systems in that the R groups can be modified to enhance specificity. Photolysis of water-soluble derivatives in aerated solutions results in release of all four NO groups. Flash photochemical studies suggest that the loss of NO is reversible in deaerated solutions, but that in the presence of oxygen the $Fe_2(NO)_3(\mu\text{-}SR)_2$ species irreversibly reacts with oxygen leading to complete decomposition.[441] Ru(salen)(ONO)(NO), salen = N,N'-ethylenebis(salicylideneiminato) dianion, and related Ru salen derivatives[442] and *trans*-Cr(cyclam)$(ONO)^{2+}$, cyclam = 1, 4, 8, 11 tetraazacyclotetradecane,[443] have been shown to release NO upon photolysis and are attractive targets for biological NO delivery. The studies by the Ford group have been reviewed.[444]

1 INTRODUCTION

The visible–UV absorption spectrum of transition metal complexes is characterized by a high density of various electronic excited states (metal-centered, metal-to-ligand-charge-transfer, ligand-to-ligand-charge-transfer, sigma-bond-to-ligand-charge-transfer, intra-ligand, ligand-to-metal-charge-transfer). The presence of electronic states of different character, structure, reactivity, and dynamics in a limited domain of energy gives to this class of molecules exceptional photophysical and photochemical properties. The richness of their photochemistry[1,2] is mainly governed by their electronic flexibility (*see* ***Photochemistry of Transition Metal Complexes***). Two contrasting behaviors following irradiation can be considered: (1) the molecular system is trapped in long-lived excited states of a well-defined structure, leading to the beautifully resolved absorption/emission spectroscopy or electron/energy transfer; (2) the molecule lands on repulsive potential energy surfaces inducing extremely fast ligand dissociation in a femtosecond timescale. The bipyridine-substituted complexes intensively studied over the last 30 years are representative of the first category,[3] whereas transition metal carbonyls illustrate the second behavior.[4] Most of the time, bound and repulsive electronic excited states coexist in a limited domain of energy and may interfere in the Franck–Condon region, generating structureless absorption spectra. The interaction between various electronic states in different regions of the potential energy surfaces leads to critical geometrical structures such as saddle points, conical intersections, or local minima. Consequently, the observed response to the light of the molecular system is entirely governed by the sequence of many concurrent elementary processes. The development of short time-resolved spectroscopy[5] (picoseconds–femtoseconds timescale) in different domains (resonance Raman, FT-infra-red, FT-electron paramagnetic resonance, emission, absorption UV/visible) has contributed to a better understanding of excited-state structures as well as of fast processes. However, several fundamental questions still remain unresolved. One important aspect is the differentiation between (1) chemically active electronic states leading to the formation or breaking of bonds, isomerization, and production of radicals and (2) long-lived excited states involved in the photophysics or subsequent secondary processes such as electron/energy transfer. The complicated mechanisms, which underlie the photoreactivity, involve different electronic states, various reaction paths, and elementary processes such as direct/indirect dissociation, internal conversion, or intersystem crossing. The simulation of the dynamics following the photon absorption should describe two different situations: (1) ultrafast direct dissociation from the absorbing state itself (adiabatic process) and (2) indirect dissociation via internal conversion or intersystem crossing (nonadiabatic process).

The determination of the timescales and of the several channels of deactivation of the excited molecule is essential. For this reason, a strong interplay between experiments and theory is mandatory. The first role of the theoretical study is to elucidate the electronic structure of the molecules, to determine the low-lying electronic transitions, and to assign

the observed bands. This is probably the easiest task and several computational methods started to emerge in the 1990 s able to describe with reasonable accuracy electronic spectroscopy in transition metal complexes. The second aspect associated with the calculation of accurate multidimensional potential energy surfaces describing the reactivity of electronic excited states is the bottleneck of the theoretical study. The main difficulty is related to the dimensionality of the problem, which cannot be solved exactly because of the large number of nuclear coordinates and electronic states. This implies a selective choice of a few degrees of freedom in the treatment of the dynamics that has to include several coupled electronic excited states, either nonadiabatically or by spin-orbit.

2 STATE CORRELATION DIAGRAMS

Until the beginning of the 1980s, the understanding of transition metal photochemistry was based on molecular orbital diagrams coupled with an analysis in terms of bonding and antibonding character.[6] It was generally assumed that photodissociation was a consequence of exciting an electron from a bonding to an antibonding orbital. However, this conceptually appealing chemical analysis has a number of drawbacks: (1) how is the observation of concurrent photochemical reactions at a given wavelength explained; (2) why visible irradiation into the metal-to-ligand-charge-transfer band leads to the loss of a carbonyl in manganese α-diimine complexes [M(R)$(CO)_3$(α-diimine)], whereas the result of this irradiation on rhenium analogs gives rise to the homolytic cleavage of the Re–R bond; (3) how is the occurrence of a given photochemical reaction upon excitation at different wavelengths with quantum yields relatively insensitive to this factor analyzed? A more spectroscopic approach based on the ligand field excited-state theory was developed simultaneously in order to analyze and predict the changes of bonding properties when going from the electronic ground state to the excited state and to explain the stereo selectivity in photosubstitution reactions.[7] The photostereochemistry and electronic selection rules in strong field d^3 and d^6 transition metal complexes have been described by means of the properties of the relevant wave functions and orbital/state correlation diagrams.[8]

On the basis of the state correlation diagram depicted in Figure 1, which connects the different stereoisomers of the pentacoordinate fragment $[Rh(NH_3)_4Cl]^{2+}$, Vanquickenborne *et al.* infer the main characteristics of the complicated photochemical mechanism in $[Rh(NH_3)_4Cl_2]^+$ and related complexes. This work gave the first evidence that the formulation of electronic selection rules was underlying the photosubstitution mechanism in d^3 and d^6 complexes. In principle, this idea was applicable to any complex with any coordination number. However, at this stage the greatest experimental detail and the most advanced theoretical development limited the theoretical study to the ligand field (d to d excitation or metal-centered) excited states of six-coordinate complexes of metals of d^3 or d^6 configurations. The development of new quantum chemical methods including electronic correlation effects and the accessibility to powerful computers has enabled the computation of states energy levels with a better accuracy (see Section 3). Nowadays, it is possible to describe semiquantitatively the electronic ground state and low-lying excited states of the reactant and primary photoproducts, and to build more reliable state correlation diagrams based on spin and symmetry properties.

State correlation diagrams have helped identify the active excited states of a number of photochemical reactions[6] on the basis of spin and symmetry rules, leading to a clearer picture of the mechanism of photodissociation. The state correlation diagram in Figure 2 that connects the electronic ground state (a^1A') and the low-lying singlet and triplet MLCT and SBLCT states of the reactant to those of the primary products describes the observed homolytic cleavage of the metal−R bond in [M(R)$(CO)_3$(α-diimine)] complexes. The qualitative mechanism underlying this photochemical reaction involves nonadiabatic transitions (intersystem crossing, internal conversion) occurring after the absorption to the low-lying ^{1}MLCT states, which lead to the biradicals primary products $R^\bullet + M(CO)_3$(α-diimine) originating from the ^{3}SBLCT dissociative state. If the state correlation diagrams are a useful mere approximation of the one-dimensional potential energy curves (PEC) and constitute a good starting point of a more realistic theoretical study, they are subject to several limitations. In particular, they give no information about the role of intersystem crossing and ignore the energy barriers that do not result from avoided crossings.

3 QUANTUM CHEMICAL METHODS

The first goal is to obtain accurate transition energies (within 0.10−0.15 eV) and reliable dipole transition moments in order to assign bands located in the UV-visible spectral domain of energy in various transition metal complexes. The second aspect relates to the calculation of PES or cuts along specific nuclear coordinates describing the reactivity of electronic excited states. When handling transition metal complexes, the quantum chemical calculations giving access to the potential energy and to the properties involved in electronic spectroscopy and photochemical reactivity (transition dipole moments, spin-orbit coupling, nonadiabatic coupling) cannot be routinely performed.[9] However, efficient theories and algorithms combined with the availability of very fast computers has enabled such challenging computations, which have to be carried out with care. This section aims at describing the theoretical procedures and the most significant developments in the field.

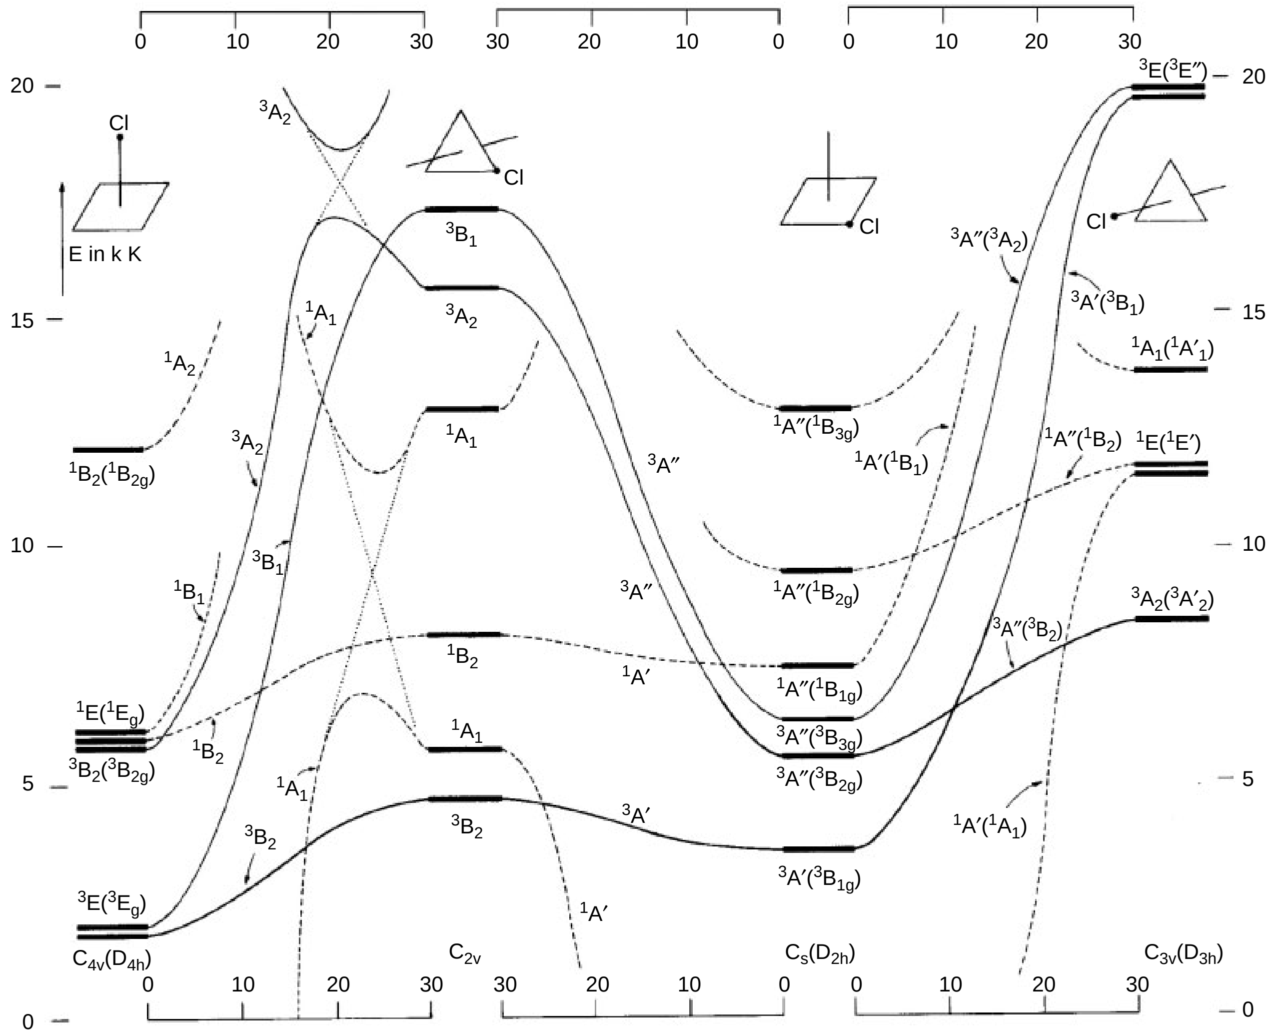

Figure 1 State energy correlation diagram connecting the four $[Rh(NH_3)_4Cl]^{2+}$ species (square pyramid (Cl axial), trigonal bipyramid (Cl equatorial), square pyramid (Cl equatorial), trigonal bipyramid (Cl axial)). Triplets are shown in full lines and singlets in dotted lines.[8] (Reprinted with permission from Ref. 8. © 1978 American Chemical Society)

The size of the molecular system, its symmetry, and the density of states as well as the saturation of the metal center d shells or the metal–ligand interactions will generate particular difficulties. The choice of the method will be a compromise taking into account the following factors: (1) the feasibility and computational cost; (2) the validity of some approximations; (3) the wanted level of accuracy; and (4) the control that can be performed on the analysis of the results. Four types of methods based on different mathematical formalisms are available for treating electronic spectroscopy in transition metal complexes:[9] (1) the density functional theory (DFT) like the delta self-consistent field (Δ-SCF) and the time-dependent density functional theory (TD-DFT); (2) the variational approaches such as the self-consistent field (SCF), configuration interaction (CI), multiconfiguration self-consistent field (MC-SCF), multireference configuration interaction (MR-CI); (3) the cluster expansion methods such as the equation-of-motion–coupled cluster single double (EOM-CCSD), the symmetry adapted cluster configuration interaction (SAC-CI); (4) the single state (SS) or multistate (MS) second-order perturbational approaches applied to zeroth-order variational wave functions and so-called single state complete active space perturbation theory second order (SS-CASPT2) and MS-CASPT2 (Scheme 1).

3.1 Variational Methods

The few attempts at describing excited states in transition metal complexes within the restricted Hartree Fock (RHF) formalism were rapidly abandoned because of computational difficulties (convergence of the low-lying states in the open-shell formalism) and theoretical deficiencies (inherent lack

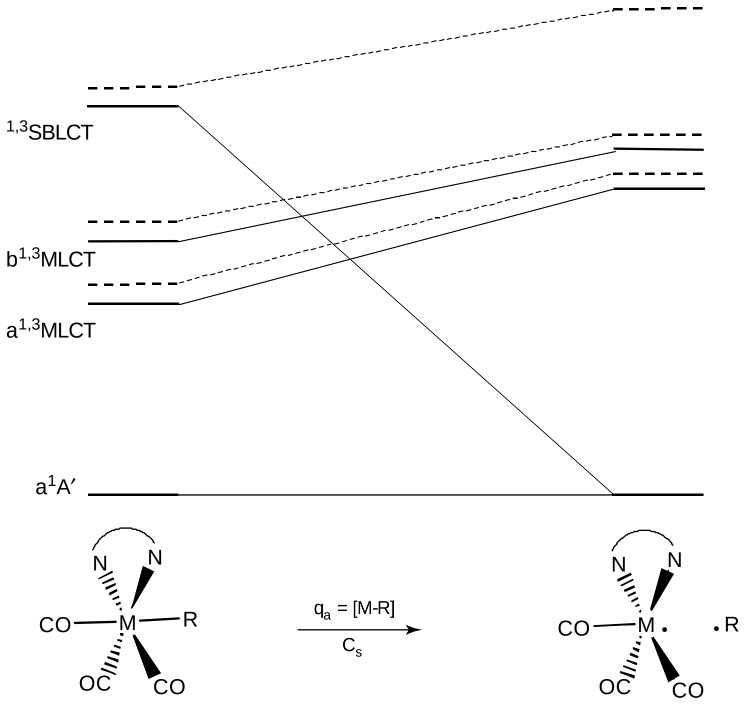

Figure 2 State energy correlation diagrams connecting the low-lying singlet and triplet metal-to-ligand-charge-transfer (MLCT) states and sigma-bond-to-ligand-charge-transfer (SBLCT) states of $(R)M(CO)_3(\alpha\text{-diimine})$ to the corresponding states of the M–R bond homolysis primary products $R^{\bullet} + {}^{\bullet}M(CO)_3(\alpha\text{-diimine})$

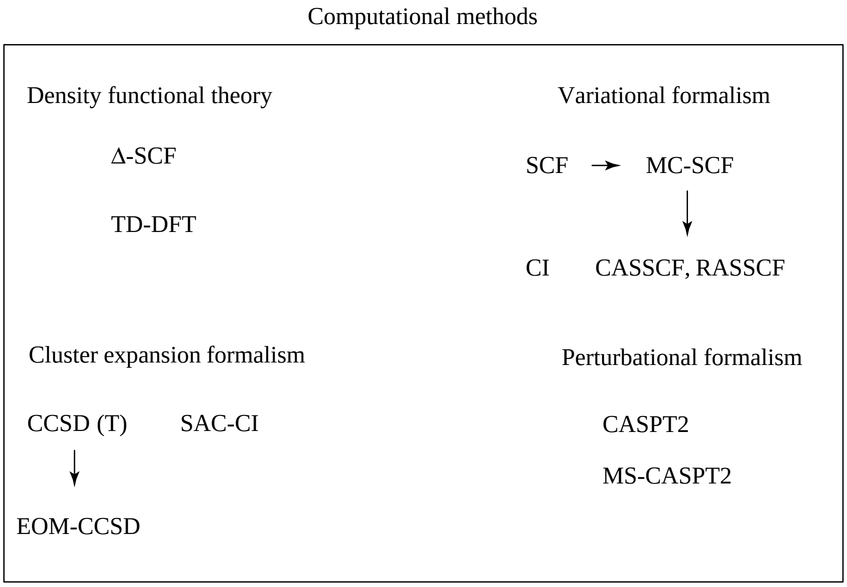


Scheme 1

of electronic correlation, inconsistent treatment of states of different multiplicities, and d shell occupations). The simplest and most straightforward method to deal with correlation energy errors is the CI approach where the single determinant HF wave function is extended to a wave function composed of a linear combination of many determinants Φ_i in which the coefficients C_i are variationally optimized.

$$\psi_{\mathrm{CI}} = \sum_i C_i \Phi_i \tag{1}$$

Within the CI formalism, the configuration mixing is introduced (multideterminantal approach) but the predetermined reference set of molecular orbitals is not reoptimized for the different electronic states. However, most of the time and especially in transition metal complexes, strong correlation effects affect the electron density. Therefore, it is necessary to optimize the molecular orbitals according to a multiconfigurational scheme including static electronic correlation effects, which describe the interaction between two electrons in a pair at large separation space. The so-called MC-SCF method and its extension CASSCF (complete active space self-consistent field)[10] or RASSCF (restricted active space self-consistent field)[11] methods have their origin in this fundamental problem. In the MC-SCF method, the energy is minimized with respect to the molecular orbitals relaxation (term κ) and the CI expansion, and the wave function is given by the following expression,

$$\psi_{\text{MC-SCF}} = \exp(-\hat{\kappa}) \sum_i C_i \Phi_i \qquad (2)$$

These methods provide zero-order wave functions used as references in subsequent CI, MR-CI, or multistates complete active space perturbation theory second order (MS-CASPT2) calculations, which take into account the dynamical correlation effects describing the interaction between two electrons at a short interelectronic distance (so-called cusp region). The MC-SCF approach is even more crucial in excited-states calculations where the mixing of electronic states and the dramatic changes of electron density during the excitation process have to be taken into account. The large variation in the number of d electrons pairs among the various electronic states is a major difficulty when correlated methods are applied to transition metal complexes. The most widely used MC-SCF method is the CASSCF based on a partitioning of the occupied molecular orbitals into subsets corresponding to how they are used to build the wave function. The problem is reduced to the partition into sets of active and inactive orbitals and to a selection of correlated electrons. This discriminating strategy based on the physics and chemistry of the study includes all configuration state functions (CSFs), which are generated by distributing the active electrons among the active orbitals in all possible ways consistent with the spin and the symmetry of the wave function. In practical applications, where the number of configurations may exceed 10^6, such a partitioning is not straightforward. The validity of the subsequent MR-CI or MS-CASPT2 treatments depends entirely on the quality of the CASSCF wave function. This strategy, which is not easily automated, cannot be used as a black box. Most of the time, the orbitals are optimized for the average energy of a number of excited states large enough to include the electronic spectrum of interest. This procedure avoids root inversions as well as convergence problems, and leads to a set of orthogonal wave functions of given spin and symmetry and to transition densities of reasonable accuracy used in property calculation (dipole transition moments). The transition energies accuracy is obtained by the addition of the remaining correlation effects by means of MR-CI or MS-CASPT2 calculations. If the active space chosen is large enough according to the physicochemical aspect of the problem, results of high accuracy will be produced by the CASSCF/CI procedure, where the configuration selection scheme on the top of the CASSCF wave function is performed by single and double replacement out of either a single reference (CI) or multireference space (MR-CI). The slow convergence of the method, the size of which increases dramatically with the number of references, and the default of size-extensivity leading to incorrect scaling of the energy with the number of correlated electrons are very limiting for a general use of the MR-CI formalism in nontrivial applications. However, the CASSCF/MR-CI approach is actually the only ab initio method leading to reliable PES describing electronic excited-state reactivity in transition metal complexes.

3.2 Second-order Perturbational Approach

An alternative to the fully variational approach depicted above is a mixed procedure where a multiconfigurational variational method is used to build a zero-order wave function supplemented by a second-order perturbational treatment of the dynamical correlation effects. The so-called complete active space perturbation theory second order (CASPT2) and its multistate extension MS-CASPT2 methods[11] are size-extensive and give very accurate transition energies as soon as the zero-order variational wave function includes the correct spectroscopy of the system under study. Otherwise the perturbational treatment is no longer valid because of the presence of intruder states interacting with the reference space, and the treatment is not included at the zero-order level. This leads to an erratic behavior of the perturbation and out of range transition energies of more than 2.0 eV. In these nontrivial cases, either a level-shift technique has to be applied with care (weak intruder states) or the CASSCF active space has to be increased (strong intruder states) as illustrated by the theoretical study of the spectroscopy of $Mn_2(CO)_{10}$ or $HRe(CO)_5$.[12,13] If this method is the method of choice for the determination of accurate transition energies in transition metal complexes (see Section 6), it seems less adapted to the calculation of PEC or PES due to the inconsistent behavior of intruder states along the reaction pathways.

3.3 Cluster Expansion Methods

The cluster expansion methods are based on an excitation operator, which transforms an approximate wave function into the exact one according to the exponential ansatz

$$\Psi = \exp(T)|0\rangle \qquad (3)$$

where T is a sum of single- to N-particle excitation operators (coupled-cluster theory)[14] or of the symmetry adapted single- to N-particles excitation operators (symmetry adapted cluster theory).[15] The simplest truncation of T is to the second-order where the single and double excitations are included in the cluster expansion (coupled cluster single double, CCSD[16] or SAC) based on the HF single determinant$|0\rangle$. When electron correlation effects are dominated by pair effects, these methods recover 90–95% of the exact correlation energy if the wave function is described by a dominant closed-shell determinant. The remaining correlation effects due to higher excitations are estimated by approximate methods like in the CCSD(T) approach where the triple excitations are included perturbationally. These methods are size-extensive by definition and independent on the choice of reference orbitals. However, these methods, which converge efficiently, are hardly generalized to multireference starting wave functions. As far as the excited states and associated properties are concerned, two cluster–expansion-based methods developed originally for open-shell situations have been proposed. The first, the so-called SAC-CI method, supposes that the major part of electron correlation in the closed-shell ground state is transferable to the excited states since the excitation of interest involves only one and/or two electrons. The mechanism of photofragmentation of $Ni(CO)_4$ by a XeCl laser at 308 nm has been studied on the basis of SAC-CI PEC.[17] More recently a detailed investigation of the excited-state structures and reactivity of $CpM(CO)_2$ (Cp = η^5-C_5H_5; M = Rh, Ir) has provided theoretical insights into the photochemistry of these molecules.[18] The origin of the low-quantum efficiencies for the C–H/S–H bond activations of $CpM(CO)_2$ has been attributed to the smaller proportion of the MLCT character in the high-energy states. In the CC-based methods, the so-called equation-of-motion–coupled cluster single double (EOM-CCSD)[19] ionization potentials, electron affinities, and excitation energies are obtained directly from the equation of motion operating on the ground-state wave function. This approach is characterized by an unambiguous treatment of excited states where the only choices are the atomic basis sets, and the excitation level of the operators is very demanding computationally and it has been applied to only one transition metal complex, namely, $FeCl_4^-$ leading to promising results for charge transfer transitions from the $^6A_1$ ground state.[20] A recent workable extension, the so-called extended similarity transformed EOM-CCSD (extended-STEOM-CC), has been applied with more or less success to a few transition metal compounds.[21]

3.4 Density Functional Based Methods

The optical spectra of transition metal complexes have long been interpreted by means of DFT methods. However, the Kohn–Sham orbitals calculated within the DFT formalism describe the electronic ground state in a single determinant scheme. While this method was well established for the ground state and the lowest states within a symmetry class from its early days, its extension to excited-state description is still in development. The first option proposed in 1977 by Ziegler and Baerends,[22] within the framework of the time-independent formalism, and generalized in 1994 by Daul[23] (so-called Δ-SCF method) is based on symmetry-dictated combinations of determinants able to evaluate in a nonambiguous way the space and spin multiplets. It has been applied with success to a variety of highly symmetric molecules.[23] However, several limitations make this approach only accessible to experts in the subject.

An alternative to the time-independent DFT method is the so-called time-dependent DFT This method based on the linear response theory is the subject of recent and promising theoretical developments.[24,25] The treatment of molecular properties by means of the linear response of the charge density to an applied field is based on a well-founded formalism that allows direct computation of polarizabilities, excitation energies, and oscillator strengths within the framework of the DFT. Only excitations corresponding to linear combinations of singly excited determinants are included like in single excitations CIs, but taking into account additional electronic correlation effects. The accuracy of the response calculation is very sensitive to the approximation made for the exchange-correlation potential v_{xc} as well as to its repercussion on its derivative $\partial v_{xc}/\partial\rho$ (derivative discontinuity in the bulk region). Owing to an underestimation of the attractive character of the exchange-correlation potential, the charge density will be too diffusible. Consequently, the ionization threshold will be systematically too low with a dramatic effect on high excitation energies and polarizabilities, which will be overestimated. Moreover, excitations involving a substantial change in the charge density like charge transfer states will be described with difficulty by conventional functionals. In spite of these drawbacks, the TD-DFT approach remains a computationally simple and efficient method able to treat practical problems in a reasonable timescale at a low cost as compared to highly correlated ab initio methods.[9,26] From an overview over recent TD-DFT calculations on transition metal complexes spectroscopy, the most important points to be considered are (1) the applied functional and (2) the level of geometry optimization of the molecule. For medium size molecules or transition metal complexes, TD-DFT results have been shown to be competitive with the highest level ab initio approaches, but cases where current exchange-correlation functionals dramatically fail are known to exist.[27,28] In a recent paper, the photochemistry of the phosphine-substituted transition metal–carbonyl complexes $Cr(CO)_5PH_3$ and *ax*-$Fe(CO)_4PH_3$ has been investigated by means of TD-DFT PEC and wave packet dynamics.[29]

4 POTENTIAL ENERGY SURFACES

The PES plays a central role in the understanding of chemical/photochemical reaction mechanisms, the quantum description of the nuclear motion being determined by the shape of the PES. In principle, photochemical mechanisms are described by reaction paths on ground and excited states PES, which can be determined according to the procedures developed for chemical reactivity. The new problem in photoinduced mechanisms is the complicated landscape of the PES characterized by the presence of a variety of critical geometries such as minima, transition states, high-order saddle points, avoided crossings, conical intersections resulting from nonadiabatic interactions between N-dimensional PES. For a given atomic basis set, the computational method used to solve the electronic problem has to be flexible enough to characterize correctly different regions of the molecular PES at the same level of accuracy. An inadequate wave function would result in a biased description of the different regions and such computed PES would not reproduce the exact Born–Oppenheimer potentials.

One of the most significant advances made in applied quantum chemistry in the past 20 years is the development of computationally workable schemes based on the analytical energy derivatives able to determine stationary points, transition states, high-order saddle points, and conical intersections on multidimensional PES.[30] The determination of equilibrium geometries, transition states, and reaction paths on ground-state potentials has become almost a routine at many levels of calculation (SCF, MP2, DFT, MC-SCF, CCSD, CI) for molecular systems of chemical interest.[31,32] The availability of reliable and efficient analytic energy gradient procedures (first and second derivative) for the search of various critical points on several interacting complex surfaces at a high correlated level (CASSCF, MR-CI, CASPT2, CCSD(T) and its extension EOM-CCSD) will have a significant impact on the theoretical study of transition metal photoreactivity. Indeed, although reaction paths are uniquely defined in any coordinate system, they cannot be determined unambiguously without the knowledge of reference points on the PES from which the analytical energy derivation procedure may start. Unfortunately, the derivative formulation for highly correlated wave functions is very complex and if analytical first derivatives are available for the standard methods, second derivatives calculations are even more complicated.

Density functional methods are competitive with the above traditional wave function methods for numerous applications such as the computation of ground-state PES. A few applications of transition metal photochemistry have been proposed on the basis of the Δ-SCF approach implying several approximations on the excited-state reaction-path definition by symmetry constraints not always appropriate in a 'coordinate driving' scheme.[33] Excited-state gradients have been recently implemented in DFT for various functionals, the feasibility of the approach having been tested for small molecules only.[34] The mathematical and computational machinery for structure optimization is based on several various algorithms, the complexity of which depends on the wanted accuracy at the electronic level. The application of these methods to transition metal photochemistry raises serious practical difficulties as illustrated above. For simple mechanisms involving the electronic ground-state interaction with one excited state, the global structure of the low-energy part of the PES can be visualized within a 3-D cross-section plotting of the energy on a grid while the critical points (minima, transition states, conical intersections) are fully optimized using rigorous ab initio correlated methods (MC-SCF).[35,36] This procedure has been extended recently to the study of the photodissociation of $Cr(CO)_6$ giving mechanistic details of the geometrical relaxation of the $Cr(CO)_5$ photoproduct.[37]

More generally, the high density of electronic states that characterizes the absorption spectrum of transition metal complexes generates a very complicated PES involving several different multiplets in the UV/visible domain of energy. As the systematic investigation of the full PES is practically intractable, the study of photochemical processes in transition metal complexes is generally based on several approximations: (1) the nuclear dimensionality is reduced to $N \leq 2$; (2) the reaction path is approximated by metal–ligand bond elongation coordinates; (3) the highest symmetry is retained along the reaction path; (4) a limited evaluation of geometrical relaxation effects in excited states is performed. These approximations are based on the following criteria: (1) the observed or calculated structural deformations on moving from the electronic ground state to the excited state; (2) the observed or calculated structural deformations on moving from the reactant to the products; (3) the temporal hierarchy of the various elementary processes participating in the photochemical behavior. The validity of these approximations is checked on the basis of the observables directly comparable with the experimental data such as the bond dissociation energies, the main spectral features, or the timescales of primary reactions. In contrast, the electronic problem is treated by means of the most accurate quantum chemical methods in order to get a semiquantitative characterization of electronic spectroscopy in the Franck–Condon region and a correct description of the dissociative processes. The analysis of the main topological characteristics of the PES represented by contour maps (2-D) or profiles (1-D) of the potentials $V(q_i)$ is the first step toward a qualitative understanding of the photochemical mechanisms.

5 WAVE PACKET DYNAMICS

The motion of the molecular system under the influence of the potential is determined by the equations of dynamics. Consequently the shape of the computed PES governs entirely this motion. As explained in the previous section, since

several approximations have to be made at the level of the dimensionality of the PES, it is very important to define clearly the initial conditions of the simulation and to estimate the hierarchy in time of the various elementary processes involved in the photochemical reactivity. In conventional photochemical experiments with long pulse duration and narrow frequency resolution, only a few near-degenerate electronic states are directly populated. The energy is not large in excess, and in a first approximation the reaction paths can be defined by the metal–ligand bond elongation coordinates corresponding to the observed photochemical reactions. In the case of very fast dissociative processes (10 fs to 1 ps), the system should not deviate significantly from this ‘pseudominimum energy path’, and many of the other vibrational degrees of freedom can be frozen. Typically, one or two coordinates corresponding to the bond elongations describing the observed photochemical reactions (CO loss or metal–R, R = H, alkyl, metal, X) are selected for building 1-D or 2-D PES, the other degrees of freedom being frozen to the Franck–Condon geometry.[38]

The quantum dynamics of photodissociation processes can be performed within the time-independent or time-dependent framework.[37] In the time-dependent picture used in the applications presented in the next section, the time-dependent Schrödinger equation is solved

$$i\hbar\frac{\partial}{\partial t}\varphi_e(t) = \hat{H}_e\varphi_e(t) \tag{4}$$

where $\varphi_e(t)$ is a wave packet (coherent superposition of all stationary eigenstates in the electronic excited state) evolving on the excited electronic state e potential. In order to describe the initial absorption followed by direct dissociation, it is assumed that the initial vibrational state ϕ_{g_i} in the electronic ground sate multiplied by the transition dipole function μ_{eg} is instantaneously promoted by the photon to the upper electronic state (Scheme 2).

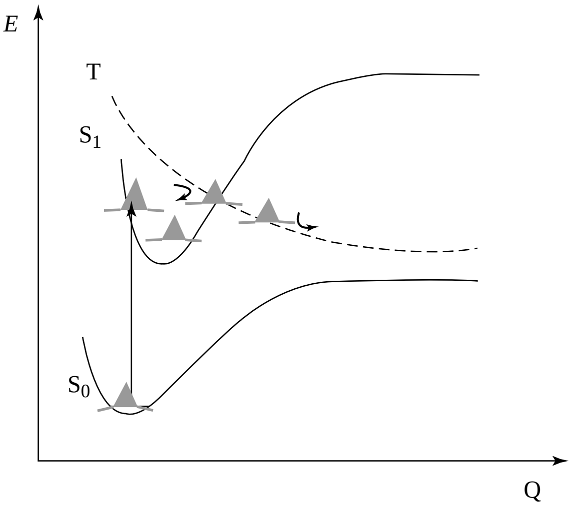
This initial wave packet that is not eigenstate of $\hat{H}_e$, starts to move under its action. The advantage of this approach is that the motion of the wave packet, the center of which remains close to a classical trajectory, can be followed in real time. The motion of the wave packet from the Franck–Condon region to the exit channel is described by the autocorrelation function

$$\mathrm{S}(t) = \langle\varphi_e(0)(0)|\varphi_e(t)\rangle \tag{5}$$

given by the overlap of the evolving wave packet with the initial wave packet at $t = 0$. The absorption spectrum is calculated as the Fourier transform of the autocorrelation function

$$\sigma_{\mathrm{tot}}(\omega)\alpha\omega \int_{-\infty}^{+\infty} \mathrm{d}t\,\mathrm{S}(t)e^{iEt/\hbar} \tag{6}$$

where $E = E_i + \hbar\omega$.[39] Wave packet calculations lead to the timescale and probabilities of dissociation and to the branching



Scheme 2

ratio between concurrent primary processes occurring from a single electronic excited state. In the cases of indirect dissociative processes involving nonadiabatic transitions (jumps between different PES), a set of coupled time-dependent Schrödinger equations has to be solved

$$\left.\begin{aligned} i\hbar\frac{\partial}{\partial t}\varphi_e(t) &= \hat{H}_e\varphi_e(t) + V_{ee'}\varphi_{e'}(t) \\ i\hbar\frac{\partial}{\partial t}\varphi_{e'}(t) &= \hat{H}_{e'}\varphi_{e'}(t) + V_{e'e}\varphi_e(t) \end{aligned}\right\} \tag{7}$$

with the same initial conditions as above but in a different basis, the so-called diabatic,[40] where the original adiabatic PES have been transformed in order to minimize the kinetic coupling between them and to introduce potential coupling terms $V_{ee'}$. This strategy is very efficient in describing simultaneously intersystem crossings and internal conversions, which are important processes in photoinduced reactivity in transition metal complexes. The wave packet approach yields important quantities such as the time evolution of electronic states population, the dissociation probabilities, or the branching ratio between concurrent processes.

6 ELECTRONIC SPECTROSCOPY

6.1 The Blue Copper Protein

In a beautiful recent work, the groups of K. Pierloot and B. O. Roos[41,42] have proposed a fairly complete understanding of the relation between the electronic spectra and the structure of the mononuclear copper-cysteinate proteins. This theoretical work is based on DFT geometry optimizations of several blue copper protein models from $[Cu(NH_3)_2(SH)(SH_2)^+]$ to

[Cu(imidazole)$_2$(SCH$_3$)(S(CH$_3$)$_2$)$^+$], the structures of which are compared to the crystal structures of plastocyanin and nitrite reductase. The effect of the protein surrounding on the spectra has been simulated by a single point-charge model. The CASSCF/CASPT2 calculated electronic spectra of the [Cu(imidazole)(SH)(SH$_2$)$^+$] model at the crystal structure, but with CASPT2 optimized Cu–S$_{\text{Cystein}}$ and Cu–S$_{\text{Methionin}}$ bond distances, reproduce the experimental absorption spectra of the blue copper protein plastocyanin and nitrite reductase with an error of less than 0.22 eV (Table 1).

The key point in this type of study is the choice of the model systems, the structure of which should be very close to the real systems. Indeed, the change in geometry has a dramatic effect on the electronic structure itself and on the electronic spectroscopy as illustrated by the assignment of the experimental bands in these systems in Table 1. It has been shown that both trigonal and tetragonal structures of models of the blue copper proteins are rather similar (nearly tetrahedral). Therefore, some proteins stabilize the trigonal structure (e.g. plastocyanin) whereas others stabilize the tetragonal structure (e.g. nitrite reductase). The electronic spectra of blue copper proteins are well characterized and have been recorded by several spectroscopic techniques. The spectra show a prominent peak centered at 2.08 eV in plastocyanin and 2.19 eV in nitrite reductase responsible for the blue color and a weak band around 1.5 eV. All the transitions reported in Table 1 correspond to excitations either to the π^*(Cu–S$_{\text{Cys}}$) (plastocyanin) or to the σ^*(Cu–S$_{\text{Cys}}$) (nitrite reductase) orbitals strongly delocalized onto S$_{\text{Cys}}$. The lowest part of the spectra is attributed to ligand field (LF) states by the authors, the upper part being characterized by the presence of high-lying charge transfer states from the π(Cu–S$_{\text{Cys}}$) or the σ(Cu–S$_{\text{Cys}}$) orbitals.

Table 1 Comparison between the calculated and experimental spectra of plastocyanin and nitrite reductase. The transition energies are given in eV

	Calculated[a]	Experimental[b]
Plastocyanin		
σ^* (Cu–S) → π^*(Cu–S)	0.55	0.63
3d$_{z^2}$(Cu) → π^*(Cu–S)	1.46	1.35
3d$_{yz}$ (Cu) → π^*(Cu–S)	1.62	1.60
3d$_{xz}$ (Cu) → π^*(Cu–S)	1.58	1.74
π(Cu–S) → π^*(Cu–S)	1.96	2.09
σ (Cu–S) → π^*(Cu–S)	2.75	2.67
Nitrite reductase		
π^* (Cu–S) → σ^*(Cu–S)	0.55	0.7
3d$_{z}^{2}$(Cu) → σ^*(Cu–S)	1.54	1.49
3d$_{yz}$ (Cu) → σ^*(Cu–S)	1.61	1.69
3d$_{xz}$ (Cu) → σ^*(Cu–S)	1.73	1.86
π(Cu–S) → σ^*(Cu–S)	1.97	2.19
σ(Cu–S) → σ^*(Cu–S)	2.81	2.74

6.2 Ru-halide Charge Transfer Complexes

Transition metal–carbonyl-diimine complexes [Ru(E)(E$'$)(CO)$_2$(α-diimine)] (E, E$'$ = halide, alkyl, benzyl, metal fragment; α-diimine = 1, 4-diazabutadiene or 2,2$'$-bipyridine) are widely studied for their unconventional photochemical, photophysical, and electrochemical properties. These molecules have a great potential as luminophores, photosensitizers, and photoinitiators of radical reactions and represent a challenge to the understanding of excited-state dynamics.[28,44] The near-UV/visible electronic spectroscopy of [Ru(X)(Me)(CO)$_2$(iPr-DAB)] (X = Cl or I; iPr-DAB = N,N'-di-isopropyl-1,4-diaza-1,3-butadiene) has been investigated through CASSCF/CASPT2 and TD-DFT calculations on the model complexes [Ru(X)(Me)(CO)$_2$(Me-DAB)] (X = Cl or I) (Table 2).

Table 2 Lowest part of the absorption spectra of [Ru(Cl)(Me)(CO)$_2$(Me-DAB)] and [Ru(I)(Me)(CO)$_2$(Me-DAB)]. Transition energies are in cm^{-1} (oscillator strengths are given in parenthesis)

	Experiment	Transition	CASPT2	Transition	TD-DFT (PBE Hybrid)

	> 30 770 (324 nm)	MLCT a^{1}A$'$ → e^{1}A$'$	25 820 (0.16)	MLCT a^{1}A$'$ → e^{1}A$'$	27 510 (0.055)

Table 3 Calculated TD-DFT transition energies (in cm^{-1}) to the low-lying singlet excited states of $[Ru(R)(Me)(CO)_2(Me\text{-}DAB)]$ (R = Cl, SnH_3) calculated as a function of various functionals and associated oscillator strengths (in parenthesis)

	Transition	BP	B3LYP	hybrid PBE	Hand HLYP
X = Cl	XLCT/MLCT $A^1A' \rightarrow b^1A'$	12 090 (0.006)	16 210 (0.011)	17 640 (0.013)	24 440 (0.021)
	SBLCT $a^1A' \rightarrow c^1A'$	20 240 (0.006)	23 310 (0.015)	24 780 (0.018)	29 840 (0.028)
	MLCT XLCT $a^1A' \rightarrow e^1A'$	24 560 (0.067)	27 500 (0.060)	28 840 (0.057)	35 890 (0.032)
X = SnH_3	SBLCT $a^1A' \rightarrow b^1A'$	19 870 (0.034)	22 020 (0.063)	22 260 (0.069)	23 560 (0.106)
	MLCT $a^1A' \rightarrow e^1A'$	25 790 (0.072)	29 760 (0.042)	28 080 (0.058)	31 440 (0.039)

The convergence on the calculated transition energies to the low-lying metal-to-ligand-charge-transfer (MLCT), X-to-ligand-charge-transfer (XLCT, X being an halide ligand), or sigma-bond-to-ligand-charge-transfer (SBLCT) has been analyzed for both methods with respect to various methodological aspects: basis set effects and functional influence on the TD-DFT results versus the influence of the size and quality of the CASSCF active space and of the level of the perturbational treatment (single state or multistate) on the CASSCF/CASPT2 transition energies. Both methods reproduce the red shift of the absorption bands well when moving from the chloride to the iodide complex as well as the displacement of the strongly MLCT absorbing state from the visible to the UV domain of energy.

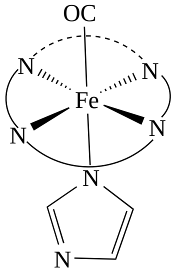
On the basis of these accurate calculations, it is shown that whereas the lowest singlet state can be assigned to a pure XLCT state in $[Ru(I)(Me)(CO)_2(Me\text{-}DAB)]$, its character is mainly MLCT in $[Ru(Cl)(Me)(CO)_2(Me\text{-}DAB)]$ in agreement with the time-resolved absorption/emission, IR, and resonance Raman experiments.[45] This remarkable difference has profound consequences not only on the spectroscopy but also on the photoreactivity of this class of molecules used as sensitizers and/or catalysts in photochemical reductions.

As illustrated by the results reported in Table 3, the TD-DFT transitions energies are dramatically affected by the nature of the functional, especially in the case of the halide compound. The influence of the functional is less dramatic for the nonhalide complex $[Ru(SnH_3)(Me)(CO)_2(Me\text{-}DAB)]$.

7 PHOTOREACTIVITY

7.1 Photodissociation of the CO-Ligated Heme Group

The initial step (ultrafast CO loss within 50 fs) of the photodissociation process of CO-ligated iron porphyrin imidazole (Scheme 3), the model system for the CO-Ligated hemoglobin and myoglobin, has been investigated by means of TD-DFT.[46] On the basis of the one-dimensional PEC



Scheme 3 After irradiation into the lowest Q bands calculated at 2.40 (1A′) and 2.42 eV (1A″) (vs. experimental values of 2.8 eV (Q_x band) and 2.30 eV (Q_y band)) and corresponding to $\pi \rightarrow \pi^*$ excitations localized on the porphyn cycle, the system will evolve on the bound part of the associated potentials (Figure 3).

calculated as a function of the Fe–CO bond elongation (Figure 3) without relaxation of the other nuclear degrees of freedom, a qualitative mechanism has been proposed.

Around 1.98 Å, it will overcome small energy barriers generated by avoided crossing between the bound 1A′ and 1A″ states and the repulsive 3A′ and 5A″ upper states calculated at 2.88 and 2.87 eV, respectively and corresponding to MLCT ($d_{Fe} \rightarrow \pi^*_{CO}$) transitions. A refined treatment of the potentials leading to a more realistic relative position of the electronic ground state and Q-band 1A′, 1A″ potential wells should confirm this mechanism and explain the observed timescale of dissociation (50 fs) characteristic of a direct ultrafast process.[47]

7.2 Photodissociation Dynamics of Metal-to-ligand-charge-transfer States in α-diimine complexes

7.2.1 *Dissociative versus Nondissociative Metal-to-Ligand-Charge-Transfer (MLCT) States in $M(H)(CO)_3$(α-diimine) Complexes (M = Mn, Re)*

The photodissociation dynamics of $M(H)(CO)_3(H\text{-}DAB)$ (M = Mn, Re), model systems for $M(R)(CO)_3$(α-diimine)

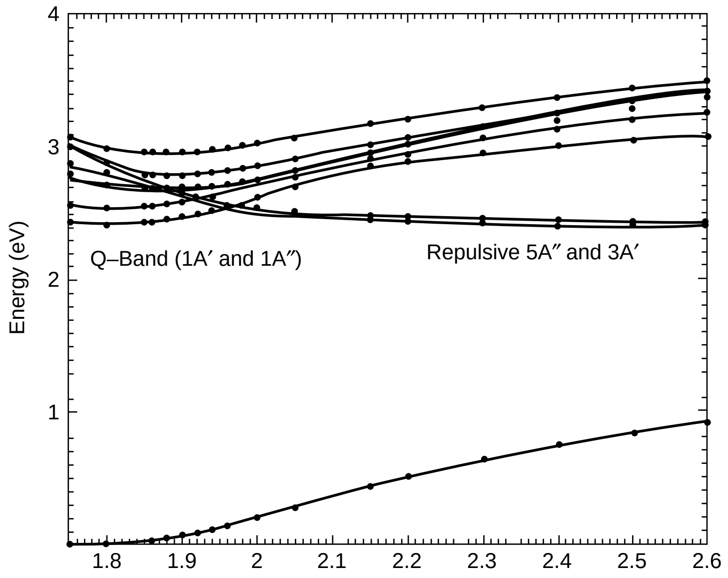


Figure 3 TD-DFT potential energy curves of the electronic ground state and low-lying singlet excited states as a function of the Fe–CO bond elongation.[46] (Reprinted with permission from Ref. 46. © 1978 American Chemical Society)

complexes (with M = Mn, Re, R representing a metal fragment or alkyl or halide groups bound to the metal by high-lying σ_{M-R} orbitals) have been investigated in two recent studies.[48,49] The main purpose was to understand the change of photochemical behavior upon visible irradiation, that is, from the CO loss and/or Mn–R bond homolysis to the Re–R bond homolysis and/or emission when going from the first-row to the third-row transition metal complexes.[44] Despite the presence of many potentially photoactive low-lying singlet and triplet excited states (nine for the manganese complex and seven for the rhenium one), it has been shown that only two states, the ^{1}MLCT ($d_M \rightarrow \pi^*_{DAB}$) absorbing state and the ^{3}SBLCT ($\sigma_{M-R} \rightarrow \pi^*_{DAB}$) state will control the photochemistry of this class of molecules. As illustrated by the contour plot of the 2-D PES calculated as a function of the q_a = [M–H] and q_b = [M–CO_{ax}], the ^{1}MLCT absorbing state itself is dissociative for the CO loss in Mn(H)$(CO)_3$(H-DAB) (Figure 4) and is bound in Re(H)$(CO)_3$(H-DAB) (Figure 5).

The dissociative character of the MLCT state in the first-row transition metal complexes is due to the weakening of the Mn–CO_{axial} bond when exciting an electron from the d_{Mn} orbital, which is responsible for the $d\pi p\pi$ Mn–CO_{ax} back bonding interaction, to the π^*_{DAB} localized on the acceptor group. This effect is less important in the third-row transition metal complexes where the metal–CO_{axial} interaction occurs mainly through the interaction with the diffused p of the metal. Moreover, the ^{3}SBLCT state presents a valley of dissociation for the metal–hydrogen bond breaking in both molecules. However, after absorption to the ^{1}MLCT in the visible energy domain, Mn(H)$(CO)_3$(H-DAB) will completely dissociate within 450 fs according to an ultrafast direct dissociative process (Figure 4) leading exclusively to the departure of the axial CO ligand. This theoretical study was the first evidence of the MLCT reactivity in transition metal α-diimine complexes currently observed experimentally.

7.2.2 *Role of the Triplet Sigma-Bond-to-Ligand-Charge-Transfer (SBLCT) State in the Photoreactivity of Re(R)(CO)$_3$(α-diimine) (R = H, Alkyl)*

As illustrated by the contour plot of the 2-D PES depicted in Figure 5 and in contrast to the manganese analogue, the ^{1}MLCT absorbing state is bound along both channels (axial CO loss and Re–H bond homolysis) in Re(H)$(CO)_3$(H-DAB). Within the 2-D approximation (q_a = Re–H, q_b = Re–CO_{ax}), one possibility of deactivation of [Re(H)$(CO)_3$(H-DAB)]* is via intersystem crossing to the ^{3}SBLCT state, this potential being repulsive for the homolytic cleavage, which is observed in a series of analogues like Re(R)$(CO)_3$(*i*Pr-DAB) (R = methyl, ethyl, metal fragment) with various quantum yields ($\phi = 10^{-2}$ for R = methyl, $\phi \approx 1.0$ for R = ethyl or benzyl).[44] After initial excitation under visible irradiation, the system gets trapped in the potential well of the MLCT state (Figure 5a). Within a very short timescale (50 fs), the ^{3}SBLCT state is populated via ^{1}MLCT $\rightarrow$ ^{3}SBLCT intersystem crossing (Figure 5b).

As soon as the wave packet reaches the ^{3}SBLCT potential, it evolves along the dissociation channel toward the formation of the diradicals H$^\bullet$ + $^\bullet$[Re(CO)$_3$(H-DAB)]. The reaction is rather slow and inefficient in this model complex with a probability of dissociation less than 2% within 2 ps.

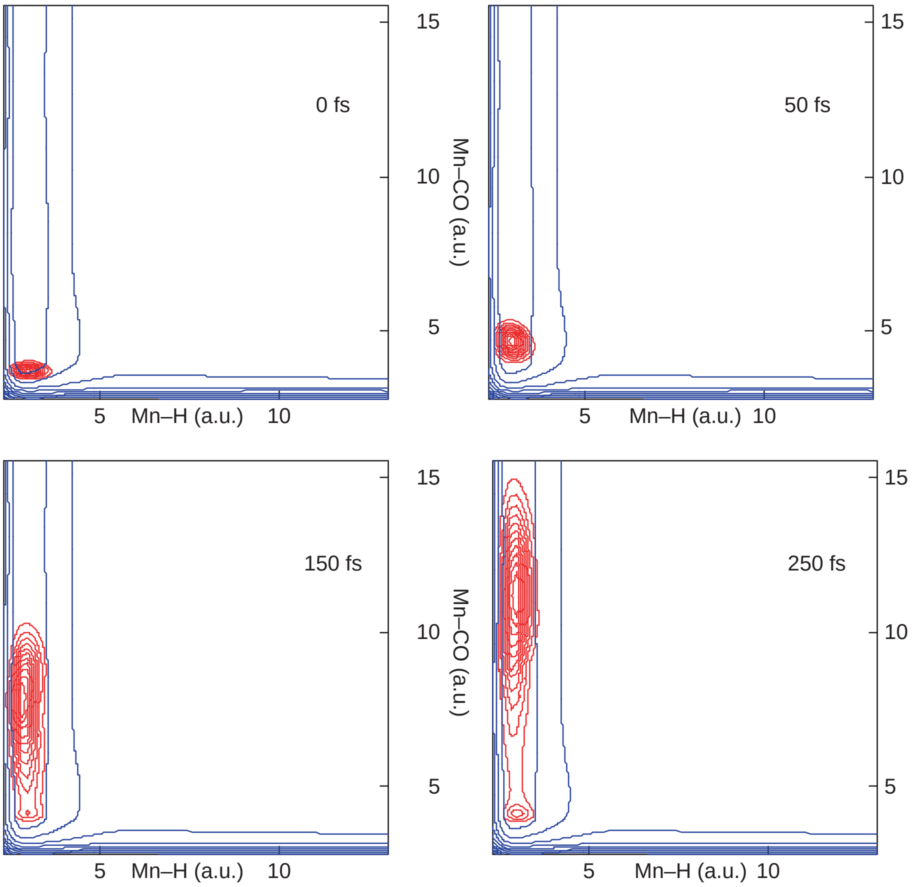

Figure 4 Time evolution of the wave packet $\Psi_{1_{\mathrm{MLCT}}}(t)$(red solid lines) on the ab initio $V_{1_{\mathrm{MLCT}}}$ (q_a, q_b) potential of the ^{1}MLCT absorbing state (contour plot in blue solid lines) of (H)Mn(CO)$_3$(H-DAB), model system for (R)Mn(CO)$_3$(α-diimine) complexes. (q_a = [Mn–H]; q_b = [Mn–CO$_{ax}$])

This example illustrates the complexity of the excited-state dynamics in this class of molecules. The early-stage dynamical behavior (in the first ps) may be tailored by the metal center, the α-diimine group, or the surrounding ligands. These chemical factors govern the character and electronic localization of the excited states, their relative position, and the presence of critical geometries. Moreover, the shape and relative positions of the PES may be also modified by the other experimental conditions like solvent effects.

7.3 Analysis and Control of Excited-states Dynamics in CpMn(CO)$_3$

Polyatomic molecules are characterized by complex internal motions leading to several possible rearrangements. With the advent of ultrafast lasers, much hope arose for achieving mode selectivity in chemical reactions based on the interaction between the laser pulses and the dynamics of the molecule. In the quest to steer complex systems, an especially attractive control scheme is the adaptive optimal laser pulse control. An algorithm 'teaches' a light field to prepare specific products on the basis of fitness information, such as product yields. This genetic algorithm iteratively creates an optimal laser pulse that prepares the desired target, solving the Schrödinger equation exactly in real time.[50] These experiments have been recently extended to transition metal carbonyls.[51] It has also been shown that feedback control can optimize individual fragmentation and ionization paths in CpMn(CO)$_3$ (Cp = η^5-C$_5$H$_5$). For such complex reactive systems, the question remains whether the optimal laser field contains a set of rational rules that govern the dynamics. A recent work combining femtosecond high-resolution pump-probe experiments and ab initio quantum calculations of the relevant PEC and wave packet simulations has enabled the deciphering of the dynamics of two competing processes in CpMn(CO)$_3$ induced by an optimal femtosecond pulse, which was generated from adaptive learning algorithms,[52]

$$\mathrm{CpMn(CO)_3} + \mathit{LaserFiled} \longrightarrow \mathrm{CpMn(CO)_3}^+ + \bar{e} \qquad (8)$$

$$\longrightarrow \mathrm{CpMn(CO)_2}^+ + \mathrm{CO} + \bar{e} \qquad (9)$$

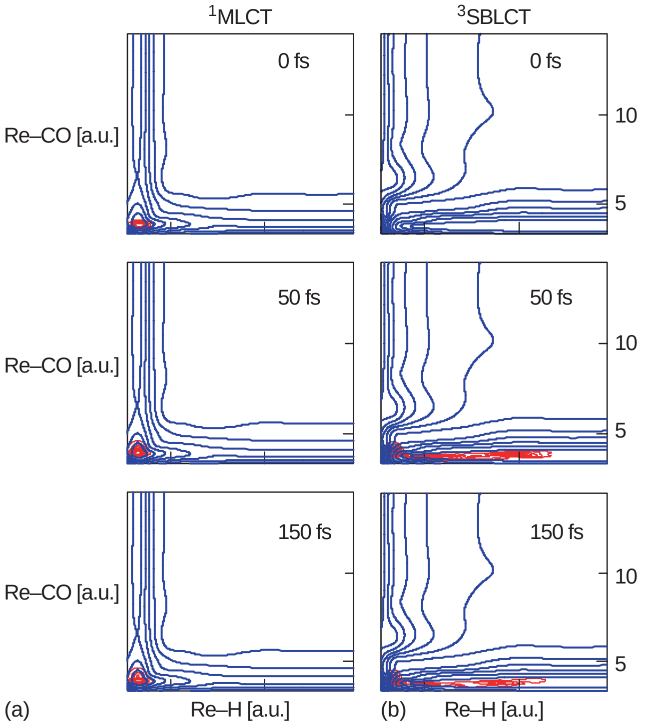

Figure 5 Time evolution of the wave packet $\Psi_{1_{\mathrm{MLCT}}}(t)$(red solid lines) on the ab initio $V_{1_{\mathrm{MLCT}}}$ (q_a, q_b) and $V_{3_{\mathrm{SBLCT}}}$ (q_a, q_b) potentials of the ^{1}MLCT absorbing state (contour plot in blue solid lines, (a)) and ^{3}SBLCT state (contour plot in blue solid lines, (b)) coupled by spin-orbit of (H)Re(CO)$_3$(H-DAB), model system for (R)Re(CO)$_3$(α-diimine) complexes. (q_a = [M–H]; q_b = [M–CO$_{ax}$])

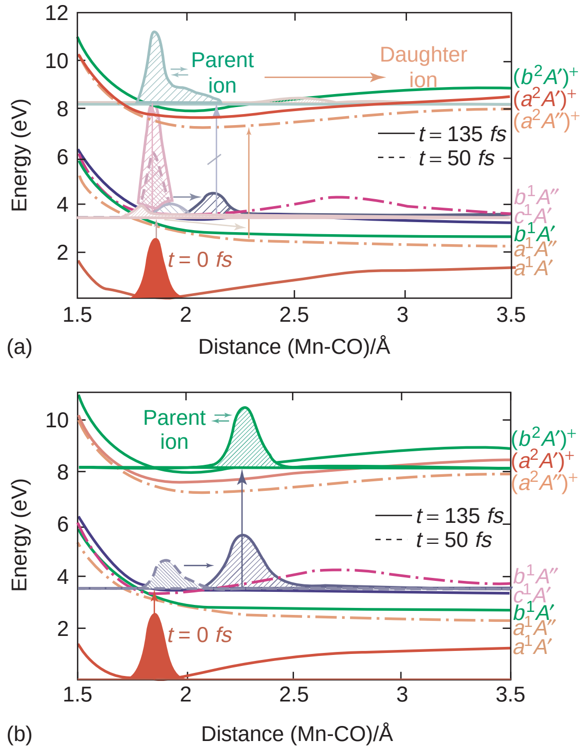

Figure 6 Adiabatic ab initio potentials with snapshots of the time evolution of the laser-induced wave packets (at $t = 0$ fs, original ground state; $t = 50$ fs, dashed envelope; $t = 135$ fs, solid envelope). (a) Simulation of the pump/probe experiment with competing pathways leading to CpMn(CO)$_3^+$ and CpMn(CO)$_2^+$ (R1 and R2 primary processes); (b) simulation of the control pathway leading exclusively to the CpMn(CO)$_3^+$ ions by quenching the internal conversion from the c^{1}A′ and b^{1}A″ absorbing states to the low-lying dissociative states b^{1}A′ and a^{1}A″

When a nonoptimal laser pulse is used in the coherent pump/probe experiment, the two fragments CpMn(CO)$_3^+$ and CpMn(CO)$_2^+$ are detected, the last one within 66 fs. The dynamics of this process is depicted in Figure 6(a), which shows the evolution of the initial wave packet prepared on the a^{1}A′ ground state (t = 0 fs) at 50 and 135 fs. Under the pump pulse (3.43 eV frequency and 100 fs duration), the system evolves to the neutral states b^{1}A″ and c^{1}A′, whereas the ionic states b^{2}A′ and a^{2}A″ are obtained by the second pulse (probe pulse of 4.852 eV and 85 fs duration). One part of the wave packet starts an oscillatory motion into the potential well of the b^{1}A″ state with a period of 80 fs, while a small percentage is transferred to the a^{1}A″ through nonadiabatic transitions, leading to the neutral species CpMn(CO)$_2$. The probe pulse will put in evidence two fragments as illustrated in Figure 6(a).

A control mechanism has been proposed on the basis of the joint analysis of the experimental and theoretical information. The control scheme leading selectively to the formation of CpMn(CO)$_3^+$ is represented in Figure 6(b). The experiment realized with an optimal laser field is simulated by one pump pulse (at 3.49 eV) followed by a probe pulse (at 4.716 eV) designed with the adequate properties of phase, frequency, and duration. Within these specific conditions, the quasi-bound state c^{1}A′ is populated selectively and the CO dissociation is quenched as illustrated in Figure 6(b). The bottleneck of this type of theoretical study is the construction of accurate multidimensional PES, taking into account other degrees of freedom important in the dynamics. Within the limit of the theoretical model, it is mandatory to perform such simulations in close collaboration with experimentalists. The confrontation between the phenomena observed in the femtosecond laser pulse experiments and the results of quantum dynamics is primordial.

1 INTRODUCTION

Photoelectron spectroscopy (PES) is the study of the electrons emitted when high-energy electromagnetic radiation interacts with matter. In a photoelectron experiment, photons of fixed energy, $h\nu$, are used, and the kinetic energy distribution of the photoelectrons is determined. In such a way, binding energies of the various electrons in atoms, molecules, and solids may be measured. PES provides the most direct experimental method of probing the allowed energy levels of electrons in substances, and characterizing their electronic structure.

Such investigations of valence electrons of transition metal molecules has led to the development and refinement of bonding models. Not only has calculation of ionization energies provided a stimulating challenge to the quantum chemist, but also such direct access to bonding information has influenced the direction of synthetic research. Ionization energies are key thermodynamic parameters in the understanding of oxidation and proton affinity, both important reactions for transition metal compounds. Binding energies also serve as a good measure of substituent effects, and can assist in monitoring the effect of chemical variation on a molecule.

In a similar fashion, studies on valence electrons in solids have proved critical in the understanding of valence bands and their relation to structure and bulk properties of transition metal materials.

High-energy photons, such as are provided by X-rays, are able to ionize core electrons of elements. The core ionization of a particular shell of a particular element occurs over a narrow energy range and is characteristic of that element. Study of core ionization thus forms the basis of a very useful analytical technique named *Electron Spectroscopy for Chemical Analysis*, or ESCA. Electrons with energies of around 1.5 keV can only escape from depths of typically 15 Å so, when applied to the solid state, ESCA is essentially a surface technique, and as such has proved very useful in the study of heterogeneous catalysis and corrosion. As the core ionization energy is to a certain extent sensitive to the chemical environment of the element, there exists the potential for distinguishing between different chemical environments, and obtaining a measure of the ‘charge’ on an atom.

This chapter is concerned primarily, though not exclusively, with the study of valence levels in transition metal molecules. There are a number of recent reviews that address various aspects of this topic.[1–7]

1.1 Photoionization

Photoionization, also known as photoemission, is normally a simple one-photon, one-electron process. The Einstein equation[8] (equation 1) defines the energetic relationship between the frequency of the monochromatic radiation, ν, and the kinetic energy of an ejected electron, E_k:

$$h\nu = I_k + E_k \qquad (1)$$

I_k is the ionization energy, or binding energy, of the kth electron in the molecule. Ionization energies (IEs) are characteristic of the molecule, and are invariant to the photon energy used. The lowest photon energy at which ionization is possible corresponds to the first ionization energy of a molecule. If the photon energy is sufficient, a whole range of different species of electrons, with different ionization energies, may be emitted in separate photoionization events. As the energies of electrons in molecules are quantized, the kinetic energy distribution of the photoelectrons consists of a series of discrete bands. A photoelectron (PE) spectrum consists of a plot of the energy distribution, $n(E)$, that is the number of photoelectrons with a particular energy, E, against the ionization energy, I_k, or alternatively the kinetic energy (KE), E_k.[9]

1.2 Interpretation of a PE Spectrum

Photoionization can be represented by equation (2):

$$\mathrm{M} + h\nu \longrightarrow \mathrm{M}^+ + \mathrm{e}^- \qquad (2)$$

where M represents the neutral species, which is in its ground electronic state, of energy $E(1)$, and M^+ the ionized system that may be formed either in its ground electronic state, of energy $E^+(1)$, or a variety of excited states of energies $E^+(j)$. It is the quantization of the energy states of M^+ that leads to the discrete band structure of a photoelectron spectrum. The jth ionization energy, I_j, is given by the difference in energy between the excited ion state, $E^+(j)$, and the molecular ground state, $E(1)$ (equation 3):

$$I_j = E^+(j) - E(1) \qquad (3)$$

Thus, a photoelectron spectrum gives directly the energy of the accessible ion states with respect to the ground state and, consequently, with respect to each other.

Photoionization can result either from the direct interaction of a photon with the ionizing electron or by an indirect process. An example of the latter is autoionization where a photon is absorbed to produce an excited state of the molecule, M*, by a resonance transition. The excited state then subsequently decays to the molecular ion and a photoelectron (equation 4):

$$\mathrm{M} + h\nu \longrightarrow \mathrm{M}^* \longrightarrow \mathrm{M}^+ + \mathrm{e}^- \qquad (4)$$

The energy of the photoelectron is the same as for direct photoionization.

Within an orbital picture of molecular electronic structure, formation of ion states can be described by removal of electrons from occupied orbitals in a molecule (Figure 1). Koopmans[10] put this model on a quantitative footing by relating the ionization energy of a molecule to the negative of the self-consistent field (SCF) orbital energy, $-\varepsilon_j$ (equation 5):

$$I_j = -\varepsilon_j \qquad (5)$$

Various approximations are involved in the derivation of *Koopmans' Theorem*, so quantitative predictions of IE are not accurate, but it is of considerable use in predicting the number and type of primary bands in the PE spectrum of a molecule, though not necessarily their energy ordering.

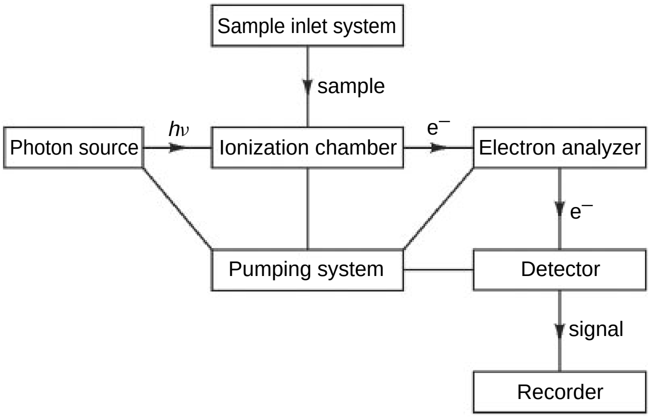

Figure 2 Block diagram showing the essential components of a photoelectron spectrometer

2 EXPERIMENTAL CONSIDERATIONS

The essential components of a photoelectron spectrometer are shown in Figure 2. They consist of a source of monochromatic radiation, an ionization chamber in which molecules or a solid can be ionized, an electron energy analyzer, an electron detector, and a recorder. A pumping system is also required to maintain a good vacuum. Gas-phase work needs a rapid pumping system, but for the electrons to avoid capture during their analysis the base pressure need be no better than 10^{-5} Torr. In studying solids, clean sample surfaces must be maintained and ultrahigh vacuum (UHV) conditions are necessary with pressures less than 4×10^{-11} Torr.

Cleanliness of all surfaces is essential to maintain the equipotentials needed for accurate electron energy analysis.

Table 1 Photon energies of characteristic lines from low energy resonance sources and X-ray sources

Line	Energy (eV)[a]	X-ray	Energy (eV)[a]
He I	21.22	Y Mζ	132.3
He II	40.81	Zr Mζ	151.4
Ne I	16.67, 16.85	Na Kα	1041.0
Ne II	26.81, 26.91	Mg Kα	1253.6
Ar I	11.62, 11.83	Al Kα	1486.6
Ar II	13.30, 13.48	Ti Kα	4510.9
H Lyman α	10.20	Cr Kα	5414.7
H Lyman β	12.09	Cu Kα	8047.8

[a] $1\ \text{eV} = 1.602 \times 10^{-19}$ J.

2.1 Light Sources

The ideal properties of a light source for photoelectron spectroscopy are a very narrow line, absence of any other lines, and a high intensity. Commonly used laboratory sources are summarized in Table 1. In ultraviolet photoelectron spectroscopy, the most useful and widely used light source is a helium discharge lamp. The He I resonance line (21.2 eV) is generated by the transition from an excited state of He ^{1}P (1s2p) to the ground state, ^{1}S (1s^2). Discharges in helium gas can also generate lines from ionized He. The equivalent transition in He^+ gives the He II line (40.8 eV), with a more energetic photon, enabling more tightly bound electrons to be ionized, and also band intensity variations to be studied. Higher lines of the $^1P \rightarrow {}^1S$ series are also present in the discharge, but they are of lower intensity and the associated satellite band structure is weak.

X-ray photoelectron spectroscopy (XPS) uses X-rays generated by allowing an intense beam of electrons to strike an appropriate target material. The inherent width of X-ray lines is greater than the line sources of ultraviolet photoelectron spectroscopy (UPS), but diffraction from a spherically bent crystal can reduce the line width to around 0.25 eV.

Table 1 gives the photon energies of common laboratory line sources.

Synchrotron radiation is continuum radiation from the infrared to the soft X-ray region produced by accelerating free electrons in a magnetic field. The construction of many synchrotron facilities throughout the world has revolutionized photoelectron spectroscopy. They provide intense, tunable photon sources over a wide range of energies. The radiation is polarized. Availability of continuously varying photon energy allows the measurement of photoionization cross sections and their variation with photon energy. Such studies greatly increase the power of a PE investigation.

2.2 Energy Analyzers

The crucial part of a PE experiment is to separate the photoelectrons according to their energy. Ideally both the spectral resolution and the sensitivity should be high, though the one requirement tends to conflict with the other. Analyzers are of two main types. Some retard the electrons and result in difference in transmission of electrons with a varying retardation potential; these produce integrated spectra. More commonly dispersive analyzers are used, in which deflecting fields separate electrons of different energies spatially and give differential spectra.

Much ingenuity has gone into the design of analyzers, resulting in a variety of systems.[11,12] A hemispherical analyzer consists of two concentric metal spheres with an entrance slit and retarding grid or lens at one end and an exit slit at the other. The voltage difference between the two spheres selects the kinetic energy of the electrons that are focused on the exit slit, the pass energy, PE. The analyzer can be operated either holding it at a constant pass energy and varying the retarding potential, R, or by keeping a constant retard ratio, (PE + R)/PE and scanning the pass energy. Constant pass energy maintains constant resolution throughout the scan. A cylindrical mirror analyzer has two coaxially arranged cylinders. The inner cylinder is grounded and the outer one has a negative voltage. Cylindrical mirror analyzers may also be operated in the two modes described above.

2.3 Detectors and Recorders

With the level of electron currents normally generated in a PES experiment, it is common to detect electrons singly using an electron multiplier, commonly called a channeltron. A channeltron is a horn shaped tube that has its inner surface coated with an emissive material. Such a device has the capacity to convert a single electron into a small pulse. A high voltage is applied between the mouth and the end of the tube; an electron entering the mouth is accelerated by the potential, strikes the wall and emits a bunch of secondary electrons. This process is repeated along the curved path of the horn until the ensuing pulse is collected at the end. The pulses are amplified and counted. Multichannel position sensitive detectors take advantage of the spatial resolution of deflection analyzers, and enable electrons over a range of kinetic energies to be counted simultaneously, thus cutting down on the time taken to achieve a good signal to noise ratio.

The advent of microprocessors has led to computer control of analyzer voltages and recording of count rates. This enables multiple scanning of spectra, with the advantage that relative band intensities are not affected by slow changes in sensitivity.

2.4 Samples

To measure a gas-phase spectrum of a transition metal molecule, the compound must possess sufficient volatility to generate a pressure of $10^{-2} - 10^{-1}$ Torr at a temperature below its decomposition point. Such conditions clearly restrict the number of compounds that can be measured in this state. Many of the more covalent transition metal compounds will survive such treatment, and gas-phase PES has been

particularly beneficial in the development of the theory of bonding in organometallic compounds.[1]

For ionic and involatile compounds, data must be obtained in the solid state. This has disadvantages in that bands tend to be broader, calibration of samples presents difficulties, and only surface layers of the sample are probed. These may well not be characteristic of the bulk. Also surfaces are very sensitive to contamination, and effective sample cleaning is needed; rigorous vacuum conditions must prevail during the experiment to prevent recontamination.

2.5 Spectral Calibration

Calibration of binding energies for gaseous samples is straightforward. Reference gases with narrow PE bands, whose IEs are known (such as He, Ne, Ar, Xe, and N_2), are run concurrently with the sample, providing an energy scale.

Calibration of analyzers to determine their transmission factors as a function of electron energy is normally achieved by the use of rare gases with known ionization cross sections.

3 THE ORBITAL PICTURE OF PHOTOIONIZATION

For a closed-shell molecule, Koopmans' approximation identifies an IE with the negative of the SCF orbital energy (equation 5); if this were the case, a PE spectrum would provide an exact mapping of the occupied orbitals of a molecule (Figure 3).

When an electron is ionized from a molecule, the electron–electron repulsion decreases. A consequence of this is that the remaining electrons become more tightly bound, and their orbitals contract. Koopmans' approximation (equation 5) assumes identical orbitals for ion and molecule and neglects this relaxation. Also, Koopmans' approximation is based on an SCF model for molecular electronic structure; this is flawed in the sense that it assumes that electrons move in an averaged potential created by the core and the other electrons. In fact, electrons correlate their motion in order to avoid each other and decrease electron–electron repulsion; thus the true molecular energy is less than that estimated by an SCF method. As there are more electrons in a molecule than in its ion, the correlation correction is larger in the former. The effect of these changes on the Koopmans' estimate for ionization energy is illustrated in Figure 4.

It can be seen that the relaxation correction decreases the Koopmans' estimate, whereas the difference in the two correlation corrections increases the estimate. The errors are thus, to a certain extent, self-compensating. Transition metal d orbitals are often associated with much greater relaxation corrections than ligand orbitals, and this can lead to an inversion of ordering between an orbital energy calculation and the associated PE bands. Thus, it is not uncommon to find from a calculation a filled metal orbital to be more stable than a ligand orbital but to give rise to the first IE of a molecule.

SCF calculations also frequently neglect relativistic effects, which may well be important, especially for third row transition metal and actinide compounds.

The most significant deduction from the orbital model is that there is a one-to-one correspondence between the primary features of a PE spectrum and the occupied orbitals of a

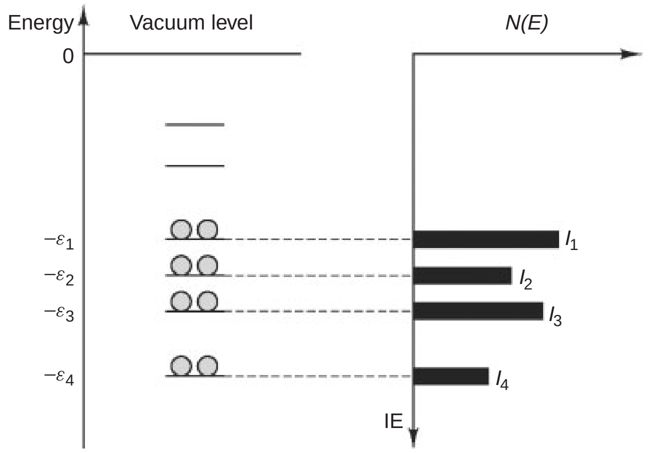

Figure 3 Representation of the relationship, according to Koopmans' theorem, between the orbital energies, $-\varepsilon_j$, of a closed-shell molecule and its ionization energies, I_j, displayed in a photoelectron spectrum

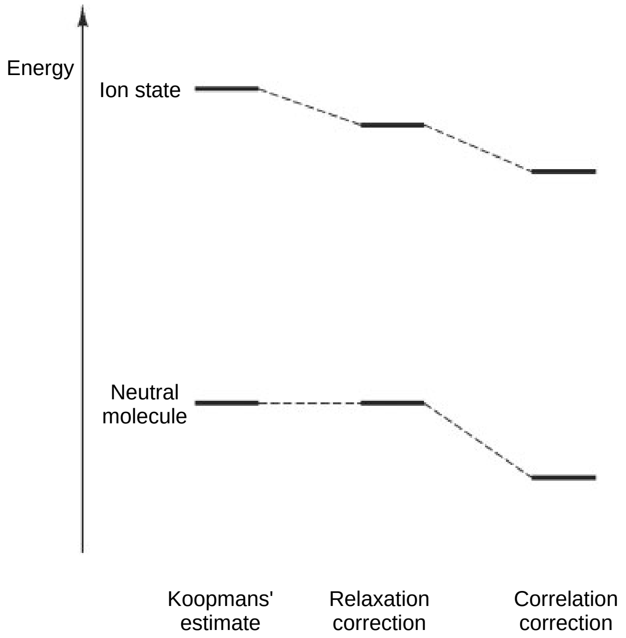

Figure 4 Diagrammatic representation of the relaxation and correlation energy corrections needed in deriving accurate IE from Koopmans' estimates

closed-shell molecule. Such is the power of this model that it is the starting point of most PE spectral interpretations. In fact, many PE bands show structure, and observations of additional bands are not uncommon. Most chemists prefer an interpretative approach, which is as simple as possible, but are ready to increase the sophistication of their models as the experimental facts demand. Consequently, an orbital approach to spectral assignment is the basis of the ensuing section.

Core binding energies also differ from the Koopmans estimate, the negative of the core orbital energy. When an inner electron leaves an atom of a molecule, the outer orbitals readjust because the nuclear charge is less effectively screened. The change due to outer shell readjustment is known as intra-atomic (or intramolecular) relaxation energy.

To the outer electrons, after ionization, the core looks like that of the atom with the next highest atomic number. This assumption, known as the equivalent core approximation, has been used in relating thermodynamic parameters to core binding energies.[13]

Though the binding energy of a particular type of core electron is characteristic of a given atom, the binding energies do vary over a narrow range depending on the chemical environment of the atom. For the initial state, the energy of a core electron is affected by the distribution of the valence electrons, as they generate a Coulombic potential that the core electron experiences. For the final state, the relaxation of the valence electrons towards the core hole will vary with the surrounding ligands. Both effects combine to give the experimental chemical shift for a molecule.

3.1 PE Spectrum and Orbital Structure of Mo(η-C_6H_6)$_2$

The PE study of the sandwich molecule Mo(η-C_6H_6)$_2$ (*see Hydrogenation*) illustrates the close relation between a PE spectrum of a molecule and its orbital structure.[14] Figure 5 shows the gas-phase He I PE spectrum of the complex, together with that of the free ligand benzene. It is immediately apparent that the majority of the ionization bands of benzene appear in the spectrum of the complex unshifted in energy and largely unchanged in shape. The fine structure of the bands, which is associated with vibrations of the molecular ion (see Section 5.1), is less well resolved and modified in the heavier molecule. The first ionization band of benzene, which is associated with ionization from the top e_{1g} π orbital, is perturbed on complexing and is split into two. In addition, the spectrum of Mo(η-C_6H_6)$_2$ contains two additional low IE bands, one considerably more intense than the other, which have no counterpart in the benzene spectrum. These are associated with ionization of the six metal d electrons of Mo(0).

The relation to the orbital structure of a sandwich molecule becomes clear on inspection of Figure 6. Bonding in the molecule is primarily produced by donation from the top π orbitals of benzene into the d_{xz} and d_{yz} orbitals of Mo, resulting in the e_{1g} MO, and back donation from the filled $d_{x^2-y^2}$ and

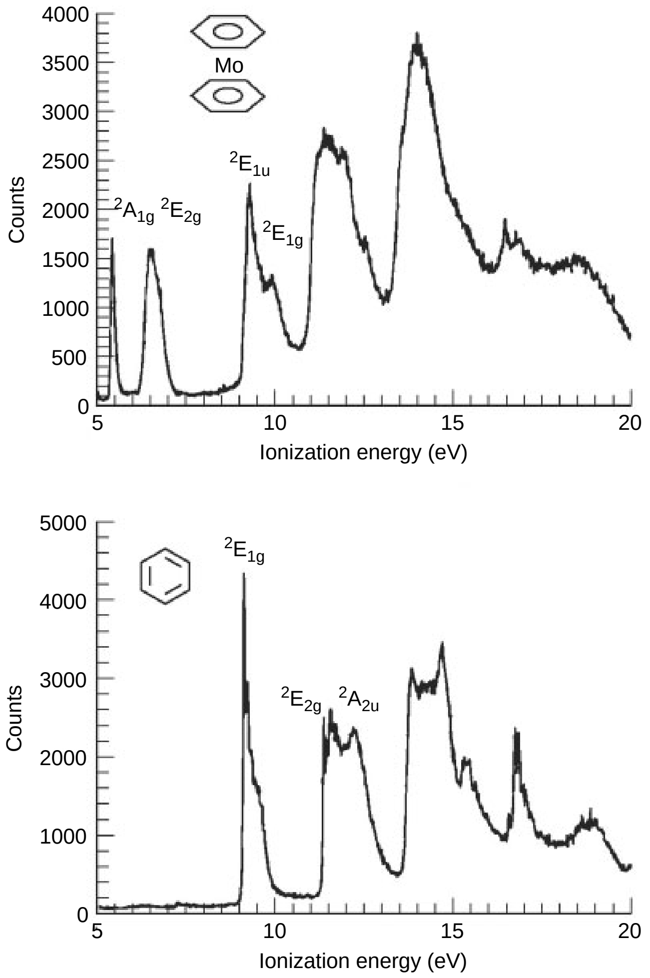

Figure 5 He I spectra of Mo(η-C_6H_6)$_2$ and C_6H_6. Bands are labeled according to the symmetry of the ion states formed

d_{xy} orbitals of Mo into the empty $e_{2u}\pi$ orbitals of benzene, resulting in the e_{2g} MO. The consequent stabilization of the e_{2g} orbitals with respect to the a_{1g} orbital, which is largely d_{z^2} in character and nonbonding, results in the e_{2g} electrons having a higher IE than the a_{1g} electrons. In a similar fashion, the metal–ligand-bonding character of the e_{1g} orbital is reflected in the higher IE for the e_{1g} electrons compared with that of the e_{1u}. Only Mo p orbitals can contribute to the e_{1u} interaction and they are less effective at bonding than the Mo d orbitals. The band assignment has been confirmed[15] by studying the intensity variation of the bands with photon energy (see Section 4.2).

4 INTENSITIES OF PE BANDS

In addition to the energy information in a PE spectrum, there is also intensity information. Whereas the derived IEs of

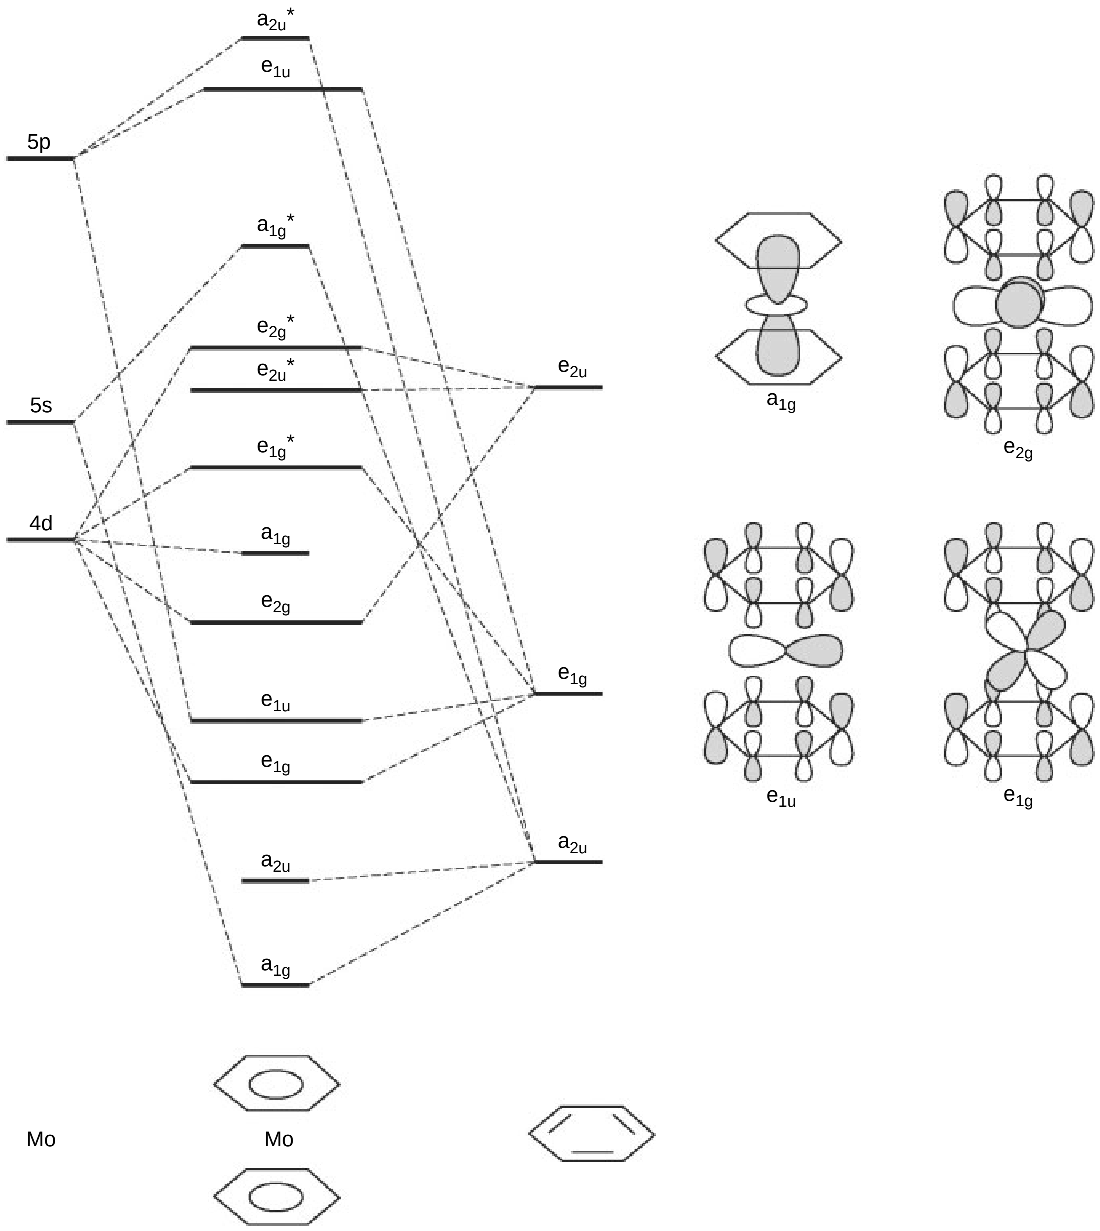

Figure 6 MO scheme for Mo(η-C_6H_6)$_2$; the 18 valence electrons occupy the orbitals up to the a_{1g} level

the photoelectrons are characteristic only of the sample being studied, the band intensities depend, in addition, on the angle of observation of the photoelectron with respect to the photon beam, the polarization of the photons, and also the photon energy. Interpretation of the variations in intensity can give further information on electronic structure.

The probability of photoionization to an ion state is termed a photoionization or photoelectron *cross section*, commonly denoted σ (ω). Photoionization is a dipole transition between the initial and final states. The only difference from discrete electronic excitations is that the final state lies in the continuum. This means that for each energy $E > 0$ there is a solution of the Schrödinger equation. This solution does not decay at infinity, but oscillates periodically and corresponds physically to an electron asymptotically free. Moreover, each energy is infinitely degenerate, corresponding to the infinite choices for the direction of the photoelectron momentum, or equivalently for each value of the photoelectron angular momentum. For example, in the hydrogen atom, for each energy $E > 0$ there is a ψ_{Elmms} final orbital, that is an s wave, a p wave, and so on. Transition probability is controlled by the dipole transition moment

$$\mathbf{M}_{\mathrm{fi}} = <\Psi_{\mathrm{f}}|\mathbf{r}|\Psi_{\mathrm{i}}> \qquad (6)$$

and the cross section is the sum of the squares

$$\sigma = \sum_{f} |\mathbf{M}_{fi}|^2 \tag{7}$$

over all final states available.[16,17] In an orbital approximation, this reduces to the interaction between the vacated orbital ϕ_i and the photoelectron wave ε_f.

4.1 Angular Variation

As angular momentum is conserved in photoionization, the wavefunction of the ejected electron is constrained by the dipole selection rule, and in the Russell–Saunders coupling limit the quantum number l must change by ± 1. For example, ejection from an s orbital gives rise to a p electron wave, whereas ejection of a d electron can give photoelectrons with p or f character. The angular distribution of photoelectrons depends on the angular momentum mix of these outgoing spherical waves. Generally the $l \rightarrow l + 1$ transition is the dominant contribution.

If the electrons are observed at an angle θ to the direction of the electric vector of a plane polarized light beam, the intensity $I(\theta)$ is given by equation (8):[18]

$$I(\theta) = \frac{\sigma}{4\pi}\left[1 + \frac{\beta}{2}(3cos^2\theta - 1)\right] \tag{8}$$

where σ is the total cross section integrated over all angles, and β, known as the anisotropy parameter, is the only parameter needed to describe the angular distribution of the photoelectrons. For a pure p wave resulting from ionization of an s orbital, β has a value of 2, so the angular distribution has a $\cos^2\theta$ distribution and the most probable direction of ejection of the s electron is at right angles to the electric vector. Equation (8) must be modified for the cases of unpolarized or partially polarized light.[12] The range of allowed values for the asymmetry parameter, β, is from -1 to 2. In molecules, because of the loss of spherical symmetry, much more extensive mixing is possible, and interpretation is correspondingly more complicated.[19] For most ionizations from atoms and molecules, β will vary with photon energy.

So far there have been few β measurements on molecules containing transition metals. A study on various organometallics, including *Ferrocene* and the group 6 hexacarbonyls, showed that the variation of β with photon energy differed according to the orbital being ionized, and was used on an empirical level to confirm some assignments.[20]

4.2 Variation with Photon Energy

As all one-electron photoionizations are allowed, photoionization cross sections, σ, for particular ion states are all of the same order of magnitude. They vary with the photon energy used, and the variation is characteristic of the nature of the vacated orbital. Studying PE cross sections is thus a very useful way of obtaining more information on electronic structure and assigning PE bands.

4.2.1 Atomic Cross Sections

Cross section variations are best understood for atoms, and a useful compilation of calculated atomic cross sections for direct photoionization exists.[21] Most qualitative features can be understood in terms of the interaction between the vacated orbital and the outgoing electron wave (equation 6). A cross section is usually highest near the threshold and after that decreases with increasing photon energy. This is a consequence of the photoelectron having a greater KE, and hence a shorter wavelength. As the electron wave becomes more oscillatory the positive and negative parts of the dipole matrix element with the vacated orbital tend to cancel one another (Figure 7(a)) and the cross section suffers rapid decay as exemplified by the 2p cross sections of the elements B to Ne (Figure 7(b), 7(c)). At very high photon energies, the cross section should vary as ν^{-3}.

For orbitals with a radial node, there is a minimum in the cross section, known as a Cooper minimum.[22,23] At some photon energy, the contributions from the inner and outer parts of the orbital will tend to cancel one another (Figure 7(d)). Figure 7(e) illustrates the occurrence of such a minimum in the cross section of the 3p electrons of the elements Si to Cl. Figure 7(f) shows the cross section of the t_1 band of $TiCl_4$, which shows a Cooper minimum at 40 eV;[24] by symmetry, this is pure Cl 3p in character (see also Section 4.2.4). If an orbital has more than one radial node, there may be a corresponding number of Cooper minima in the cross section. The minima may occur just above threshold, as is the case for the 3s orbital of Na, or several hundred eV, as is found for 4d and 5f electrons of transition elements. Rules for Cooper minima, which have been arrived at by experimental and theoretical investigations, are as follows:

1. Cooper minima only appear in $l \rightarrow l + 1$ transitions.
2. They occur only for outer and near outer subshells, and only for those orbitals with radial nodes.
3. They are generally not zero minima because even though the $l \rightarrow l + 1$ dipole matrix element vanishes, the $l \rightarrow l - 1$ one does not.

With such minima, the photon energy may be tuned to minimize the contribution from certain types of orbitals to a PE spectrum. The angular parameter, β, can vary substantially in the region of a Cooper minimum as the contribution from the $l \rightarrow l + 1$ wave is small, leading to domination of β by the $l - 1$ wave.

Orbitals with high angular momentum (i.e. d or f orbitals) often have maxima in their ionization cross sections some way above threshold. This is in contrast to s and p orbitals

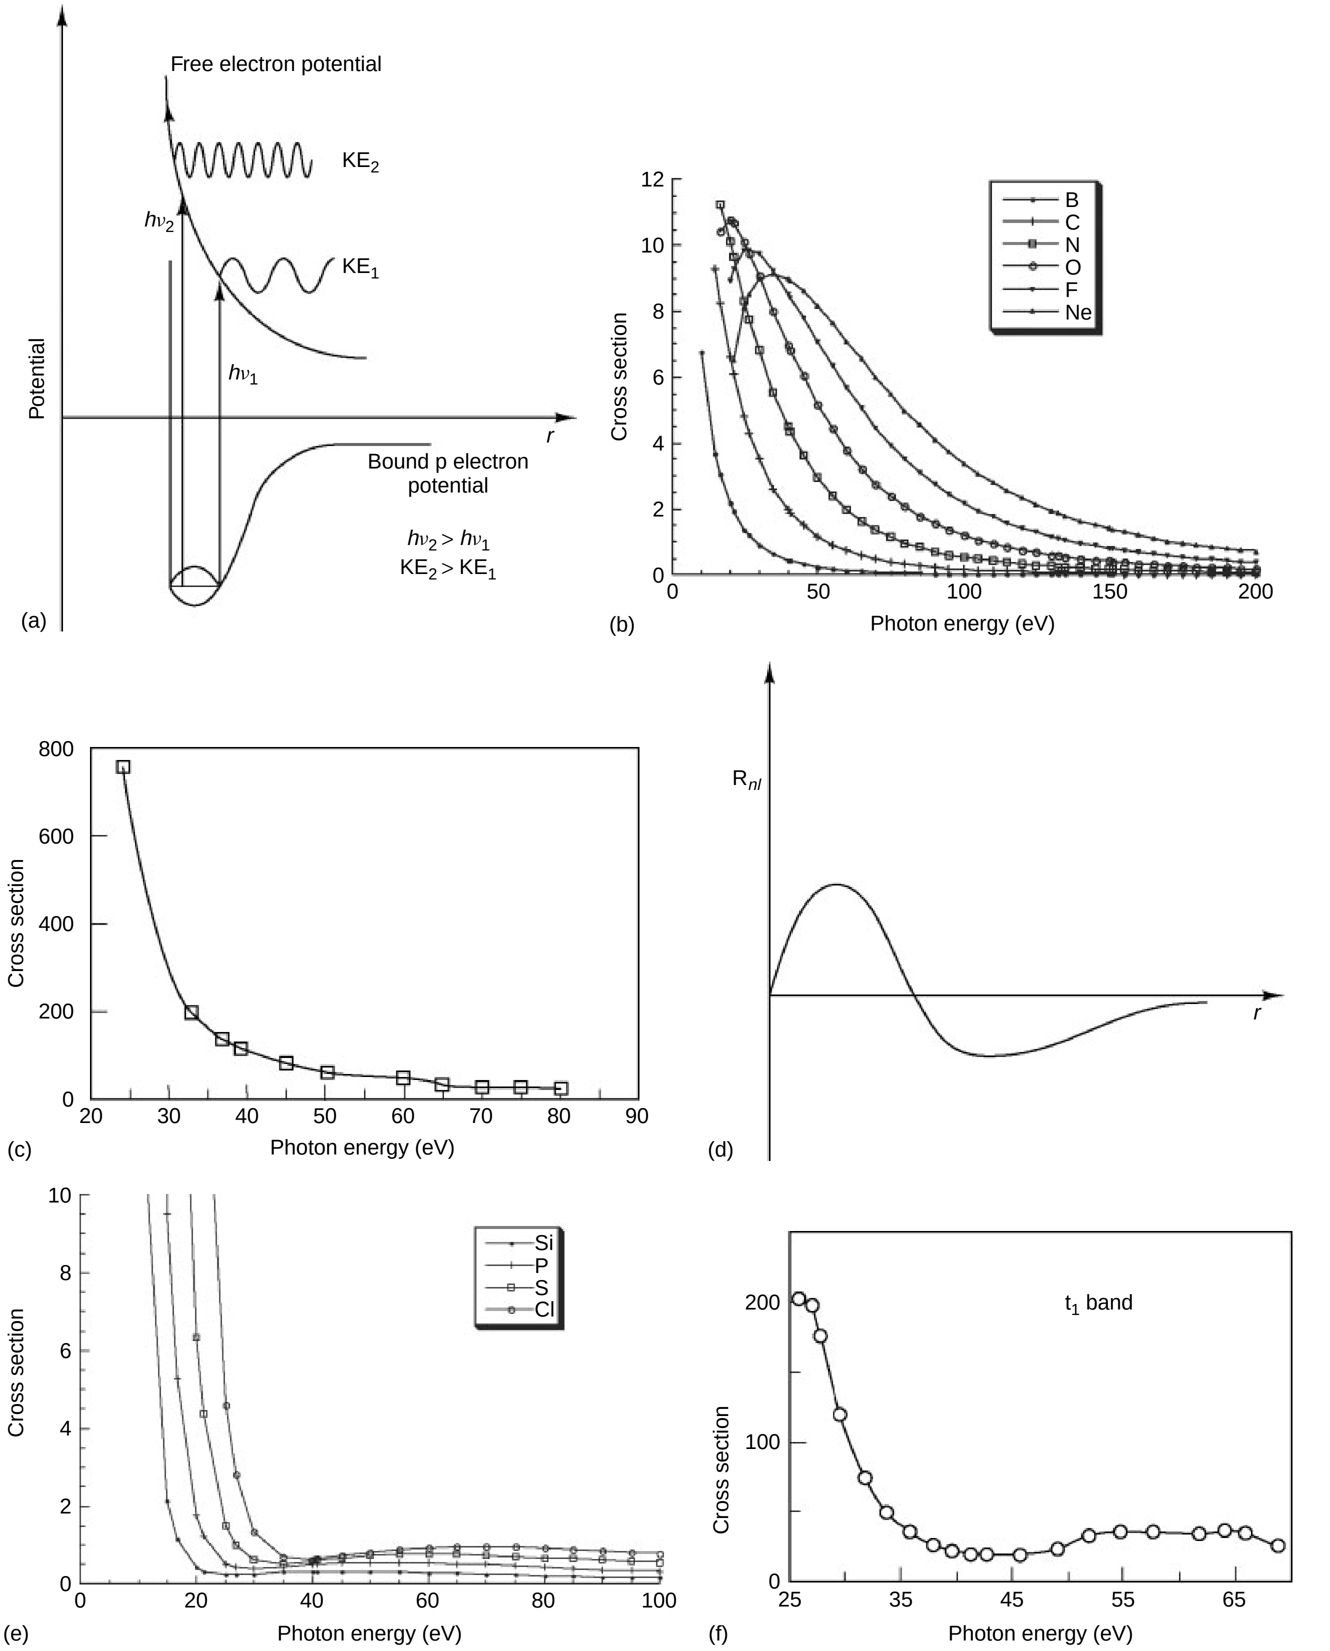

Figure 7 (a) Representation of the interaction of a bound 2p electron and electron waves of low and high kinetic energy; (b) calculated 2p cross sections for B-Ne (c) experimental cross section for a C 2p electron (d) potential and radial wavefunction for a 3p electron; (e) calculated 3p cross sections for Si-Cl (f) cross section for t_1 band of $TiCl_4$, which has Cl3p character

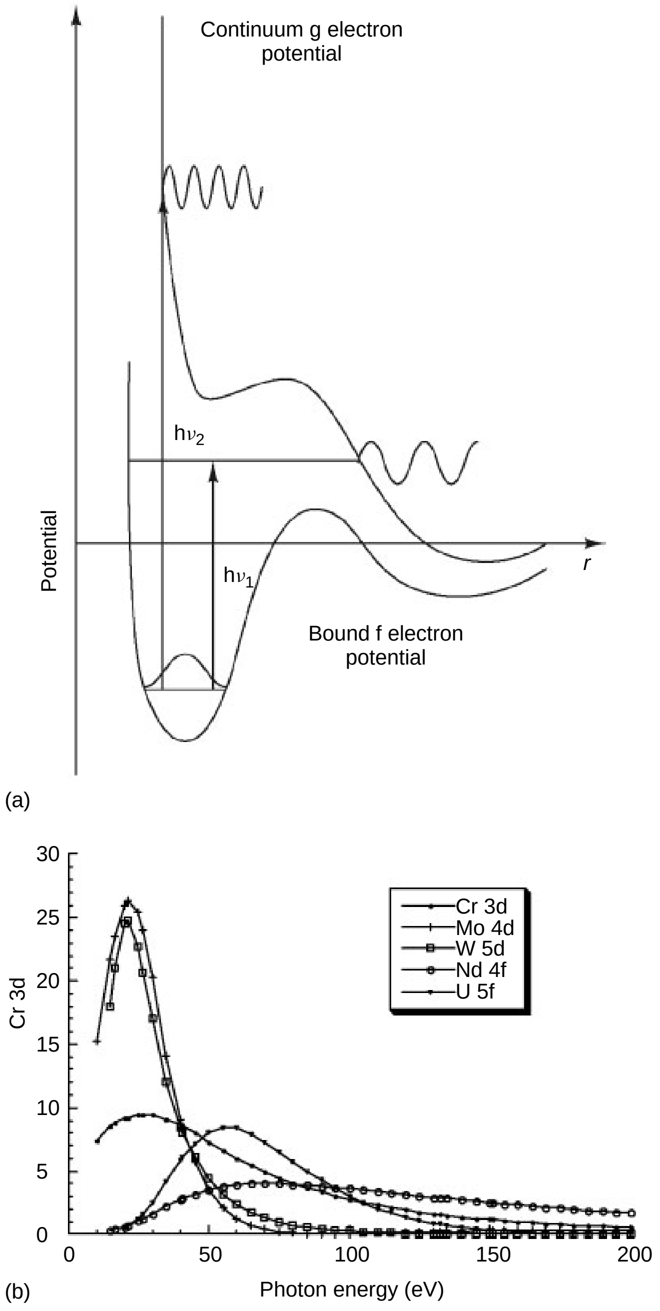

Figure 8 (a) Schematic representation of the radial potential and wavefunctions for a bound f electron and a continuum g electron, illustrating the origin of the delayed maximum; (b) calculated ionization cross section of d electrons for Cr, Mo, and W and f electrons for Nd and U

where maxima, if they exist, tend to be very close to threshold. The effective potential experienced by an electron in an atom is given by the central field potential[25] and the radial wave equation is given by equation (9):

$$\left[\frac{d^2}{dr^2} + \frac{l(l+1)}{r^2} + V(r)\right]\Psi_{nl}(r) = E\Psi_{nl}(r) \tag{9}$$

$V(r)$ is the Coulombic potential, which is attractive, and $[(l(l+1)/r^2)]$ is termed the centrifugal repulsion term and results from the solution of the angular part of the Schrödinger equation. For high values of l, the effect of the centrifugal term is to create a double well potential, which has an intermediate range maximum that may be positive. Figure 8(a) illustrates the case for a bound f electron that exists in the inner well, escaping as a g electron wave. At low photon energies, the ensuing wave has insufficient energy to penetrate the centrifugal barrier, so the interaction between the f electron and the g wave is small. At higher photon energies, the interaction improves and the cross section will pass through a maximum before decaying owing to the normal oscillatory effects.

Figure 8(b) shows the calculated cross sections for Cr 3d, Mo 4d, W 5d, Nd 4f, and U 5f orbitals. The delayed maxima for the f electrons occur at a higher photon energy than those of the d electrons as the centrifugal barrier is higher in the former case. This results in f electrons having very low cross sections at He I energies. The ionization cross section of the f electrons of $U(\eta\text{-}C_8H_8)_2$ (see Section 4.2.5) shows a delayed maximum at 39 eV.[26] The maximum cross section for Cr is lower than for Mo and W, and this is generally the case for first-row transition metal compounds. However, as 3d orbitals have no radial nodes, their cross sections decay much less rapidly with photon energy than those of 4d and 5d metals. Similar features are apparent when comparing 4f and 5f cross sections.

In the critical energy region between 20 and 40, d and f electron cross sections tend to increase, or decay rather more slowly than those of s and p electrons. As a consequence, changes in relative band intensity between He I and He II spectra can often be used to distinguish between metal and ligand bands. This is illustrated in the He I and He II PE spectra of Re_3Cl_9 and Re_3Br_9[27] (Figure 9).

A Cooper minimum occurs around 39 eV for Cl 3p ionizations, which makes their He II cross sections very low. Br 4p cross sections are calculated to drop by a factor of 16 between He I and He II photon energies. The peaks associated with Re character tend to gain in intensity relative to the halide ones as the photon energy is increased. For the chloride, the lowest IE bands are associated with metal–metal-bonding orbitals of the Re_3 cluster, whereas for the bromide the lowest IE bands are bromine 4p in character. For both compounds, the covalent nature of the metal–halide σ bonds results in metal-like cross section behavior in the highest IE ionizations of the spectra shown.

4.2.2 Autoionization and Giant Resonances

All the cross section variations discussed above are the result of direct ionization. If autoionization (Section 1.2) occurs, it can have a substantial effect on PE band intensities at photon energies close to an autoionizing resonance frequency.

Resonant excitation of inner electrons can also have considerable effects on the photoionization cross sections of d

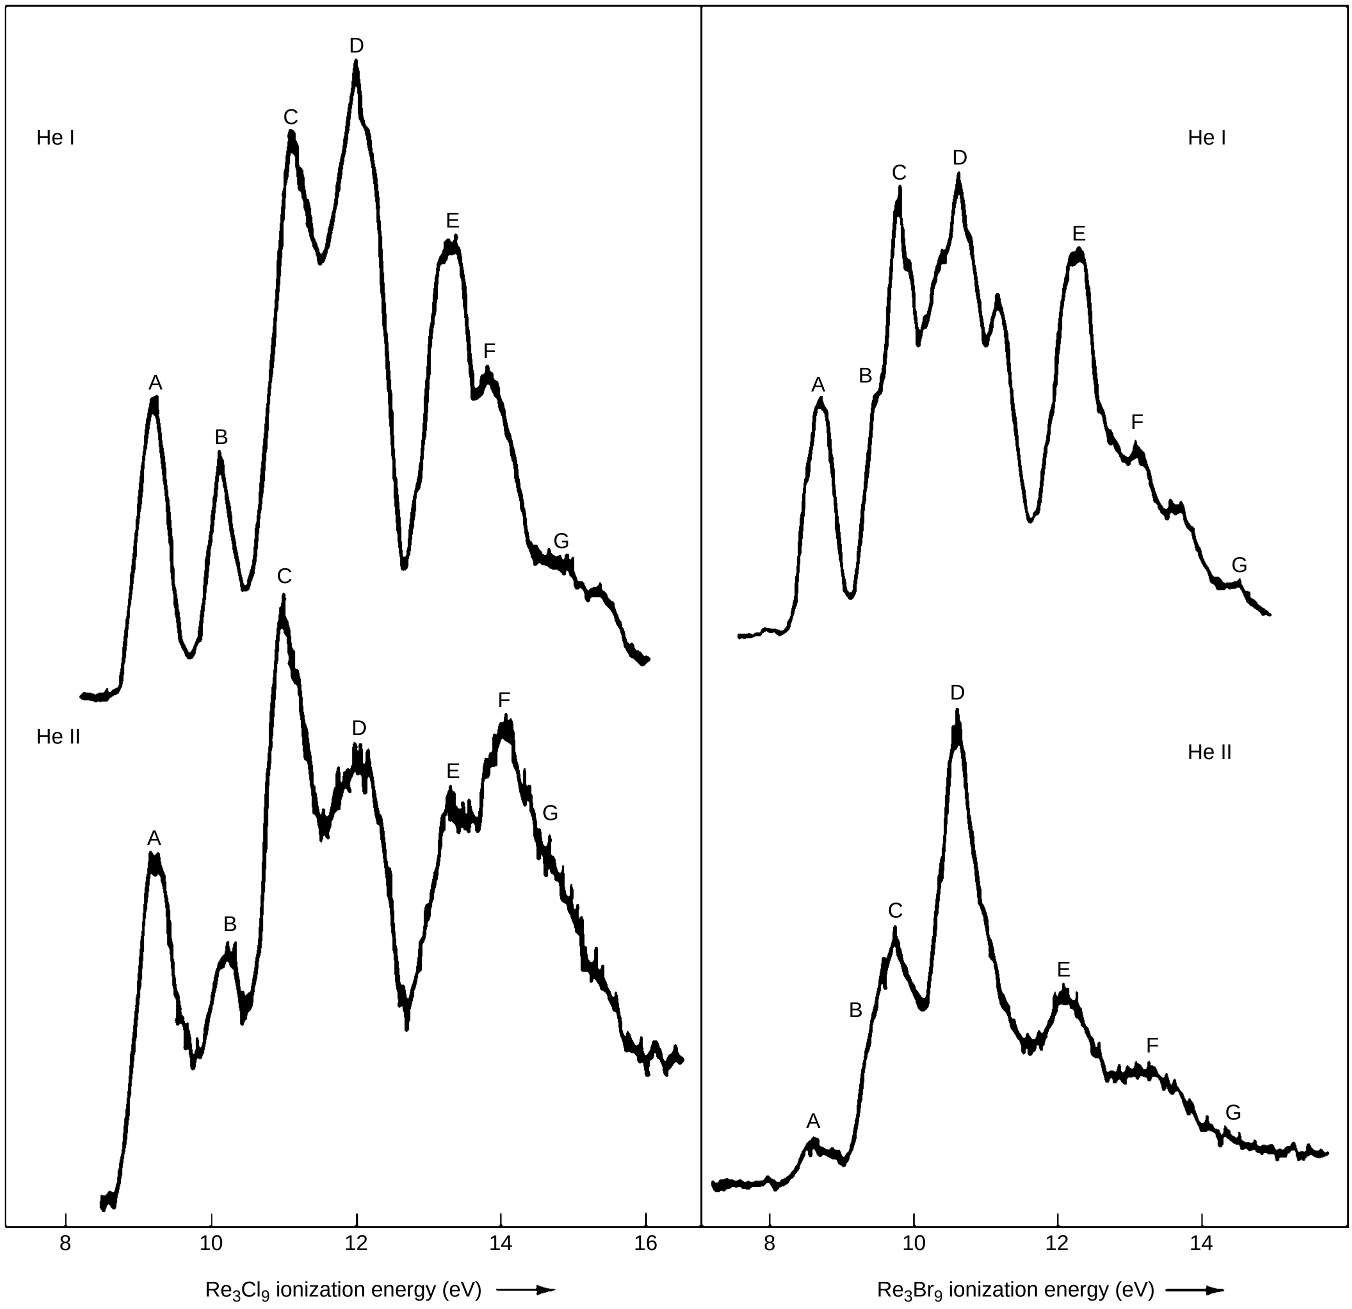

Figure 9 He I and He II PE spectra of Re_3Cl_9 and Re_3Br_9

and f electrons. Let us take the principal quantum number of the ionizing d and f electrons as n. If the photon energy is sufficient, an electron can be promoted from an inner np or nd shell to an empty nd or nf orbital. When d and f electrons are bound, the wavefunctions have nearly all of their amplitude in the inner well of their potential, which results in very large probabilities for transitions from inner p to valence d (or inner d to valence f) orbitals of the same principal quantum number. The spatial proximity results in strong interactions between the np or nd hole and the $n\mathrm{d}^{x+1}$ or $n\mathrm{f}^{x+1}$ states, and the energies of the configurations are spread over many eV, many of which lie above the np or nd ionization threshold. One possible fate of such excited states is termed super Coster–Kronig (SCK) decay, whereby the d or f electron falls back into the hole and another d or f electron is ionized. As far as its KE is concerned, the ionized electron is indistinguishable from one resulting from direct photoionization resulting in the same ion state (Figure 10).

In an independent particle picture, one has a discrete state, like $3\mathrm{p}^{-1}3\mathrm{d}^{x+1}$, interacting with the continuum $3\mathrm{d}^{x-1}\varepsilon\mathrm{f}$, $\varepsilon\mathrm{p}$. Configuration interaction mixes the discrete state, which loses its separate existence, in the continuum. The transition moment

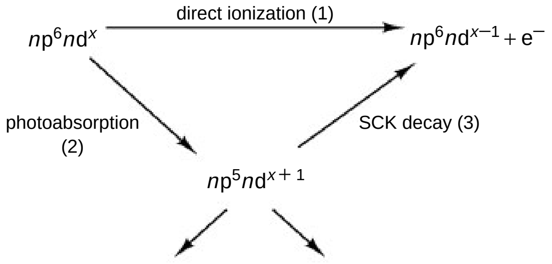

Figure 10 Illustration of two channels for ionization of a d electron, direct photoionization, and photoabsorption followed by SCK decay

associated with the excitation into the discrete configuration, which can be very large if initial and final orbitals are strongly localized in the same region of space, for example, 3p → 3d, interferes with that due to the original continuum, giving rise to sharp features in the cross section, with the characteristic 'Fano profile'[28,29]

The strength of the resonance, and the shape of the profile, is governed both by transition moments, for example, $<3p|\mu|3d>$, and the interaction between the discrete and continuum state, for example, $<3p^{-1}3d^{x+1}|1/r_{12}|3d^{x-1}\varepsilon f>$. The increases are preceded by a dip in the cross section; somewhat counterintuitively, opening another channel for photoionization can lead to a decreased ionization probability. As well as possessing momentum, the photoelectrons possess phase. Interference between the two channels, the direct and indirect processes, lead to the resonance shape. This phenomenon is generally called autoionization, and, in particular for core excitation and decay all involving orbitals of the same principal quantum number, SCK decay. As a consequence, d and f cross sections are strongly modified in the resonance region. The process is only effective for high angular momentum electrons because the centrifugal barrier associated with their effective potential is necessary to retain the excited electron. The lifetime of the excited state is very short, and uncertainty-broadening leads to the effect on PE cross sections being spread over many electron volts.

Figure 11 shows the d band cross sections for the group 6 hexacarbonyls $M(CO)_6$, where M = Cr, Mo, or W;[30] the effect of the resonance absorption on the cross sections is clearly evident at energies around that needed for inner *n*p shell ionization, which is indicated on the energy scale. Two resonances are seen for W 5d ionization as the spin–orbit splitting of the 5p core hole is of the order of 10 eV and is sufficiently large to be resolved.

Giant resonances are also evident in the $U(\eta\text{-}C_8H_8)_2$ f band cross section at 97.5 and 107.5 eV (Section 4.2.5); the 5d core electrons of the uranium atom ionize at 101 and 110 eV.[26]

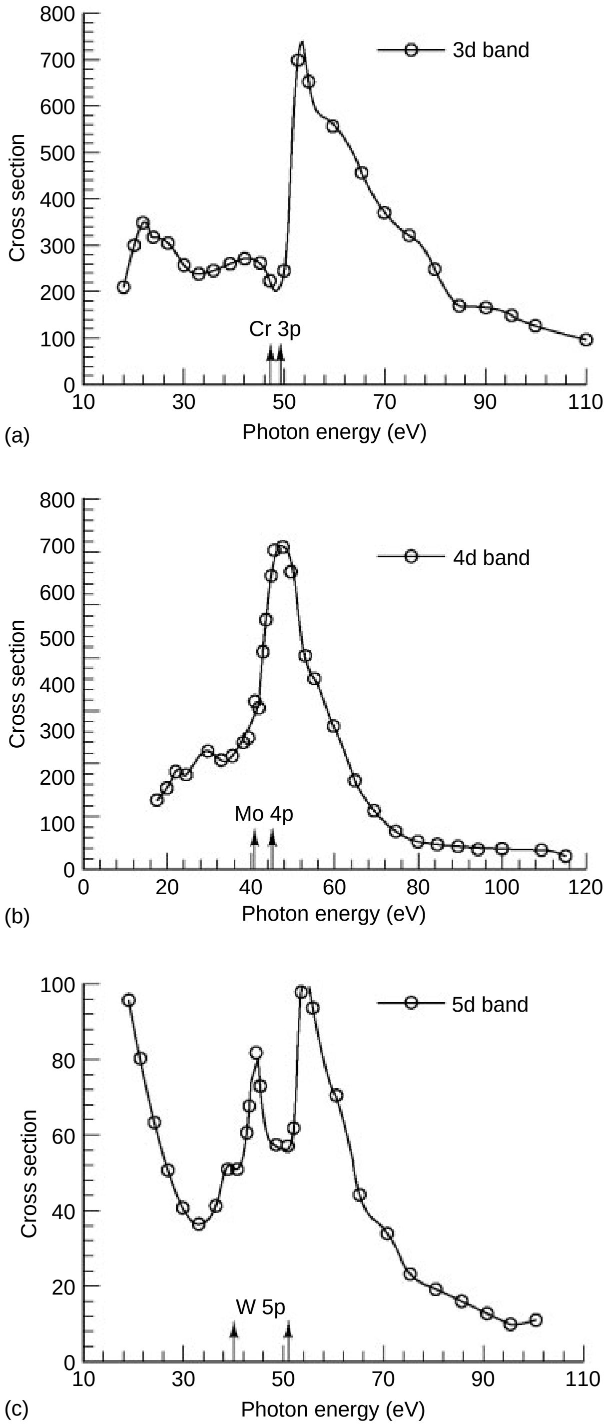

Figure 11 Photoionization cross sections of the d (t_{2g}) electrons of (a) $Cr(CO)_6$, (b) $Mo(CO)_6$, and (c) $W(CO)_6$, as a function of photon energy. The cross sections are given in arbitrary units. The vertical arrows mark the ionization energies of the 3p, 4p, and 5p electrons of Cr, Mo, and W, respectively

4.2.3 Molecular Cross Sections; the Gelius Model

Cross sections of molecules show many of the features of the atoms that constitute them; the characteristic patterns of ionization from atomic orbitals are carried over to the molecular orbitals to which they contribute. The most commonly used model for interpreting molecular

photoionization cross sections is the Gelius model,[22,23] in which the one-electron cross section, σ_j, for the jth MO is given by equation (10). The summation is carried out over all the AOs, $\chi_i{}^{\mathrm{A}}$, on the different atoms, A, which contribute to the MO, ϕ_j:

$$\sigma_j = \sum_{\mathrm{A},i} P_{j,i,A}\sigma_i^A \tag{10}$$

The $\sigma_i{}^A$ are one-electron atomic cross sections and the $P_{j,i,\mathrm{A}}$ are factors describing the weight of the contribution of the AOs to the MO. In a LCAO MO treatment they are given by the squares of the coefficients $c_{j,i,\mathrm{A}}$ of the AO χ_i in the MO ϕ_j (equation 11):

$$P_{j,i,A} = (c_{j,i,A})^2 \tag{11}$$

The model is valid when the contribution of the overlap electron density to the cross section is negligible and the effects of the anisotropy of the molecular ion potential on the outgoing electron wavefunction are small. Both of these conditions are most likely to hold when the photoelectron KE is high. At low photon energies, molecular effects on ionization cross sections are well documented, but even in these regions atomic effects are evident and the Gelius model provides a good basis for molecular cross section interpretation.

4.2.4 Molecular Effects and Shape Resonances

Though many of the features of molecular PE cross sections can be attributed to atomic effects, some features, such as shape resonances, are critically dependent on the form of the molecular potential.[25,31] This itself is determined in part by the physical shape of the molecule, from which the name of the effect derives. Shape resonances manifest themselves as increases in cross section, which are frequently sharp and generally at relatively low PE kinetic energies. They are generally viewed as attributable to momentary trapping of the electron in a quasi-bound continuum orbital created by an effective potential of the molecular ion, or, excitation into antibonding orbitals located in the continuum.[32]

An alternative, though not incompatible, view of shape resonances, is to regard them rather like Extended X-ray Absorption Fine Structure (EXAFS), where an ionizing electron is scattered from neighboring atoms, and so has maxima and minima in its amplitude as a function of its energy, as a result of the scattered waves reinforcing or interfering with the outgoing wave. In this model also, it is apparent that the resonances are a function of the shape and size of the molecule.[30,33]

It has been observed empirically that the a_1 bands of tetrahedral molecules show shape resonances. OsO_4 provides an example.[34] The $^2A_1$ band shows a sharp rise in intensity around 52.5 eV (Section 7.1). The related $^2A_1$ band of $TiCl_4$

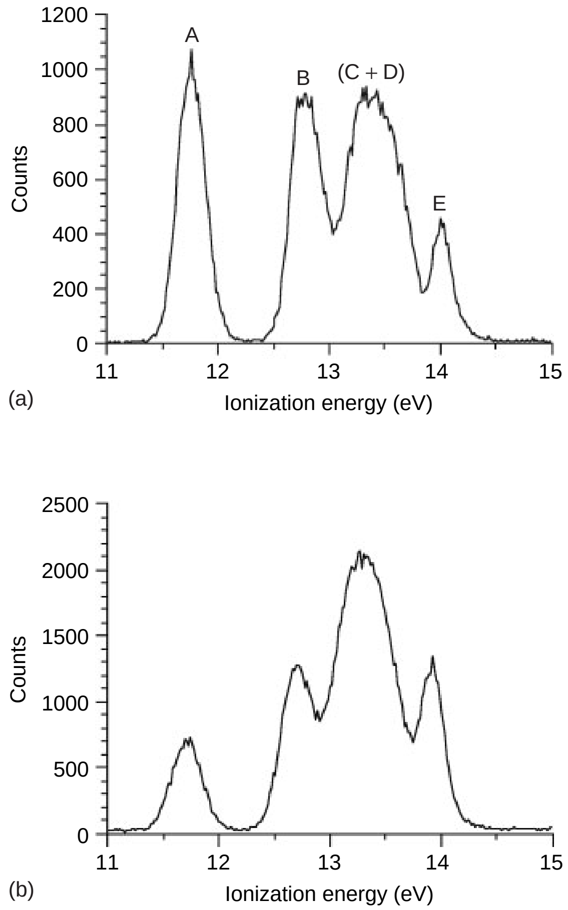

Figure 12 The PE spectrum of $TiCl_4$, acquired at (a) 24 and (b) 40 eV. Bands A and E are the t_1 and a_1 ionizations respectively and have predominantly Cl character. While A shows a Cooper minimum at 40 eV, E is relatively intense owing to a shape resonance

shows a shape resonance at a lower photon energy of 40 eV (Figure 12).[24]

Maxima in the PE ionization cross sections of metallocenes and related sandwich molecules have been identified and assigned to shape resonances.[35–37] The molecular potential for this series of molecules is expected be very similar throughout the series and largely independent of the nature of the metal. For bis-cyclopentadienyl metal compounds, a shape resonance occurs in a region between 36 and 40 eV, whereas the $p \rightarrow d$ resonances occur over a range of 43 to 75 eV depending on the metal. Bis-arene and cycloheptatrienyl-cyclopentadienyl compounds show similar features.[37,38] In the most part, the shape resonances are most apparent in the metal-based orbitals, the strength of the resonance increasing with the metal character. An exception to this is the ionization cross section from the e_1'' HOMOs (highest occupied molecular orbitals) of cobaltocene and nickelocene.[36] These antibonding d orbitals show smaller $p \rightarrow d$ resonances than the more metal localized a_1' and e_2' orbitals, in accord with the expectation of

their respective metal characters, but significantly stronger shape resonances.

These and other instances of the presence of shape resonances in the region of 40 eV photon energy provides a cautionary note for the interpretation of relative increases in band intensity in He II spectra, compared to He I spectra as attributable to metal d character.

4.2.5 *Evidence for Covalency from Cross Section Variation*

Though cross section variation can be studied to a very limited extent using line sources, synchrotron radiation is far superior for investigations of this type. Synchrotron studies are used extensively on transition metal solids for deconvoluting valence bands into partial densities of states from the contributing AO. Studies on transition metal molecules have demonstrated the power of the technique for band assignment and the investigation of covalency.

Uranocene, U(η^8-C_8H_8) provides an excellent example.[26] The f ionization band, the first of the spectrum, shows two characteristic features, a delayed maximum and a giant resonance. Figure 13(a) shows the cross section of this band. The next two bands are primarily ring C 2pπ bands of e_2 symmetry. They show the characteristic decay associated with nodeless 2p orbitals (Figure 13(b)). The second band, however, has, superimposed on this decay, a maximum around 40 eV and a double resonance between 95 and 125 eV. This indicates partial 5f character and assigns the orbital to the e_{2u} orbital. The third band is consequently associated with the e_{2g} orbital and its higher IE is indicative of the fact that the U 6d orbitals form more effective bonds that the 5f in this instance.

The group 8 *Metallocene Complexes*, ferrocene, ruthenocene, and osmocene, have been studied using synchrotron radiation over the photon energy range 16–115 eV.[35] They have an orbital structure very similar to that of Mo(η-C_6H_6)$_2$ (Figure 6). The d ionization bands have the cross section variations shown in Figure 13. They all show cross section features attributable to nd resonant photoemission in the region of np → nd resonant absorption, that of Ru being particularly strong. Ferrocene shows a Fano dip in its cross section profile at 55 eV and no maximum. For Ru and Os, the cross sections are very low (around 100 eV) as they approach the Cooper minima in the d cross sections. For the Fe 3d orbital, which has no radial node and hence no Cooper minimum, the cross section stays relatively high. For the metallocenes, the e_1 ring π orbitals form two sets of MOs: one of e_1' symmetry, which has a possible contribution from metal p orbitals, and one of e_1'' symmetry, to which metal d orbitals can contribute. The relative intensities, or branching ratios, of the two bands lying above the d bands in IE are plotted in Figure 14. These two bands, which differ in their cross section behavior, are assigned to the e_1' and e_1'' MOs. In all cases, the higher IE band shows features characteristic of d cross section behavior:

1. At low photon energies, they are less intense in the region where the d cross section is less than that of C 2p orbitals.

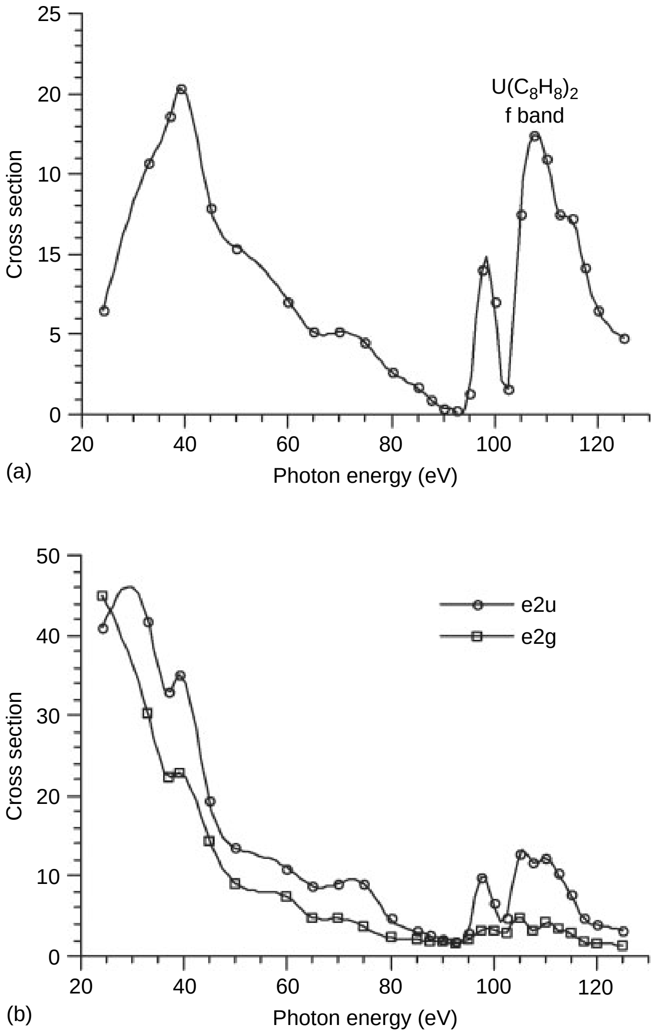

Figure 13 PE cross sections of uranocene (a) f band showing a delayed maximum and a giant resonance (b) e_{2u} and e_{2g} bands, the e_{2u} band shows features characteristic of f character

2. They show minima and maxima over the resonance region at energies corresponding to those found in the d band.
3. For Ru and Os, they become less intense at high photon energies in the region of the Cooper minima. For Fe, at high photon energies the branching ratio of the higher energy band continues to increase.

This behavior confirms that the higher IE bands are associated with the e_1' ionizations and that the e_1'' orbitals have d character.

5 SPECTRAL FEATURES OF TRANSITION METAL MOLECULES

PE bands frequently exhibit structure as a result of a variety of vibrational and electronic states accessible to a molecular

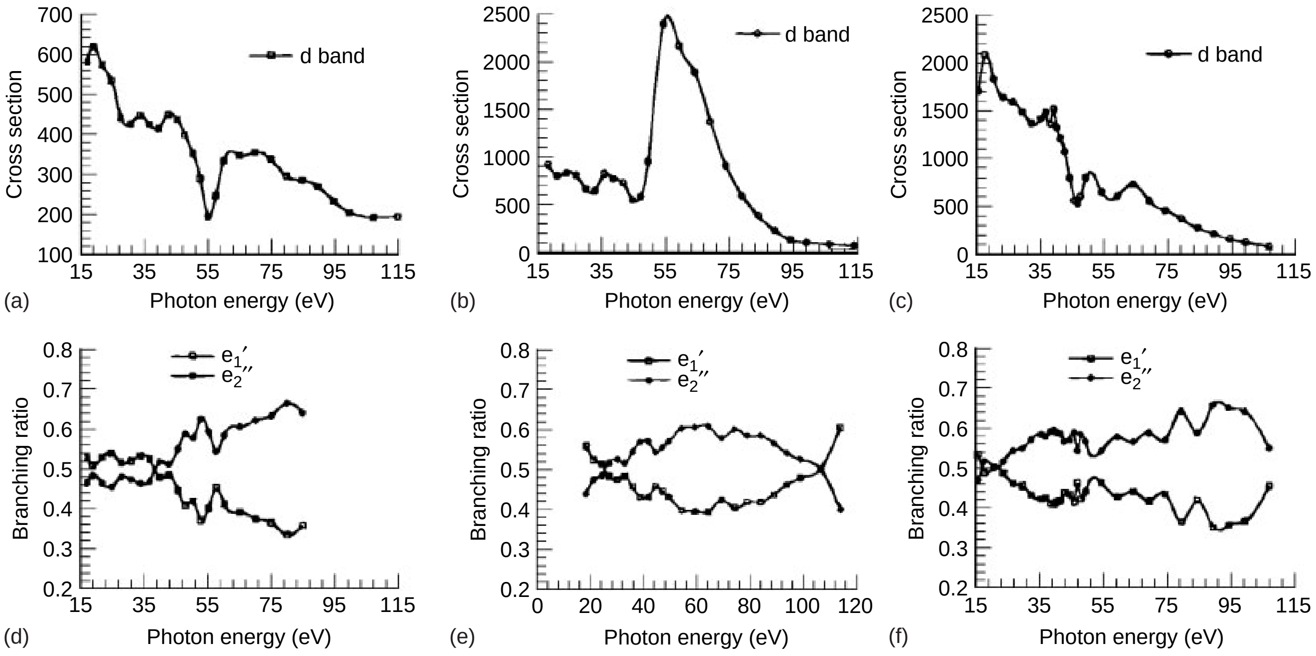

Figure 14 Photoionization cross sections (arbitrary units) of the d bands of (a) Fe(η-C_5H_5)$_2$, (b) Ru(η-C_5H_5)$_2$, and (c) Os(η-C_5H_5)$_2$. Branching ratios of the e'_1 and e''_1 orbitals of (d) Fe(η-C_5H_5)$_2$, (e) Ru(η-C_5H_5)$_2$, and (f) Os(η-C_5H_5)$_2$

ion formed by removal of an electron from a single molecular energy level. Even if such structure is unresolved, it can affect the band shape. Such structure is not only of intrinsic interest, but can be of considerable help in assigning PE bands and providing detailed information on the molecular electronic structure.

5.1 Vibrational Structure and Band Profiles

Photoionization may give rise to molecular ions either in their ground vibrational state or in one of a number of vibrationally excited states. It takes around 10^{-15} s for an electron to leave a molecule, so that during this time the motions of the atomic nuclei that make up the vibrations are effectively frozen. The vibrational timescale is of the order of 10^{-13} s. The transitions are governed by the Franck–Condon principle and can be represented by vertical lines on a potential energy diagram (Figure 15). In a PES experiment, the neutral molecules are almost invariably in their ground vibrational level. If there is little difference between the potential energy surfaces of the neutral molecule and the molecular ion state, the most probable transition is to the lowest vibrational level of the ion state, and the peak corresponding to the $\nu'' = 0 \rightarrow \nu' = 0$ transition dominates; the associated IE is known as the adiabatic IE. Significant changes in the potential energy surface result in transition to higher vibrational levels being more probable, and can result in an extensive vibrational progression being visible in a PE band. The IE associated with excitation to the most probable vibrational state is called the vertical IE.

The most likely cause of a significant difference between the molecular and ion state potential energy curves is that the electron removed is strongly bonding or antibonding. Vibrational progressions are therefore often associated with ionization from bonding or antibonding MOs. The separation of the vibrational levels observed in a PE band is characteristic of the ion state. Comparison of the measured vibrational frequency with that of the comparable vibration in the molecule can indicate which is the case. If the vibrational structure is unresolved, as is often the case in transition metal molecules with their many low-frequency vibrations, the band shape can still give some indication of the bonding nature of the vacated orbital; narrow bands are associated with nonbonding orbitals and broad bands with bonding (or antibonding) orbitals. Selection rules require that on ionization from nondegenerate orbitals only totally symmetric vibrations are excited.

Detection of vibrational structure in PE bands of transition metal molecules requires good resolution and careful control of surface potentials. Repetitive rapid scanning of spectra and addition using a calibrant line have been used effectively to correct for potential drift.[39] For the group 6 hexacarbonyls, $M(CO)_6$ where M = Cr, Mo, or W, not only ν(CO) but also ν(M–C) have been detected in the metal bands. Figure 16 shows the first PE band of the He I spectrum of $Mo_2(O_2CMe)_4$, a molecule with a quadruple metal–metal bond.[40,41] It is assigned to the $^2B_{2g}$ ion state corresponding to ionization from the δ symmetry metal–metal-bonding orbital.[42] A vibrational

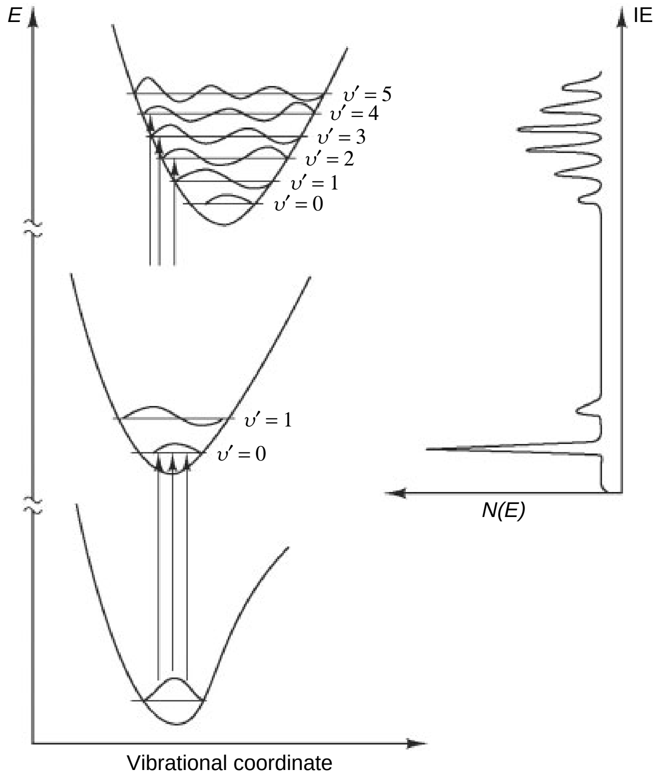

Figure 15 Potential energy curves showing the form of vibrational wavefunctions of a molecule and states of a molecular ion to illustrate the origin of vibrational excitation in ionizing transitions. The resultant PE bands are represented on the right

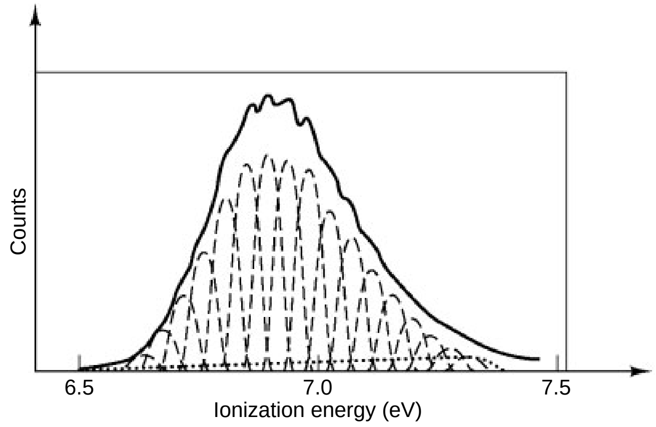

Figure 16 He I PE spectrum of the first IE band of $Mo_2(O_2CMe)_4$ and simulated analysis of the vibrational structure

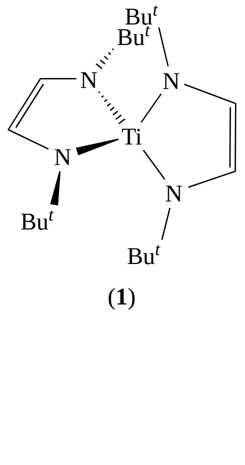
progression is clearly visible over the top of the band, and the whole band shape has been fitted with 18 vibrational components. The vibrational spacing is calculated to lie between 355 and 365 cm^{-1}, and corresponds to the a_{1g} Mo–Mo stretching vibration in the $^2B_{2g}$ ion state. Comparison with a value of 406 cm^{-1} for the equivalent stretch in the molecular ground state suggests that the metal–metal-bonding is reduced in the ion, and a Franck–Condon analysis gives an increase of around 0.1 Å in the Mo–Mo distance between the molecule and the ion. Though this bond weakening may in part be attributed to removal of a bonding electron, the effect of the positive charge in the ion on the overall bond strength must also be considered.

The first band of the PE spectrum of Ni(η^5-C_5H_5)(NO) shows a vibrational progression (Figure 17). In the initial assignment, band A_1 was assigned to a ligand band and band A_2 to a metal ionization.[43] However, cross section studies[44] showed them to have an identical ligand origin and that they were vibrational components of a single primary ligand band with a separation of $1850 \pm 81\,cm^{-1}$ corresponding to excitation of the NO stretch in the molecular ion.

5.2 Jahn–Teller Splitting

Ionization from a filled degenerate set of orbitals leads to a degenerate ion state that, for a nonlinear molecule, will be susceptible to Jahn–Teller distortion (see *Jahn–Teller Effect*). This distortion is brought about by excitation of one of the Jahn–Teller active degenerate vibrational modes of the undistorted molecule. When the distortion is small, and the vibrational intervals sufficiently large, a single band profile showing a Jahn–Teller vibrational progression is observed. Such is the case for ionization of the t_1 band of OsO_4 (Section 6.1).[45] When the distortion is large and the individual vibrational levels are unresolved, the band profile may show two or more separate maxima, each corresponding to a distinct electronic state of the molecular ion (Figure 18).

Such is the case with the first ionization band of [Ti{(*t*-Bu)NCH=CHN(*t*-Bu)}$_2$] (**1**), which is shown in Figure 19. The compound has D_{2d} symmetry and a closed-shell ground state. The HOMOs are a degenerate pair of e symmetry and fully occupied with four electrons. The compound is best regarded as a Ti(IV) derivative with the diazabutadiene ligands each doubly reduced. The highest lying occupied orbitals of the complex are principally composed of the neutral ligand π symmetry lowest unoccupied molecular orbitals, LUMOs. These ligand π_3 orbitals are doubly occupied in the complex and are C–C π bonding and C–N π antibonding. On



(**1**)

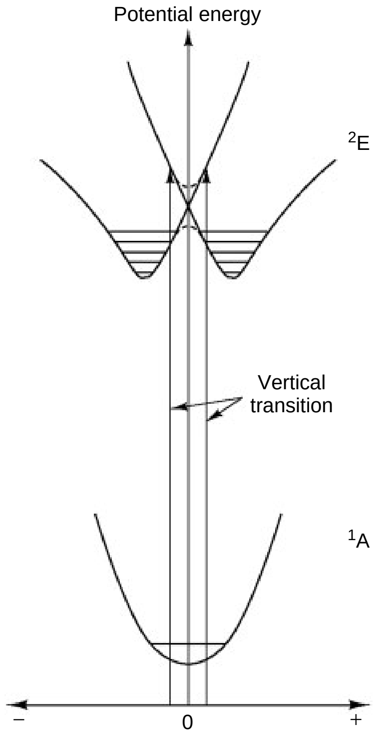

Figure 18 Representation of the potential energy surfaces involved in photoionization from a nondegenerate ground state of a molecule to a ^{2}E Jahn–Teller active state of a molecular ion. The distortion coordinate is the Jahn–Teller active vibration. The vertical arrows represent the most probable transitions

ionization from the e^4 configuration, a Jahn–Teller unstable ^{2}E state is produced. The compound distorts by deformation of a chelate ring, the C–C bond lengthens, and the C–N bonds shorten as is found for a singly reduced diazabutadiene ligand. This effectively traps two electrons on one ligand and one on the other. Such a ground state structure is found for Ga[(*t*-Bu)NCH=CHN(*t*-Bu)]$_2$,[46] which is isovalent with [Ti{(*t*-Bu)NCH=CHN(*t*-Bu)}$_2$]$^+$. The first ionization band shows two well-separated maxima, the first corresponding to the ground state with inequivalent rings, the higher energy one to states where the remaining electrons are trapped in rings of inappropriate dimensions.

5.3 Spin–Orbit Splitting

The ion states formed by removal of an electron from a fully occupied degenerate level may also be split by spin–orbit

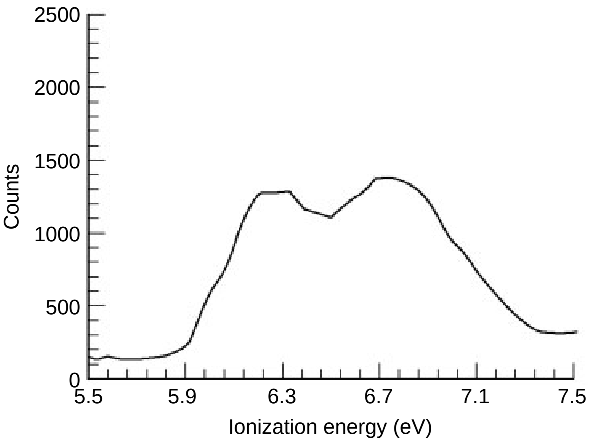

Figure 19 First IE band of the He I PE spectrum of [Ti{(*t*-Bu)NCH=CHN(*t*-Bu)}$_2$], showing a double maximum owing to dynamic Jahn–Teller distortion of the ^{2}E ion state

coupling. If the degenerate level occupied by the resultant unpaired spin has orbital angular momentum, the spin and orbital angular momentum can either reinforce or oppose each other, giving two allowed states. The magnitude of spin–orbit coupling is a function of the atoms present in a molecule; as it is primarily a relativistic effect, it increases with the atomic number of an atom, and decreases with the angular momentum of the orbital involved, that is, for orbitals of the same principal quantum number it is greater for p than d orbitals, and for d than f orbitals. If the splitting is sufficient in comparison to the inherent bandwidth, PES can resolve spin–orbit split ion states, so ionization from a filled degenerate level may give rise to more than one band.

In valence shell spectra, such resolution is commonly observed in third row transition metal compounds for 5d based electrons, where the atomic spin–orbit-coupling parameters, ζ_{5d}, are of the order of 0.3–1.0 eV. It has yet to be observed, however, for first and second row transition metal compounds for 3d and 4d valence electrons, as ζ_{3d} lies in the range 0.01 to 0.1 eV and ζ_{4d} in the range 0.02 to 0.2 eV. For example, in $[Os(\eta\text{-}C_5H_5)_2]^+$ the $e_2{}^3$ configuration leads to well-separated ion states, $^2E_{5/2}$ and $^2E_{3/2}$, with the associated PE bands being of equal intensity and separated by 0.35 eV.[35] Spin–orbit splitting in a transition metal compound can also arise from the presence of heavy ligand atoms, and is frequently resolved for bromide and iodide compounds but not for chlorides (for Cl $\zeta_{3p} = 0.073$ eV, for Br $\zeta_{4p} = 0.305$ eV, for I $\zeta_{5p} = 0.628$ eV). When both a third row metal and a halide are present, second order effects can determine the splitting and the intensity distribution of the ion states.[47]

When orbitals are contracted in the core, spin–orbit effects are much greater and many p, d, and f core ionization spectra show multiplet structure.

Spin–orbit and Jahn–Teller effects compete to lift the degeneracy of a degenerate ion state. Whether this results in distorted states, as a consequence of Jahn–Teller distortion, or undistorted states, with defined angular momentum, depends on the relative magnitudes of the two effects. If both are of the same order, anomalous intensity distributions may be evident. The PE spectrum of $W(\eta^7\text{-}C_7H_7)(\eta^5\text{-}C_5H_5)$, which is isoelectronic with $[Os(\eta\text{-}C_5H_5)_2]$, has $^2E_{5/2}$ and $^2E_{3/2}$ bands of unequal intensity (Figure 20).[46] In this case, the mixing between the d orbitals and the ring $e_2\pi$ orbitals is extensive. The d orbitals give rise to spin–orbit splitting, whereas the ring lifts the degeneracy by Jahn–Teller distortion. The net result is a complex vibronic structure with two bands separated by spin–orbit coupling but having unequal intensities.

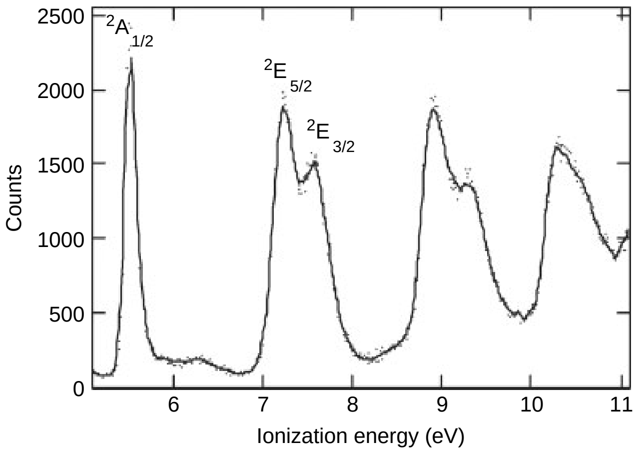

Figure 20 PE spectrum of $W(\eta^7\text{-}C_7H_7)(\eta^5\text{-}C_5H_5)$ showing two spin–orbit components for the ^2E band with unequal intensity owing to the Ham effect

5.4 Exchange Splitting

When ionizing from closed-shell molecules, removal of one electron leads to a doublet ion state. For an open shell molecule, which has one or more incompletely filled subshells, ionization by a simple one-electron process may lead to more than one spin state of the molecular ion. For example, $Nb(\eta\text{-}C_6H_5Me)_2$ is a 17-electron compound (see *Subunit*) contrasting with an electron count of 18 for $Mo(\eta\text{-}C_6H_6)_2$, but it has a similar orbital structure. There is one less electron to occupy the orbital scheme (Figure 6), and the outer configuration is $e_{2g}{}^4a_{1g}{}^1$, giving a $^2A_{1g}$ molecular ground state. Three ion states are accessible by ionizing electrons from the two orbitals. Ionization of the a_{1g} electron gives a $^1A_{1g}$ ion state, but ionization of an e_{2g} electron may give either a triplet or a singlet ion state of symmetry $^3E_{2g}$ or $^1E_{2g}$, respectively. Figure 21 shows that the three accessible states are spectroscopically resolved.[48] If the ionization cross sections of the a_{1g} and e_{2g} orbitals were equal, the intensity ratios of the bands would be 1:3:1.

In these cases, there no longer exists a relationship between the number of PE bands and the number of occupied orbitals, and photoionization can generate a large number of ionic states. The rules for predicting the ion states formed and the relative intensities of the PE bands have been derived by a fractional parentage method and can be summarized as follows:[49]

1. If a closed shell is ionized, all states arising from the coupling of the positive hole with the open shell will be realized, the relative cross sections for the production of these states being proportional to the total (i.e. spin–orbit) degeneracies.
2. If the orbitals belonging to different subshells are assumed to have the same one-electron cross sections, the integrated ionization cross section of a particular subshell is proportional to the occupancy of that orbital in the subshell of the molecule.
3. If an open shell is ionized, the relative probabilities of producing different ionic states will reflect the fractional parentage coefficients, which may be proportional to spin–orbit degeneracies (if the ground-state configuration generates only one term), but in general will not.

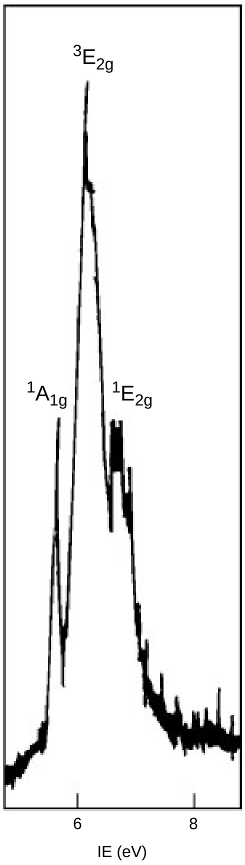

Figure 21 He I PE spectrum of Nb(η-$C_6H_5Me)_2$ showing three bands corresponding to $^1A_{1g}$, $^3E_{2g}$, and $^1E_{2g}$ ion states

4. If a molecule contains two or more open shells, the coupling that already exists between the different open shells in the molecule must be considered. The probability of ionization is usually expressed in terms of Racah coefficients and fractional parentage coefficients.

For exchange splittings to be spectroscopically resolved, the exchange integrals between the electrons involved must be relatively great. This is the case with the open f shells of the lanthanides, and the ionization patterns of the lanthanides are very characteristic of the number of f electrons being ionized.

Exchange splittings can also be detected for ionization of closed-shell cores in open shell molecules and ions, though care must be taken to distinguish band structure resulting from exchange splitting from spin–orbit (Section 5.3) and shake-up structure (Section 5.5). The structure is most likely to be resolvable when the core and the open valence shell have the same principal quantum number, as the exchange integrals are greatest when the electrons concerned occupy the same spatial region. The simplest cases are found in the core s electron spectra of S state ions like Mn^{2+}, which has a ^6S state from the d^5 configuration. Ionization of an s core orbital produces no orbital angular momentum so only two states are produced,

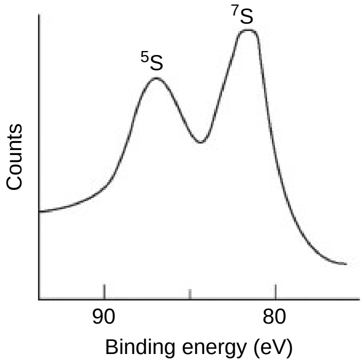

Figure 22 Multiplet splitting in the Mn 3s core ionization of Mn(η-$C_5H_5)_2$

^5S and ^7S, resulting from coupling of the spin of the core hole to the five unpaired valence electrons. Figure 22 shows the multiplet splitting in Mn(η-$C_5H_5)_2$, which is 5.2 eV.

5.5 Many-electron Processes

PE spectra can show bands corresponding to ion states that cannot be accessed from the ground-state molecular configuration by the removal of one electron. Such signals can normally be represented by removal of one electron synchronized with excitation of another; they are hence referred to as many-electron processes, and the additional satellite structure accompanying the primary band as shake-up structure. A classic example of a two-electron transition is the very weak band found in the spectrum of atomic mercury for the process shown in equation (12):[50]

$$\mathrm{Hg(5d^{10}6s^2 : {}^1S) + h\nu \longrightarrow Hg(5d^{10}6p^1 : {}^2P) + e} \qquad (12)$$

In a one-electron description, this corresponds to the ionization of one s electron and the excitation of the other to a p orbital. Two-electron transitions occur because the motions of the electrons are not completely independent but are correlated. One technique that MO theory uses to introduce some measure of electron correlation is called configuration interaction. The ground state for Hg can be improved over the single $5d^{10}6s^2$ (^1S) configuration wavefunction by mixing it with a state of identical symmetry from a different (but higher energy) configuration $5d^{10}6p^2$ (^1S); the result is a lower energy wavefunction (equation 13):

$$\Psi(^1\mathrm{S}) = \Psi(\mathrm{s}^2) + \mu\Psi(\mathrm{p}^2) \qquad (13)$$

The magnitude of μ, the mixing coefficient, determines the relative strength of the satellite peak.

Shake-up structure can be very intense in core spectra. Study, in the solid state, of the redox pairs $[FeCl_4]^{2-/1-}$ and $[CuCl_4]^{3-/2-}$ show strong 3p satellites in the metal

core spectra for the Cu(II) and Fe(II) complexes.[5] This indicates considerable electronic reorganization on oxidation. Creation of the metal core hole increases the effective nuclear charge on the metal. The filled metal–ligand-bonding orbitals become more metal in character and the half-filled antibonding orbitals more ligand like. This electronic reorganization is reflected in the appearance of satellite bands. For these compounds satellite peaks also appear in the valence spectra.

Very intense shake-up structure is also commonly associated with the C and O 1s core spectra of metal carbonyls and with CO bound to metal surfaces.[48] For example, the C and O 1s core spectra of $Cr(CO)_6$ are shown in Figure 23(a). In these cases, Metal to Ligand Charge Transfer (MLCT) is implicated. If the CO unit has a core hole, the state where an electron occupies the 2π orbital and the metal has a hole in the d shell is of lower energy than that where the CO is ionized and the d shell remains intact. (Using a core equivalent picture, it is as though, when the hole is on the C atom, the CO group has been transformed into NO.) The 2π orbital is now lower in energy than the metal d orbital. As the metal d orbitals commonly overlap with the 2π orbital, it is the mix of these that will differ in the ground-state wavefunctions for the neutral species and the core ionized species. When the two wavefunctions differ substantially, there is a high probability of accessing valence excited states on core ionization as well as the ground state, and strong shake-up bands result. This is illustrated diagrammatically in Figure 23(b).

For small molecules weak shake-up bands in valence PE spectra have been detected by careful study, but for transition metal molecules the multiplicity and breadth of the valence PE bands make detection of weak shake-up structure difficult.

6 CALCULATION OF IONIZATION ENERGIES

The availability of accurate energy data on electronic states from PE spectroscopy has provided important benchmarks for electronic structure calculations. Such calculations, in their turn have been very valuable in establishing correct assignments of PE spectra. Though this article is primarily concerned with the experimental phenomena, it is useful to illustrate the accuracy of various methods for calculating ionization energies.

6.1 Ionization Energies in ab initio and Density Functional Theory

Ab initio theory provides two basic approaches to calculating ionization energies.[6] One uses Koopmans' Theorem (KT), which has been discussed in Section 1.2, and only requires a single SCF calculation of the ground state. The ΔSCF approximation, where the IE is equated with the difference of the molecular ground-state energy and the energy of the ion in the appropriate electronic state, requires a separate SCF calculation for each ionic state. The difference is termed relaxation energy, which always lowers the KT value. These methods may be refined by separate correlation of the ground and ionic wavefunctions, thus obtaining correlated values of the IEs (see Section 3, Figure 4). Both relaxation

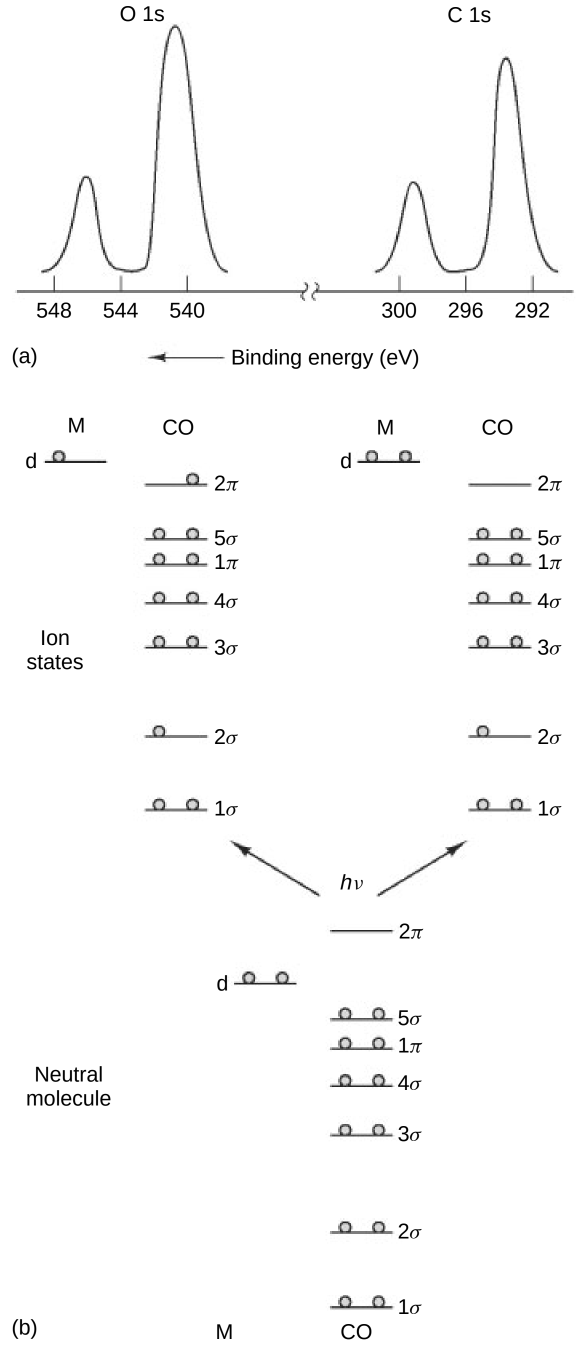

Figure 23 (a) C 1s and O 1s spectra of $Cr(CO)_6$ (b) Schematic energy level diagram for a neutral metal CO system and two ionic states with a 2σ (C 1s) core hole

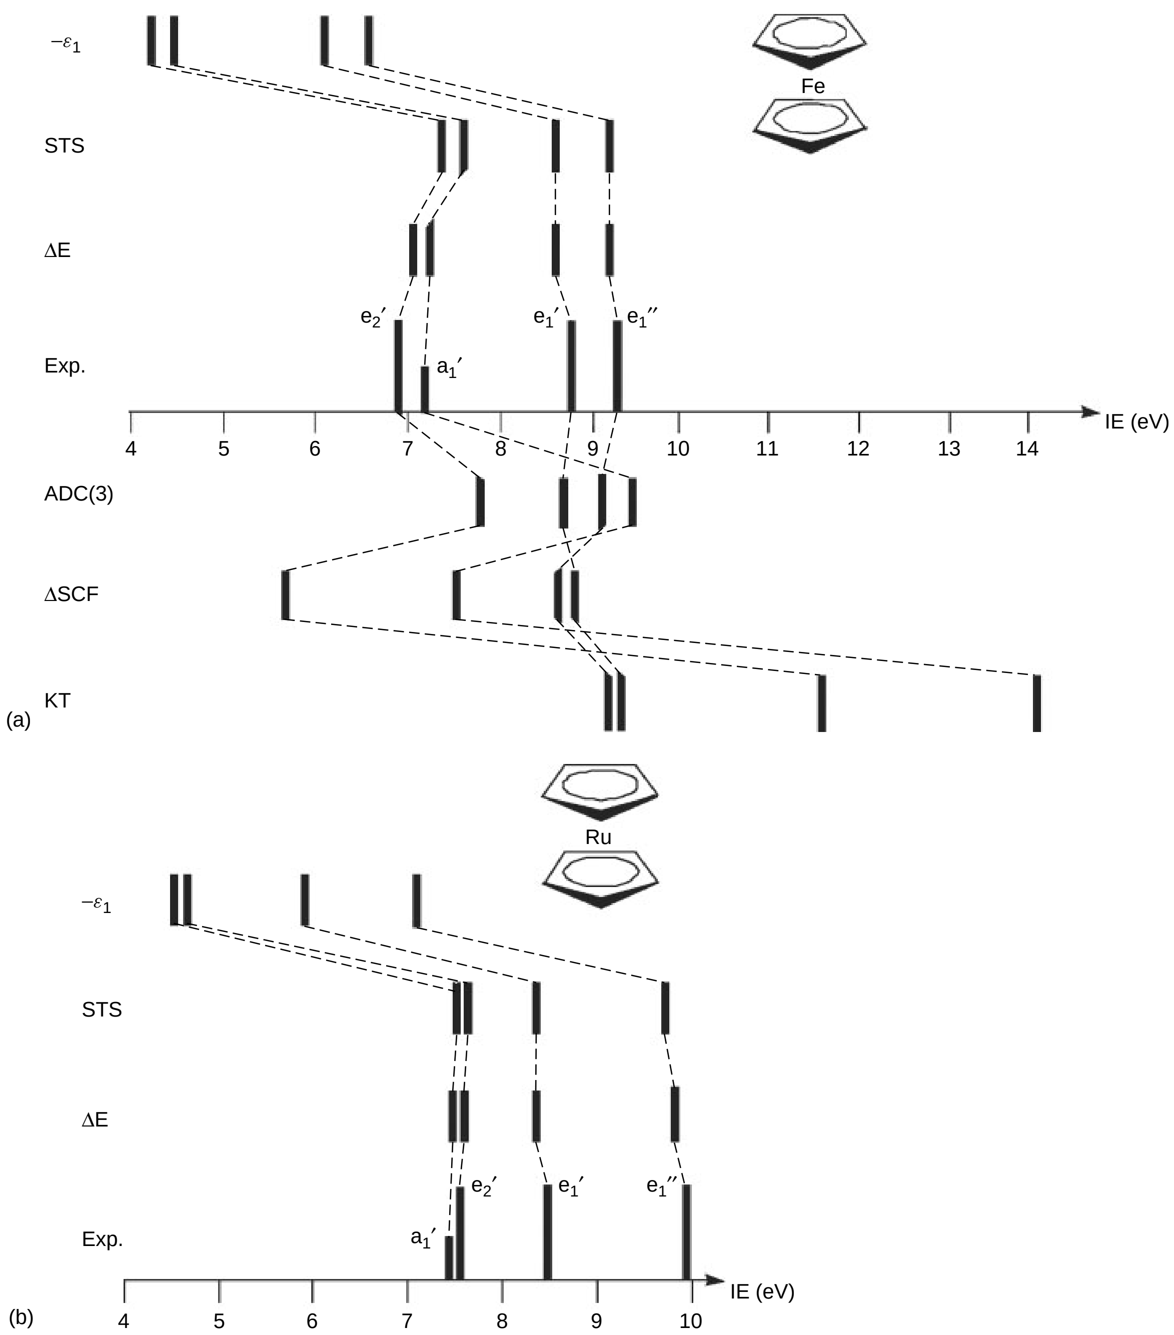

Figure 24 Comparison of experimental and calculated IE for 9a0 ferrocene (b) ruthenocene. Correlation corrections (ADC(3)) ab initio ion state calculations (ΔSCF) Koopmans theorem (KT)

and correlation effects in transition metal compounds can be very substantial in an ab initio framework.

A popular alternative is to employ density functional theory (DFT) methods. Kohn-Sham (KS) orbital energies in the ground state are a more reliable predictor of the ion state ordering than Koopmans' theorem. There are good theoretical reasons for interpreting them as approximate vertical IE.[49] For transition metal compounds ΔE methods, the DFT equivalent of ΔSCF, give good numerical results. Problems are associated with the DFT treatment of states of multideterminantal nature, like in the case of open shell ground-state systems.

6.2 IE of Simple Metallocenes

The metallocenes form useful benchmarks to test the quality of IE calculations and to illustrate the success of

modern DF calculations to replicate vertical IE.[6] Their PE spectra are reliably assigned and they provide a testing ground for the calculation of exchange splitting and spin–orbit coupling. Figure 24 provides a visual comparison of DFT methods and ab initio methods for ferrocene. Kohn-Sham one-electron energies ($-\varepsilon_I$), IE calculated by the Slater transition state method (STS) and the ΔE method (direct calculation of the molecular ions in their ground and excited states) comprise the DFT methods and KT, ΔSCF, and Algebraic Diagrammatic Construction (ADC)(3) the ab initio ones. The experimental vertical ionization energies for $Fe(\eta\text{-}C_5H_5)_2$ are also shown. For $Ru(\eta\text{-}C_5H_5)_2$, only experimental and DFT values are given.

Both the Slater transition state values and the ΔE values for the IE are in excellent agreement with experiment. What is also impressive is that the negative of the Kohn-Sham orbital energies, although about 3 eV less than the IE, have the same ordering and energy separations as do the ion states. Values from the ab initio methods are erratic in their ion state ordering, and the values for the ligand based bands are significantly more accurate than those for the metal bands. The advantage of DFT methods in ion state assignment is evident throughout, and the numerical precision of the DFT ΔE method is impressive.

Figure 25 shows comparisons between theory and experiment for $Os(\eta\text{-}C_5H_5)_2$ and $Mn(\eta\text{-}C_5H_5)_2$. In the case of $Os(\eta\text{-}C_5H_5)_2$ (Figure 25(a)), the $^2E_2'$ ion state is split by spin-orbit coupling to form $J = 5/2$ and $J = 3/2$ ion states (see Section 5.3). DFT calculation on the ion states including spin – orbit-coupling models the splitting well. The splitting of the $^2E_2'$ and $^2E_1''$ states is a consequence of their Os 5d orbital character, that of the $^2E_1'$ state is Os p orbital based, a d orbital contribution here being disallowed on symmetry grounds.

Calculation of exchange splittings is illustrated by the PE spectrum of $Mn(\eta\text{-}C_5H_5)_2$. Manganocene exists in the gas phase in a predominantly high spin form with $S = 5/2$. Ionization of the half-occupied d orbitals only gives quintet states, but ionization from the doubly occupied ligand orbitals gives rise to both quintet and septet states. The experimental and calculated values are represented in Figure 25(b). Agreement is not as close here as in the closed-shell molecules.

The calculation suggests that the principal ligand band centered at 8.8 eV should be assigned to three of the ligand ion states, not four as previously thought. The $^5E_1''$ ion state arising from ionization of the e_1'' ligand orbitals is found at considerably higher IE than the other ligand bands. It has the same symmetry as the lowest accessible ion state from high-spin manganocene, which originates from a largely metal-based ionization. Presumably strong interaction between these two ion states is responsible for the energy shift. At the temperature of the experiment, some manganocene also exists in a $S = 1/2$ ground state. The triplet ground state of the associated ion, $^3E_2'$, can also be detected in the PE spectrum. The calculation gets good numerical agreement with the experimental value for this state but underestimates the separation from the $^5E_1''$ state of the predominant ion species.

7 CASE STUDIES

This section illustrates some of the problems in transition metal chemistry that PES has clarified.

7.1 Osmium Tetroxide: an Example of a Tetrahedral Molecule

The valence electronic structures of d^0 tetrahedral transition metal molecules are of the form

$$(1a_1)^2(1t_2)^6(2t_2)^6(1e)^4(2a_1)^2(3t_2)^6(1t_1)^6$$

Table 2 Symmetries of Os and O atomic orbitals in the T_d symmetry of OsO_4

Symmetry	Os	O[a]
a_1	6s	2s, 2p (σ)
E	5d	2p (π)
t_2	5d, 6p	2s, 2p (σ), 2p (π)
t_1	–	2p (π)

[a]The O 2p orbitals are classified σ and π with respect to the Os–O direction.

where the numbering scheme ignores orbitals correlating with the core orbitals of the constituent atoms. Symmetry analysis of the possible contributing AOs is given in Table 2. The e and the a_1 orbitals are rigorously π and σ respectively with respect to the metal–oxygen interaction, whereas the t_2 orbitals may have both π and σ contributions. The t_1 orbital is nonbonding for a metal with no valence shell f orbitals. The $1a_1$ and $1t_2$ orbitals are essentially O 2s core-like orbitals and are not probed in the He I spectra, so we expect bands corresponding to five primary ion states: $^2A_1$, ^2E, $^2T_1$, and two $^2T_2$. The He I spectrum shows five separated bands, 1–5 (Figure 26(a)).

Assignment of the spectra has been surprisingly controversial for such a small molecule,[34] but illustrates well how detailed analysis of band structure along the lines of Section 5 can illuminate such a problem.

Vibrational structure is resolved on the first four bands. Band 5 is broad, doubtless containing unresolved vibrational structure, but it shows two maxima. In bands 2, 3, and 4, only the totally symmetric a_1 stretching vibration is excited. Band 1 shows, as well as a symmetric progression, an e progression, which indicates that the ion state is not tetrahedral. This is consistent with the band being assigned to a Jahn–Teller distorted ^2T state.

The five bands show considerable relative intensity changes with photon energy (Figure 26(a)). Measurement of their photoionization cross sections shows that only band 5 has any significant Os 5d character; the cross section shows a double maximum in the region of the Os 5p → 5d giant resonance (Figure 26(b)). Os 5d character is expected in at least two of the bonding levels, of e and t_2 symmetry, because of the presumed strong multiply bonded character of OsO_4.

This poses a conundrum. If band 5 is assigned to just one primary ion state, leaving bands 2–4 to be assigned to the other three, we must conclude that none of the orbitals associated with bands 2–4 has any significant metal 5d–oxygen bonding character. The classic picture of multiple bonding in OsO_4 would have to be abandoned. If, on the other hand, two primary ion states are associated with band 5, bands 2–4 must arise from just two primary ion states. The most likely pair of bands to arise from the same primary state is bands 2 and 3. They have very similar cross section characteristics, whereas those of band 4 are very different, and they have

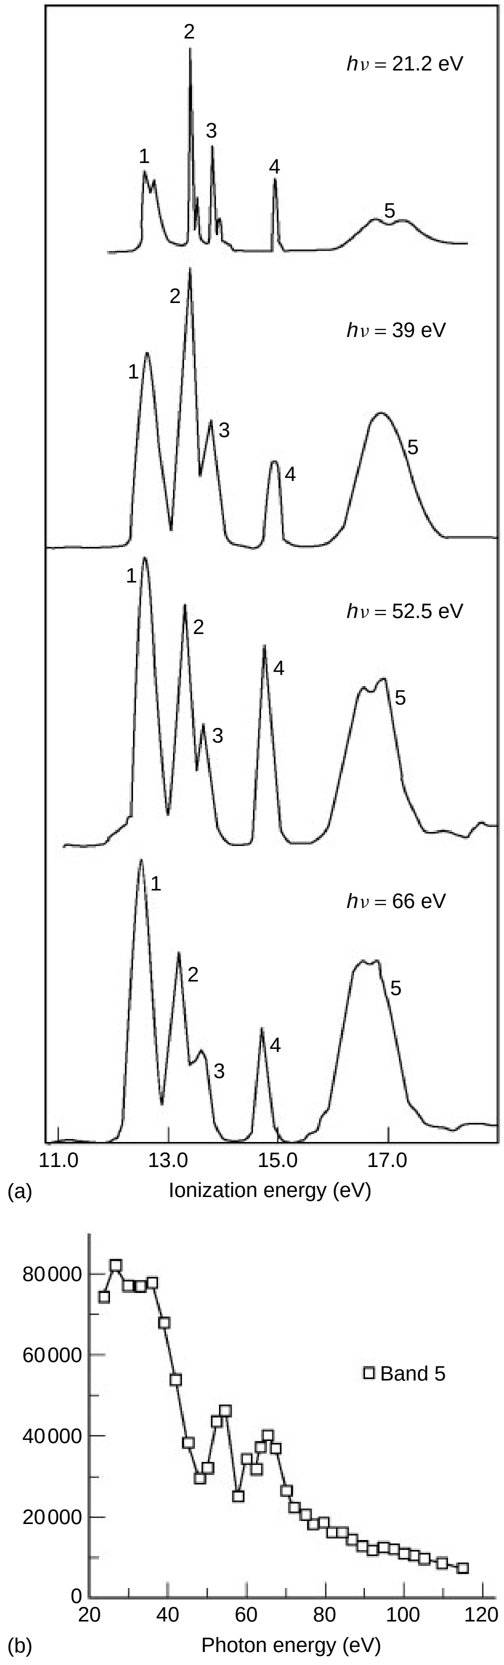

Figure 26 (a) PE spectra of OsO_4 at various photon energies; (b) cross section of band 5

similar vibrational structure. The relative intensity of bands 2 and 3 is 2:1 over a wide photon energy range, the lower energy ion state being the more intense. The splitting pattern is not that expected of Jahn–Teller distortion of a ^{2}T ion state (Section 5.3), but is rather like that found for spin–orbit splitting. The presence of only a totally symmetric stretching frequency supports the assignment to spin–orbit components. Two facts rule out the origin of the spin–orbit splitting being an Os 5d contribution. Firstly, the cross section variation shows minimal 5d contribution to the associated orbital; secondly, splitting of a ^{2}T state where the orbital origin is d gives an energy ordering $E'' < U'$, namely, the doubly degenerate spin–orbit state is of lower energy than the fourfold degenerate one. This is the reverse order from that found experimentally. To obtain the energy ordering $U' < E''$, the orbital origin of the splitting must be p. Such a splitting may arise from interaction with either the valence 6p orbitals or the underlying core 5p orbitals or a combination of both. The primary ion state must therefore be $^2T_2$, leading to the assignment of band 1 to $^2T_1$.

The MO scheme shown in Figure 27 is based on this assignment. The energy levels are seen to be determined by the metal contribution with the orbitals with Os 5d character lying lowest, followed by the a_1 with Os s character, then the Os p-type orbitals, and lastly the nonbonding orbitals with no Os character. This is in contrast to the classical view of a tetrahedral molecule, in which the σ bonding orbitals are generally considered to be more tightly bound than the π bonding orbitals.

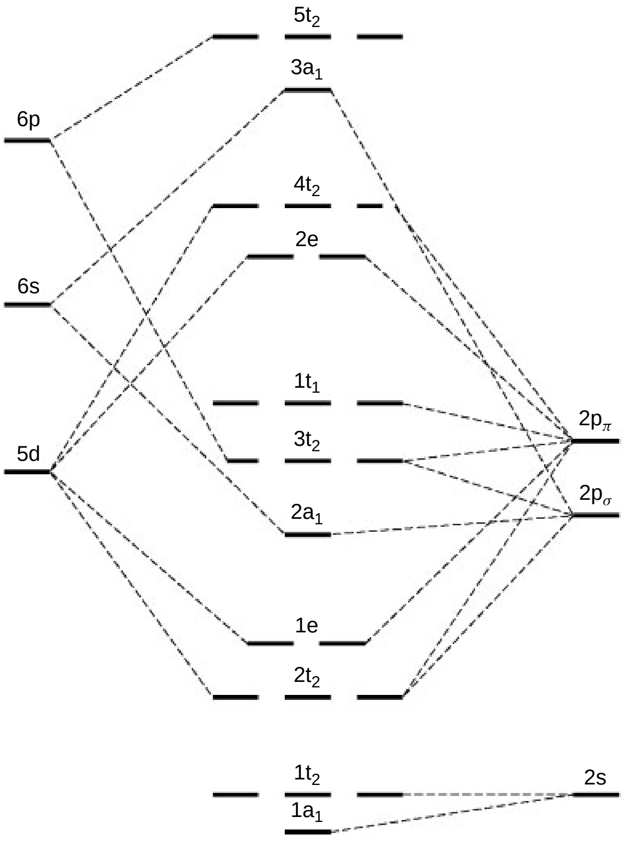

Figure 27 MO scheme for OsO_4 based in the interpretation of its PE spectrum. The MOs are filled with 32 electrons up to the $1t_1$ level

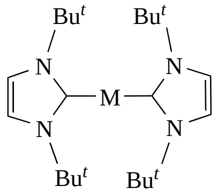
7.2 Carbene Complexes of Pd and Pt

Isolation of stable carbenes by the deprotonation of imadazolium salts has opened up new routes to the synthesis of transition metal carbenes. The bis(carbenes) of the group 10 metals are particularly striking being stable two-coordinate complexes (**2**).



(**2**)

Figure 28 shows their PE spectra[51] and that of the free carbene.[52] The HOMO of the carbene is a σ symmetry orbital on the two-coordinate carbon, the carbon 'lone pair'. In the low IE region, the spectrum also shows ionization from the two highest π levels; above 10 eV (not shown), the spectrum is dominated by ionizations from the Bu^t group. In the spectra of the complexes, the two π bands are relatively unperturbed.

For the Pd carbene complex, the ligand lone pair band appears to be halved in intensity. The two carbene σ orbitals form σ_u and σ_g combinations; the former can overlap with the metal p valence orbitals and the latter with a s + d(z^2) hybrid. The lower lying PE band corresponds to the less strongly bonding σ_u orbital. Ionization from the strongly bonding σ_g orbital lies under the main band of the spectrum and is not identifiable. For the Pt complex, the σ_u orbital is more tightly bound and its PE band overlaps with those of the ligand π orbitals. The spectra of the Pd and Pt complexes show additional bands at lower IE attributable to the metal ionizations; they all show an increase in relative intensity in the He II spectrum.[51] They are most conveniently classified as σ, π, and δ with respect to the C-M-C axis. For Pd, the σ band lies under the He self ionization; it is fully visible in the He II spectrum. For Pt, it lies at higher energy. Calculations suggest that this is a nonbonding orbital of s-d(z^2) character so the stabilization relative to Pd is probably due to the relativistic stabilization of the Pt 6s orbital. The Pt π and δ bands are split by spin–orbit coupling but lie at similar average energies to the unsplit Pd ones. Overall the spectra demonstrate strong σ interactions between the carbene and the metal and negligible π bonding. Pt binds the carbene more strongly than Pd.

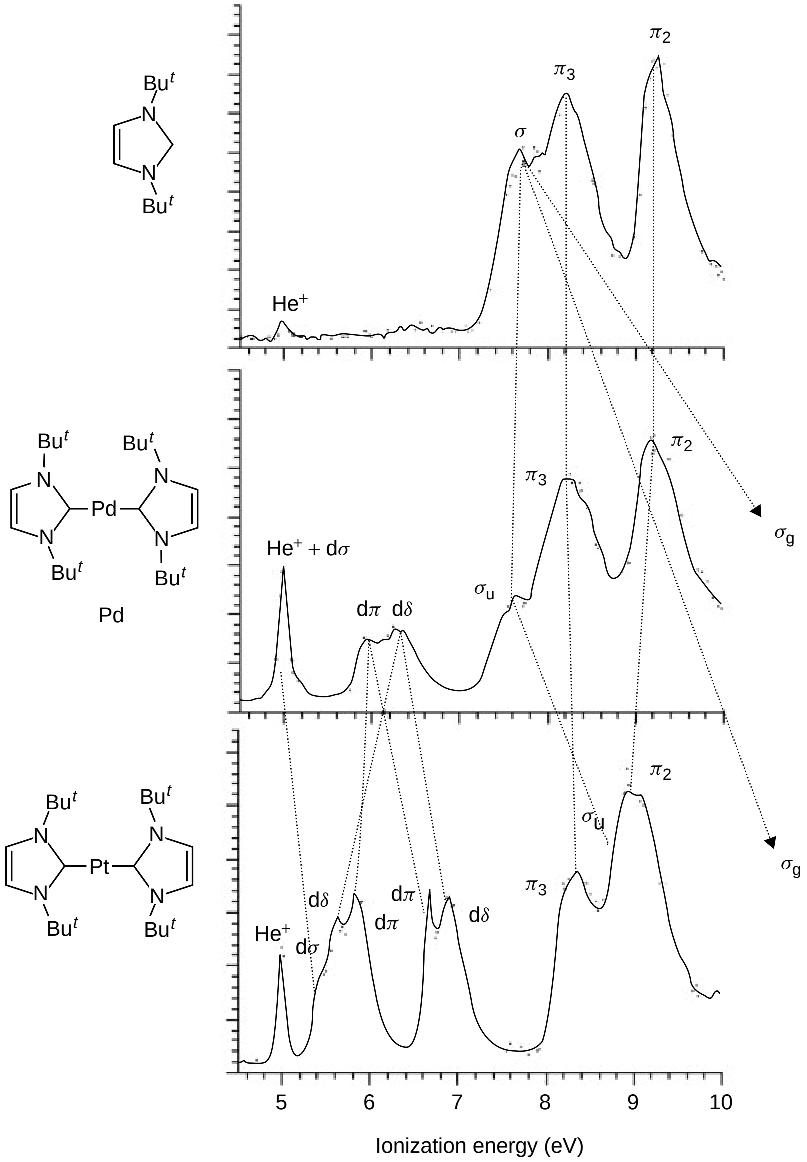


Figure 28 PE spectra of $C_3H_2N_2Bu^t_2$ and its complexes with Pd and Pt

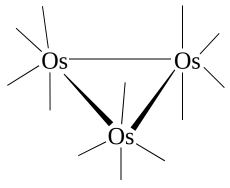
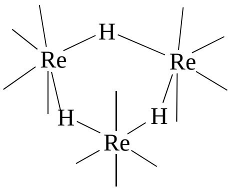
7.3 $Os_3(CO)_{12}$ and $Re_3H_3(CO)_{12}$: an Investigation of Two Carbonyl Clusters

The electronic structure of transition metal clusters is difficult to probe by electronic absorption spectroscopy, which has proved so fruitful in revealing the d orbital orderings of classical complexes, because of the multiplicity of overlapping absorption bands. The one-to-one correlation between occupied orbitals and PE bands means that PES can give valuable information on the smaller clusters. The information obtained has given support to the semiempirical theoretical treatments of this class of molecules.

$Os_3(CO)_{12}$ (**3**) and $Re_3H_3(CO)_{12}$ (**4**) are isoelectronic. They both have D_{3h} symmetry with four terminally bonded carbonyl groups attached to each metal atom (these are indicated by lines in (**3**) and (**4**)). In the Os compound, the Os atoms are directly bonded in an equilateral triangle, whereas in the Re compound, the metal–metal interactions are symmetrically bridged by the three hydrogens.



(**3**)



(**4**)

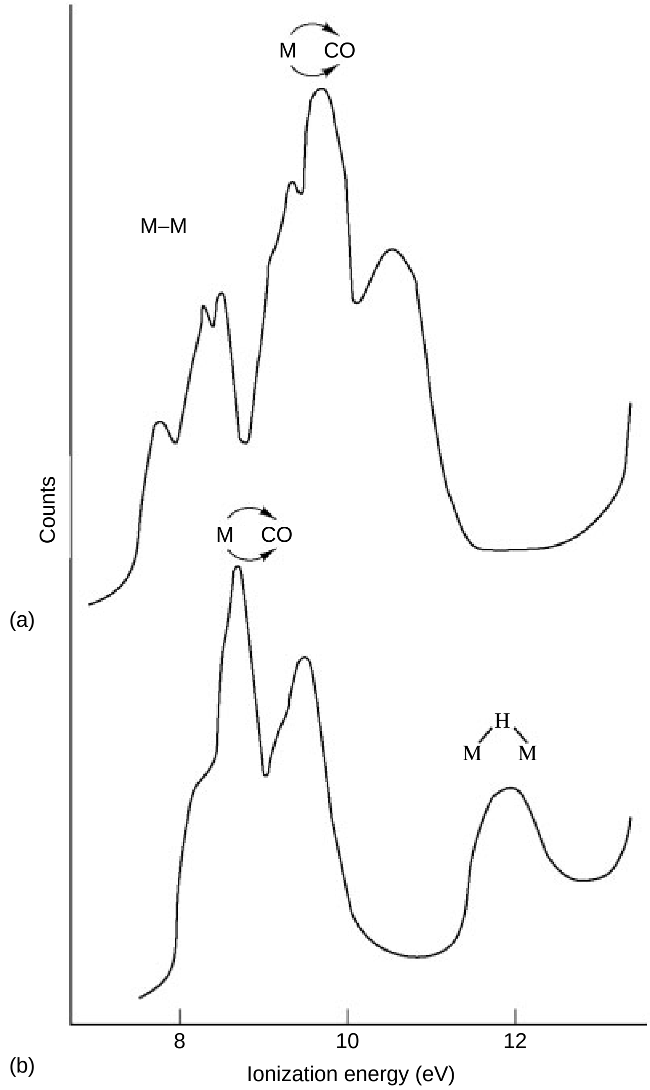


Figure 29 He I PE spectra of (a) $Os_3(CO)_{12}$ and (b) $Re_3H_3(CO)_{12}$

Six of the d electrons of each metal are involved in back bonding to the four associated CO groups and the rest are available for binding the triangular cluster. In the case of $Os_3(CO)_{12}$, each metal has two electrons for cluster binding and the metal triangle may be regarded as being held together by three single bonds. In the D_{3h} symmetry of the molecule, they are constituted by occupied orbitals of a_1' and e' symmetry. The PE spectrum of $Os_3(CO)_{12}$[53] (Figure 29(a)) shows as its first band ionization from the Os–Os bonding a_1' orbital, followed by a spin–orbit split e' band. The remainder of the d band structure is assigned to metal–carbonyl back bonding orbitals. It is generally found to be the case that metal–metal bonds have lower IE than metal–carbonyl back bonding electrons.

In the PE spectrum of $Re_3H_3(CO)_{12}$[53] (Figure 29(b)), the metal–metal-bonding bands have disappeared, to be replaced by a broad band lying between the d band and the main carbonyl ionizations. Also, the metal–carbonyl back bonding ionizations have shifted to lower IE. An MO scheme for $Re_3H_3(CO)_{12}$ is readily derived from that of $Os_3(CO)_{12}$ by considering the effect of moving a proton from each of the Os nuclei to the edge-bridging positions (Figure 30). The back bonding orbitals are raised in energy as the metal nuclear charge is now less, but the a_1' and e' cluster orbitals are considerably stabilized by the protonation.

Comparison of the He II band intensities with those from the He I spectrum confirm that the band at ca. 12 eV in the spectrum of $Re_3H_3(CO)_{12}$ comes from an orbital with a high degree of H 1s character. The role of the bridging hydrogens in the cluster is not just to provide the necessary electrons for the cluster-electron count, but also to stabilize the cluster-bonding orbitals.

7.4 Phosphametallocenes

An extensive chemistry has been developed of organometallic compounds where P replaces C-H in aromatic carbocyclic rings coordinated to transition metals. In many cases the phosphametallocenes resemble closely the all carbon parent. In other cases, the structures and chemistry differ. PE spectroscopy has helped identify the causes of these similarities and differences. The spectra of the phosphametallocenes are more complex than the carbocyclic analogs as ionization bands from the P lone pairs occur in the low-energy region and frequently overlap with the ring π and even the d bands. Comparison of the spectra of $Mo(\eta^6\text{-}P_3C_3Bu^t_3)(CO)_3$ with $Mo(\eta^6\text{-}C_6H_3Bu^t_3)(CO)_3$ showed that the P substituted compound had the higher d ionization energy.[54] Substituting P into the ring decreases the HOMO–LUMO gap; this makes the rings better acceptors of electron density from the metal and increases the strength of δ back bonding.

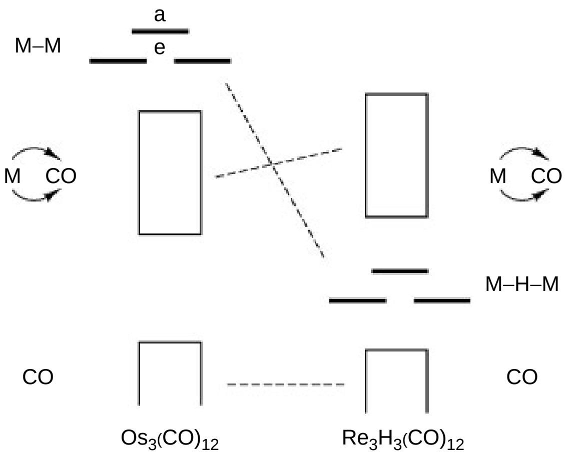

Figure 30 MO schemes for the isoelectronic molecules $Os_3(CO)_{12}$ and $Re_3H_3(CO)_{12}$, showing the energy relation between their MOs as three protons are removed from the Os nuclei and placed in bridging positions between the metal atoms

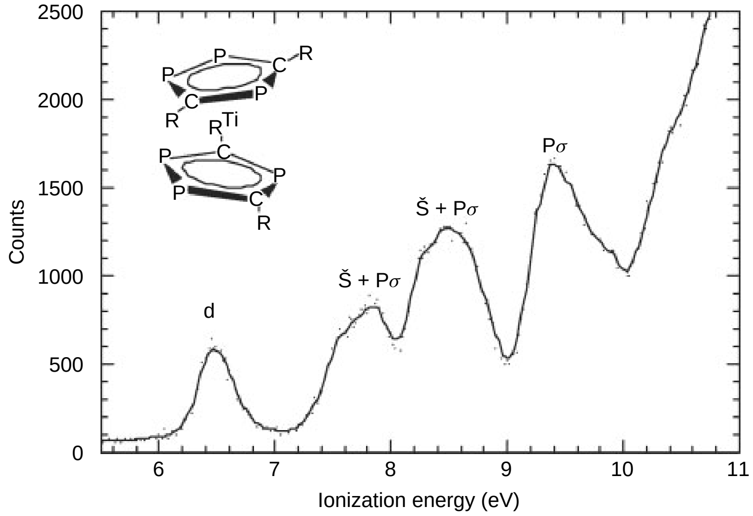

Figure 31 PE spectrum of Ti(η^5-$P_3C_2Bu^t_2$)$_2$

The capacity to form δ bonds makes P containing carbocyclic rings particularly good at stabilizing low oxidation states in early transition metals. A striking example is the hexaphosphatitanocene, Ti(η^5-$P_3C_2Bu^t_2$)$_2$, the parent titanocene, Ti(η^5-C_5H_5)$_2$ being unknown. Also, the degeneracy of the ring π orbitals is lifted and one combination is preferred for δ bond formation by the metal resulting in a diamagnetic compound for this Ti(II) species. The PE spectrum (Figure 31) shows the d band to have an ionization energy of 6.5 eV.[55]

Phosphorus substitution has also increased the number of four-membered ring compounds. P has a natural bond angle around 90° so less strain is present in P_2C_2 rings than C_4 rings. The series of compounds M(η^4-$P_2C_2Bu^t_2$), M=Ge, Sn, and Pb, have both lone pairs on the P atoms and also on the group 14 metal. PE studies (Figure 32) have shown that the metal lone pair is significantly more stable than the P ones, which explains why the molecules coordinate Lewis acids at the P atoms.

8 CONCLUSION

Photoelectron spectroscopy is the most direct method of investigating electronic structure. The orbital structure of a molecule is reflected in the band structure of a PE spectrum. Detailed assignment of a spectrum is facilitated by varying the photon energy used for spectral acquisition. Effects of chemical substitution on molecular energetics can be probed

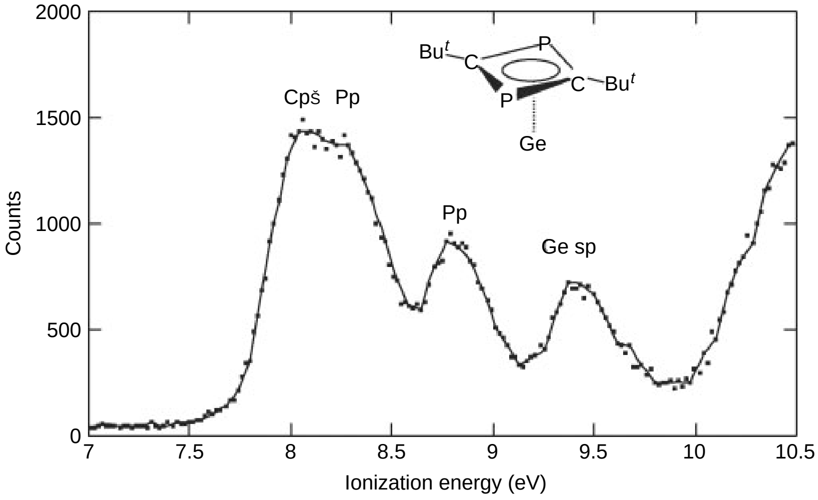

Figure 32 PE spectrum of Ge(η^4-$P_2C_2Bu^t_2$)$_2$

directly. PES enables the determination of ionization energies, which are important thermodynamic parameters, and also are invaluable benchmarks in the testing of electronic structure calculations.

1 INTRODUCTION

1.1 General Introduction[1–4]

Photosynthesis is a biological process carried out by plants, algae and certain bacteria, whereby light energy is converted into chemical energy. The stored energy is then used to sustain life processes. The vast majority of photosynthesis is carried out by organisms that contain *Chlorophylls* or related compounds as principal *pigments*, and this article is limited to discussion of these organisms. The emphasis in this article will be on those aspects of photosynthesis that draw most heavily on the concepts and methodologies of inorganic chemistry. This includes properties of *Excited States* and photochemical reactions, structures of pigments and *proteins* involved in energy transduction, and in particular the role of metal ions in many of these structures and processes. In most cases, literature references are to recent comprehensive reviews and not to the original publications.

While this article attempts to be a brief but comprehensive introduction to the field of photosynthesis, certain important aspects of the subject are covered in other articles of this encyclopedia and are therefore omitted. Chief among these is the manganese-containing oxygen-evolving complex of Photosystem II, treated in ***Manganese: The Oxygen-evolving Complex & Models***. Additional information can also be found in articles on ***Iron: Heme Proteins & Electron Transport***; ***Electron Transfer Reactions: Theory***; ***Long-range Electron Transfer in Biology***; ***Iron–Sulfur Proteins***; and ***Copper Proteins with Type 1 Sites***.

1.2 Temporal Stages of Photosynthesis

Photosynthesis is an extremely complex series of chemical and physical events ranging in time scale from the essentially instantaneous process of photon absorption to the much slower processes of plant growth, which may take years. The overall process is conveniently although somewhat arbitrarily divided into four temporal stages: (1) Photon absorption and *excitation transfer*, (2) Primary *Photochemistry*, (3) Stabilization of high energy intermediates and (4) CO_2 reduction and long-term energy storage. The chemical transformations of photosynthesis have often been divided into the *light reactions* and the *dark reactions*, with stages 1–3 included in the light reactions and stage 4 in the dark reactions. The term light reactions is something of a misnomer, as the vast majority of the processes are thermal reactions, with only one or two (depending on the class of organism) as true photochemical reactions. The dark reactions are those processes by which carbon dioxide is incorporated into organic compounds, which are then further metabolized into other molecules the organisms can use for cellular processes.

1.3 The Photosynthetic Unit

The vast majority of the pigments in a photosynthetic organism are not chemically active, but function primarily as an *antenna*. They absorb photons and transfer energy to a highly organized integral *membrane* protein called a *reaction center*. The antenna system, its associated reaction center and ancillary electron transfer carriers are collectively known as a *photosynthetic unit*.

The energy transfer process in the antenna system is generally considered to take place according to a resonance transfer mechanism first proposed by Förster (see below). The antenna system increases the effective cross-section of photon absorption by increasing the number of pigments associated

with each photochemical complex. The intensity of sunlight is sufficiently dilute so that any given chlorophyll molecule only absorbs at most a few photons per second. If each chlorophyll had an entire electron transfer system associated with it, the system would be idle the vast majority of the time. By incorporating many pigments into a single chemical unit, the biosynthetically expensive reaction center and electron transport chain can be used to maximum efficiency.

The essence of photosynthetic energy storage is light-induced *redox* chemistry that takes place in the reaction center. X-ray crystallographic structures of several reaction center complexes are now available, and they have contributed immensely to the molecular level understanding of the mechanism of the electron transfer processes that take place in the reaction center. These structures along with the pathways and kinetics of electron transfer that take place within them are discussed in more detail below (*see* ***Long-range Electron Transfer in Biology***).

1.4 Types of Photosynthetic Organisms and Evolutionary Origins[1,5]

A remarkable variety of organisms carry out photosynthesis. These range from very primitive *bacteria* to higher plants, inhabiting almost every ecosystem on the planet. The living world is often divided into three main groups: *eubacteria*, *archaea*[6] (together known as *prokaryotes*) and *eukaryotes*. Photosynthesis is very widely distributed among the eubacteria, sometimes called the true bacteria, as well as the more advanced eukaryotic cells.

Chlorophyll-based photosynthesis has never been described in any members of the archaea. Some halophilic archaea carry out an energy storage process that is sometimes literally described as photosynthesis, using a membrane protein called *bacteriorhodopsin*. Bacteriorhodopsin utilizes a purple pigment called retinal. This process works by light-induced ion translocation rather than by light-induced electron transport as is found in all chlorophyll-based photosynthetic organisms.[7] Halobacteria, which grow in extremely salty water, are facultative aerobes; they can grow when oxygen is absent. Purple pigments, known as retinal (a pigment also found in the human eye), act similar to chlorophyll. The complex of retinal and membrane proteins is known as bacteriorhodopsin, which generates a proton gradient that powers an ADP-ATP pump, generating ATP from sunlight without chlorophyll. The structural and mechanistic aspects of bacteriorhodopsin-based energy storage are fundamentally different from those of chlorophyll-based photosynthesis, and these are almost certainly independent evolutionary developments.

Eukaryotic photosynthetic organisms include various types of algae, mosses, ferns and higher plants. In all these organisms, photosynthesis is confined to a subcellular organelle known as the *Chloroplast*. In many ways, the chloroplast is similar to certain types of photosynthetic bacteria, and can be regarded as a semiautonomous miniature cell within the larger eukaryotic cell. All pigments associated with photosynthesis are made and localized in the chloroplast, as well as numerous *proteins* that carry out the chemical processes associated with photosynthesis. The chloroplast also contains its own DNA, which codes for many chloroplast proteins, and contains its own protein synthesis machinery. However, many chloroplast proteins are coded for by nuclear DNA and imported from the cytoplasm, so the chloroplast is not completely functional on its own. It is now generally accepted that chloroplasts arose by a process called endosymbiosis.[1] In this process, a primitive photosynthetic bacterium was symbiotic with a primitive eukaryotic cell. The bacterium gradually lost autonomy, eventually becoming what are now known as chloroplasts. This process occurred several times in the past.[8] Primary endosymbiosis resulted in green algae, red algae, and glaucocystophytes. All other groups of algae are the result of secondary endosymbiosis of a eukaryotic algae. In fact, Chlorarachniophytes and Cryptophytes still maintain the vestigial nucleus of the endosymbiont, called a nucleomorph.[9,10]

The evolutionary history of the proteins involved in photosynthesis is only now becoming clearer. Recently, the entire genomes of many photosynthetic and nonphotosynthetic organisms have become available. This has allowed for large-scale phylogenetic analyses to be performed on genes involved in photosynthesis.[11] A search was undertaken for photosynthesis specific genes by finding all genes shared within all the photosynthetic organisms, and subtracting from this set all homologous genes also found in nonphotosynthetic organisms. Remarkably, only a very small set of genes were specific for photosynthesis. This finding supports the hypothesis that most of the genes involved in photosynthesis were recruited from other pathways. It was also found that extensive horizontal gene transfer has taken place among photosynthetic bacteria and indeed all classes of bacteria, as analyses of individual genes pointed to differing phylogenetic relationships among organisms, and supported different tree topologies.[11] Thus, the evolution of photosynthesis has been as much horizontal as vertical.

1.5 Organization of the Photosynthetic Membrane[1]

In eukaryotic photosynthetic organisms, the first three temporal stages of the photosynthetic energy storage process take place almost exclusively within or on membranes inside the chloroplast, called *thylakoid membranes*. In most chloroplasts, many of the thylakoid membranes are stacked together into what are called *grana membranes*. The unstacked membranes are called *stromal membranes*. The stacking of membranes into separated granal and stromal membrane regions is thought to facilitate the distribution of excitations between the two photochemical systems in oxygenic photosynthesis (see below).

The final stage of carbon fixation largely occurs in the soluble portion of the chloroplast, called the *stroma*. In *prokaryotic*

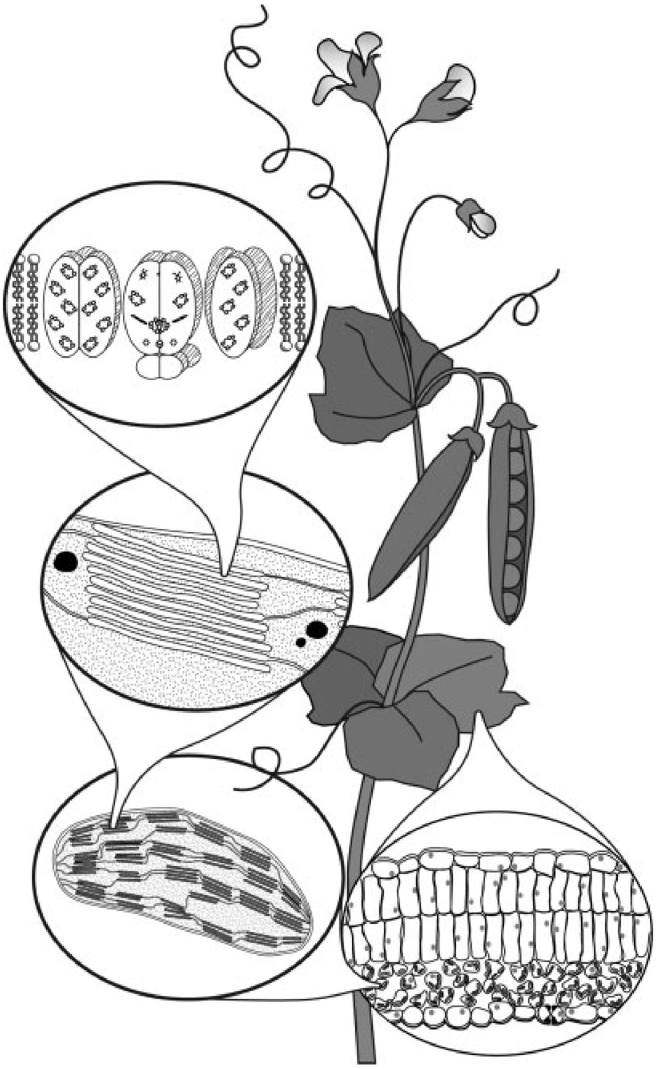

Figure 1 Exploding diagram of the photosynthetic apparatus of a typical higher plant. The first expansion bubble shows a cross-section of a leaf, with the different types of cells; the dark spots are the chloroplasts. The second bubble is a chloroplast; the thylakoid membranes are the dark lines, the stroma is the stippled area. The third bubble shows a grana stack of thylakoids. The fourth bubble shows a schematic picture of the molecular structure of the thylakoid membrane, with a reaction center flanked by antenna complexes. (Ref. 1. Reproduced by permission of Blackwell)

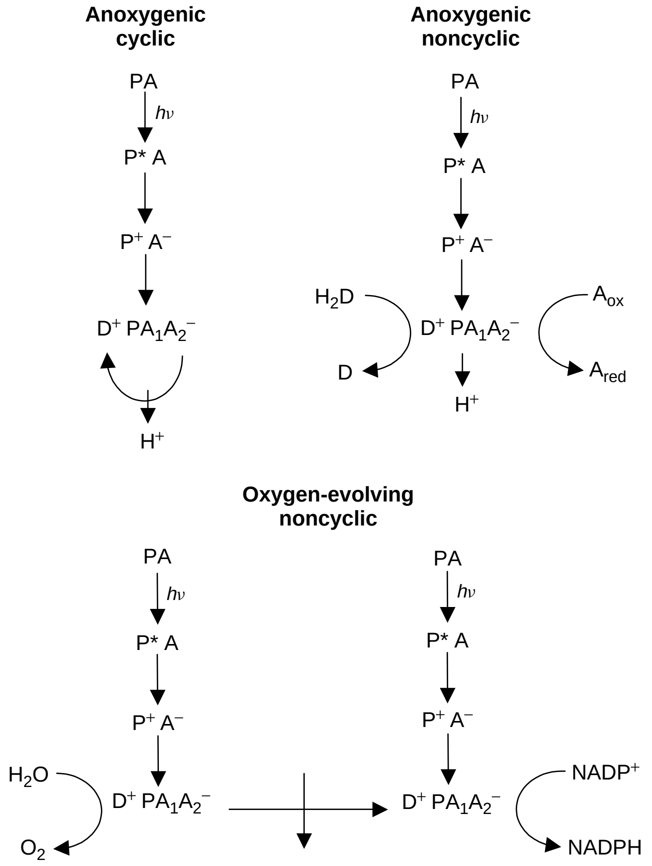

Figure 2 Cyclic and noncyclic patterns of electron flow in photosynthetic organisms. The anoxygenic cyclic pathway is found in purple bacteria and in the filamentous green bacteria. The anoxygenic noncyclic pathway is found in the green sulfur bacteria. These organisms can also carry out cyclic electron flow, which is not shown. The oxygen-evolving noncyclic pathway is found in cyanobacteria, prochlorophytes, and all eukaryotic chloroplasts. Cyclic electron flow around Photosystem I can also take place in these organisms. Abbreviations: P, reaction center photoactive pigment, eg P700; D, electron donor; A, electron acceptor; H^+, hydrogen ions that are moved across a membrane, coupled to electron flow; $h\nu$, light absorption. (Ref. 5, by kind permission of Springer Science & Business Media)

photosynthetic organisms, the first three stages take place within a specialized region of the inner cell membrane, while the carbon fixation reactions take place in the cytoplasm. Figure 1 shows a schematic diagram of the chloroplast.

1.6 Patterns of Photosynthetic Electron Transport

The photochemical electron transfer step and the initial secondary reactions that stabilize the photochemical products all take place within the reaction center complex. For subsequent turnovers of the reaction center to take place, there must be a way to remove electrons from the reduced acceptor and replace them to the oxidized donor. Figure 2 illustrates some of the different patterns of electron transport found in various photosynthetic organisms.

In many organisms, a cyclic process takes place, in which the reduced electron acceptor transfers its electron through a series of carriers back to the oxidized donor. Energy conservation is achieved by coupling proton translocation across a membrane to the electron flow. This type of cyclic electron flow occurs in eukaryotes under some conditions and in many anoxygenic photosynthetic bacteria. No NADPH is produced, only ATP. This process occurs when cells may require additional ATP, or when there is no $NADP^+$ to reduce to NADPH. In other organisms, noncyclic electron flow takes

place, in which one freely available *substrate* is oxidized and another is reduced. Perhaps the most important pattern is the noncyclic electron flow found in oxygen-evolving organisms, in which H_2O serves as the oxidizable substrate and CO_2 is the ultimate electron acceptor, although the pyridine nucleotide $NADP^+$ serves as an intermediate acceptor. In this case, it is necessary for two photochemical steps to cooperate. This is described in more detail below. All these modes of electron flow can lead to proton pumping and electrical potentials across the membrane, and the energy stored in these gradients (called the *protonmotive force*) can be used to make ATP.

In addition to the ATP formed by both cyclic and noncyclic flow, reduced and oxidized substrates are accumulated during noncyclic electron flow. The oxidized substrates are waste products and are excreted by the cell. The reduced compounds provide much of the energy necessary for carbon reduction. In those organisms that primarily carry out cyclic electron flow, the highly reducing compounds required for carbon reduction are not generated as direct products of light-driven electron transport. Instead, energy-dependent reverse electron flow from a weak reductant takes place.

2 PHOTOSYNTHETIC PIGMENTS[3]

2.1 Structure and Distribution of Photosynthetic Pigments

Hundreds of distinct pigments are found in various photosynthetic organisms. They can be grouped into three main classes: chlorophylls (including bacteriochlorophylls), carotenoids, and bilins. The chlorophylls are cyclic tetrapyrroles with a central Mg. They are found in both antenna and reaction center complexes of all types of photosynthetic systems, and their presence can be regarded as the unique signature of a photosynthetic organism. Figure 3 shows structures of some of the various chlorophylls and other photosynthetic pigments, and Table 1 indicates the distribution in different classes of photosynthetic organisms.

The photophysical and photochemical properties of chlorophylls are ideally suited for their roles in photosynthetic energy storage. They are unquestionably the product of an extensive chemical and biological evolutionary process, and many organisms have developed specialized chlorophylls that enable them to inhabit particular environments that are enriched in certain wavelengths of light. Other organisms have large antenna complexes that contain up to thousands of pigments. This enables them to survive in extremely dim light. For example, a green sulfur bacterium has been found growing photosynthetically 100 meters deep in the Black Sea, where a single molecule of bacteriochlorophyll receives a single photon once every eight hours.[12] Other organisms grow inside rocks, in harsh environments such as deserts, where they receive only very minimal light.

Carotenoids are found in all native photosynthetic organisms. They serve a dual function, as both accessory antenna pigment and also are essential in photoprotection of photosynthetic systems from the effects of excess light, especially in the presence of oxygen. Bilins are open-chain tetrapyrroles that are present in antenna complexes called phycobilisomes. These complexes are found in cyanobacteria and red algae. Structures of representative carotenoid pigments are shown in Figure 3.

2.2 Spectroscopy of Chlorophylls[3]

Chlorophylls and bacteriochlorophylls typically exhibit three intense electronic absorption bands in the visible and

Table 1 Distribution of photosynthetic pigments

[a]All cyanobacteria contain Chl *a*, and some types contain in addition Chl *b* or Chl *d*. [b]Purple bacteria contain either Bchl *a* or *b*, but not both in the same species.

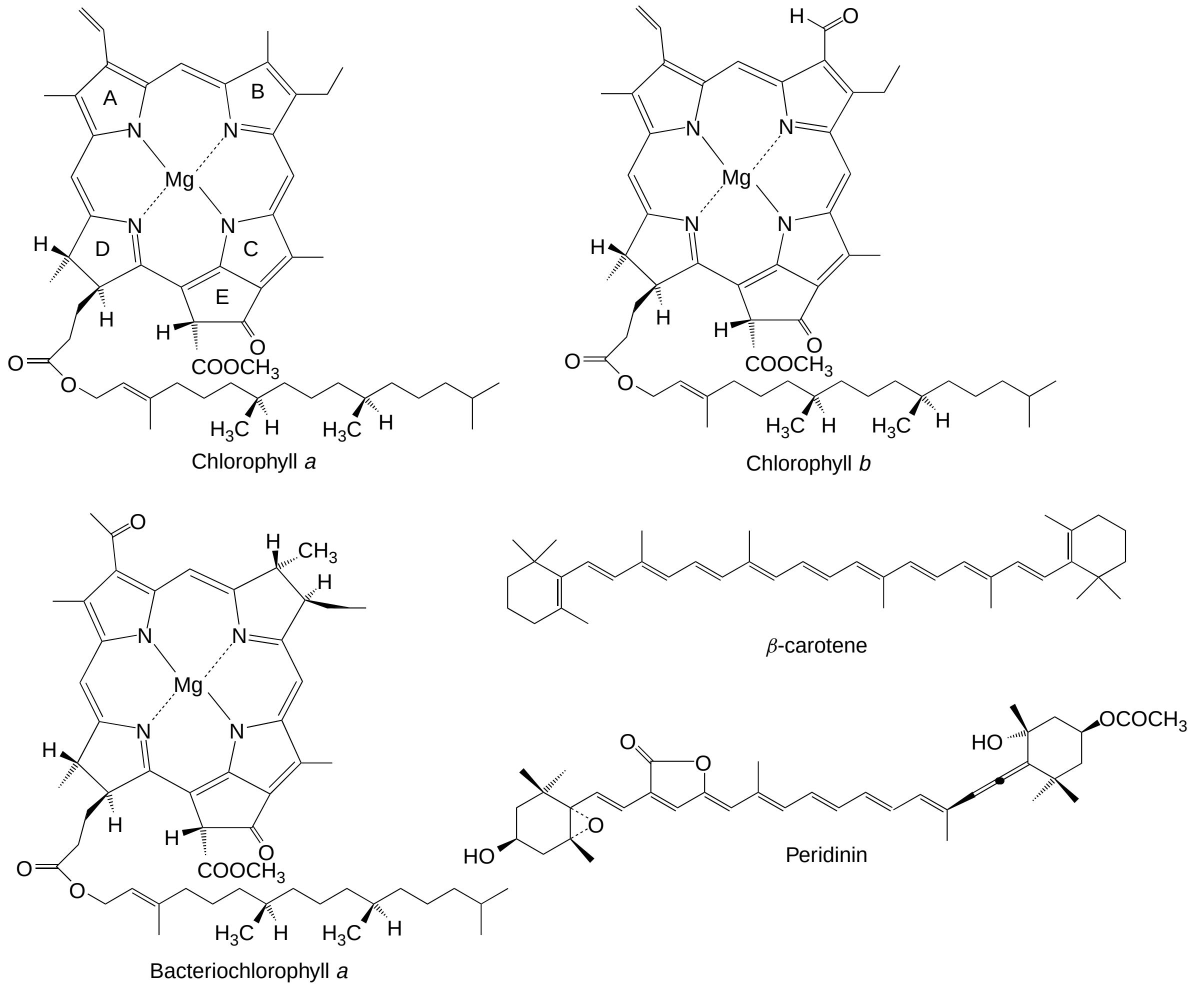

Figure 3 Structures of chlorophylls and other photosynthetic pigments

near IR regions of the spectrum. These are designated the Soret (sometimes called the B band), the Q_x and Q_y bands, from shortest to longest wavelength. Figure 4 shows the absorption and fluorescence spectra for chlorophyll *a* and bacteriochlorophyll *a*. Table 2 lists the wavelengths and extinction coefficients for a number of chlorophylls and bacteriochlorophylls in vitro. The same pigments in vivo invariably exhibit red-shifted absorption bands, sometimes by over 100 nm. The transitions are $\pi \rightarrow \pi^*$ in nature, and involve electron redistribution over the entire conjugated part of the macrocycle. The Quinone (Q) bands are nondegenerate transitions owing to the low symmetry of the molecule. The x and y subscripts refer to the direction of the transition dipole moment with reference to the molecular axes. The lowest energy Q_y band is invariably polarized along the axis bisecting rings A and C (see Figure 3), while in most cases the Q_x band is polarized along the axis bisecting rings B and D. The four orbital model of Gouterman for the electronic states of porphyrins (*see* ***Iron Porphyrin Chemistry***), while admittedly somewhat oversimplified, is adequate for many purposes.[13] More accurate calculations of the electronic properties of many chlorophylls and bacteriochlorophylls are now available.[14,15]

The conjugated chlorophyll macrocycle has intense visible and near-infrared absorption, with an extinction coefficient in the longest wavelength Q_y band of approximately $100\,mM^{-1}\,cm^{-1}$ (Figure 4 and Table 2).[1,16] The chlorophylls therefore absorb well in the region of the spectrum in which the solar spectrum has its most intense output, as shown in Figure 5.[1] The presence of the closed-shell Mg^{2+} ion ensures a long excited-state lifetime in the nanosecond range, in contrast to transition metal-containing porphyrins, which decay in picoseconds owing to internal charge transfer processes. This long excited-state lifetime facilitates a high quantum yield of photochemistry, in that extremely rapid competing pathways for excited-state decay are not present. The metallated pigments are generally much more abundant than are the free base porphyrins, although metal-free chlorophylls, known as *pheophytins*, are present in small quantities in many photosynthetic systems and function as essential redox carriers in reaction centers (see below).

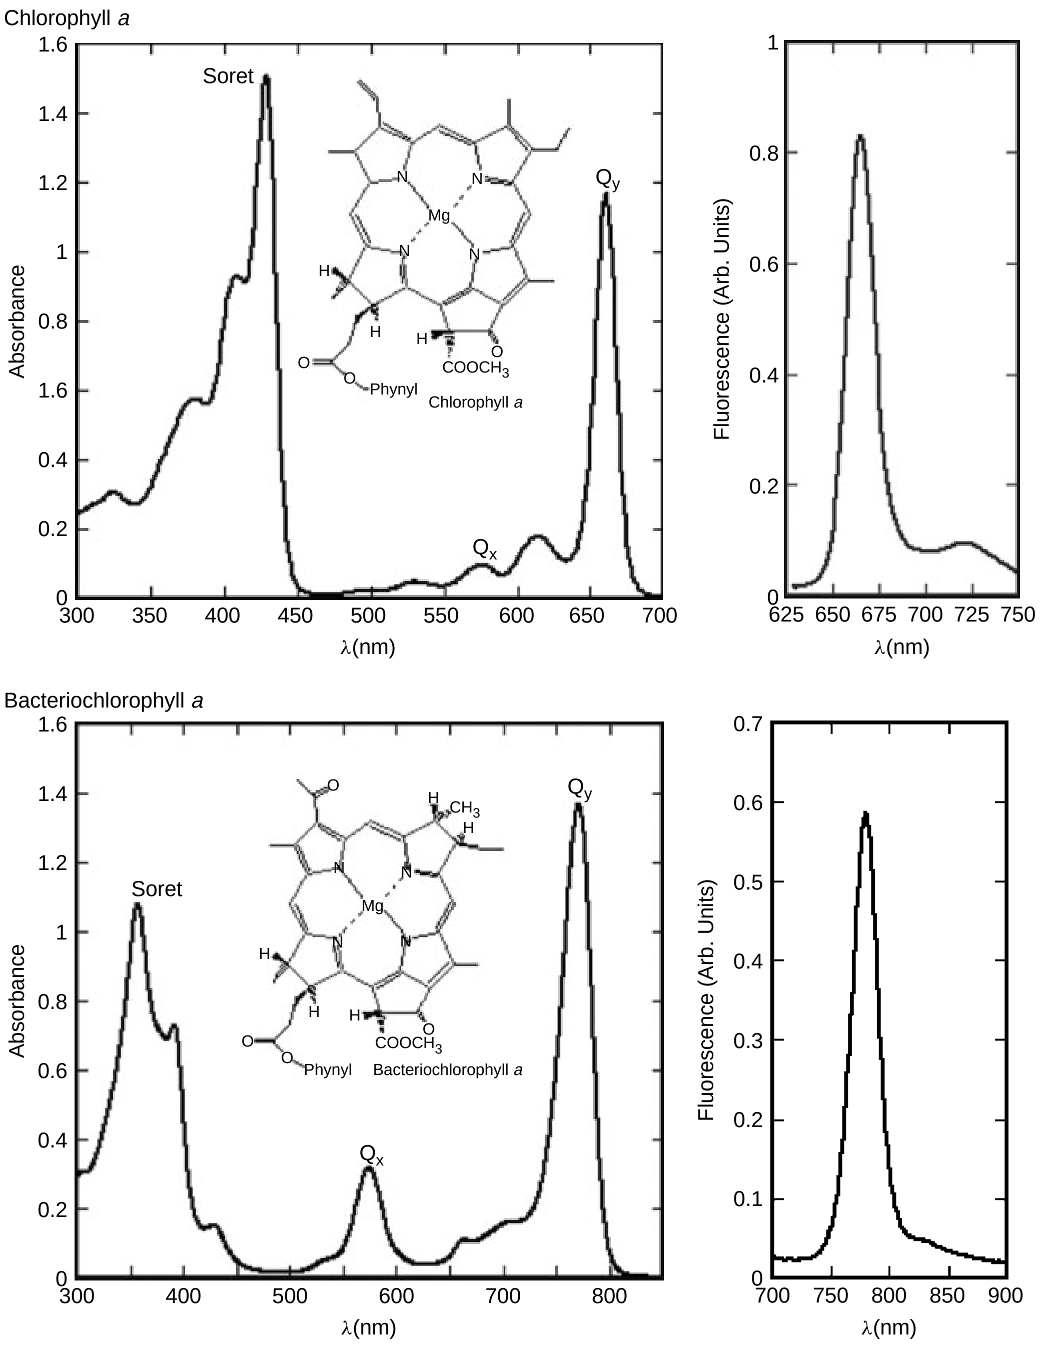

Figure 4 Absorption spectra of chlorophyll *a* and bacteriochlorophyll *a* in diethyl ether. (Ref. 1. Reproduced by permission of Blackwell)

The fluorescence emission of chlorophylls and bacteriochlorophylls is invariably emitted from the lowest energy excited sate, with typical Stokes shifts of 10–15 nm from the Q_y absorbance maximum. Fluorescence lifetimes of 2–5 ns are usually observed for monomeric pigments in organic solvents. Fluorescence of chlorophyll and bacteriochlorophyll in vivo is very strongly quenched; excited-state lifetimes are typically a few tens of picoseconds and fluorescence quantum yields are at most a few percent. The dominant excited-state decay pathways in vivo are excitation transfer, in which the excited state is transferred from one antenna pigment to another and ultimately photochemistry to form charge-separated states. The rate of photochemistry in the photosynthetic reaction center is fast enough compared to fluorescence and other nonradiative decay pathways so that the quantum yield of photochemistry is nearly unity.

The quantum yield Φ_i for any process that deactivates the excited state is given by the rate constant for that process

Table 2 Absorption properties of chlorophylls and bacteriochlorophylls in vitro[a]

Compound	Solvent	Absorption Maxima (nm)		
		Soret	Q_x	Q_y
Chlorophyll *a*	Diethyl ether	430	578	662 (90)

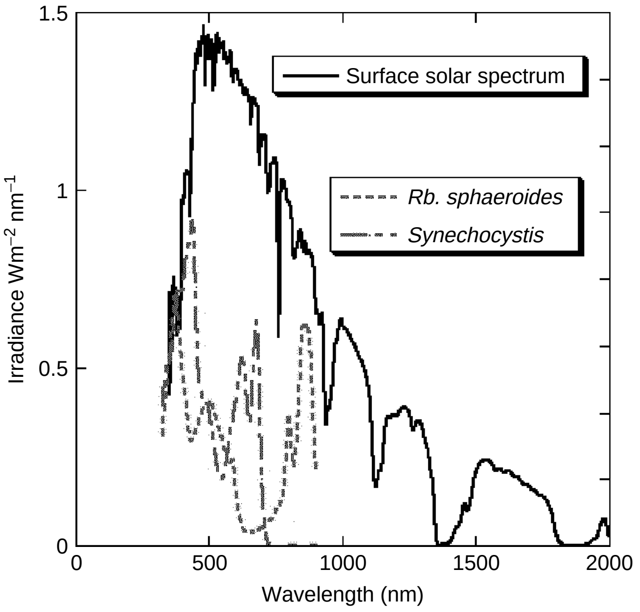

Figure 5 Solar spectrum superimposed on absorption spectrum of chlorophyll. (Ref. 1. Reproduced by permission of Blackwell)

(k_i) divided by the sum of rate constants for all possible excited-state decay processes (k_t) for further details.

$$\Phi_i = \frac{k_i}{k_t} \quad (1)$$

where

$$k_t = \sum_i k_i = k_f + k_p + k_{nr} \quad (2)$$

and k_f is the rate constant for fluorescence, k_p is the rate constant for photochemistry and k_{nr} is the rate constant for all other nonradiative processes, such as internal conversion and *Intersystem Crossing*. The excited-state decays by a set of parallel first-order pathways with an observed rate constant k_t equal to the sum of the rate constants for all pathways.[17] Because the photosynthetic system is basically a solid-state system without free diffusion in solution, the observed rate constants are usually first order. Multiexponential excited-state decays are often observed, however, reflecting both the complexities of the energy transfer network and also heterogeneity in the samples.

3 ENERGETICS AND EFFICIENCIES OF PHOTOSYNTHESIS

3.1 Redox Properties of Excited States[18,19]

The essence of photosynthetic energy storage is the photoinduced electron transfer process that takes place in the reaction center complex. This is most easily understood by considering the redox properties of the excited states of the reaction center pigments. Excited states typically have chemical properties that are dramatically different from those of the *Ground State* molecules. In particular, the redox potentials of the molecule are greatly modified by electronic excitation. A great deal of evidence from both organic and inorganic photochemistry indicates that the excited state can be both a stronger oxidant and a stronger reductant than is the ground state. Qualitatively, this can be understood as the electron occupying the excited orbital serving as a strong reductant, while the remaining hole can act as a strong oxidant.

It is not possible to measure excited-state redox potentials directly with a conventional redox titration, owing to their transient nature. However, redox potentials of the excited state can be estimated, using the ground-state potentials and the excitation energy.[18,19] If the entropy change upon excitation is small, which appears to be the case for many systems, the midpoint redox potential for the excited state of the pigment (P) acting as a reductant is given in equation (3):

$$E_m\left(\frac{P^+}{P^*}\right) = E\left(\frac{P}{P^*}\right) - E_m\left(\frac{P^+}{P}\right) \quad (3)$$

where $E_m(P^+/P^*)$ is the midpoint redox potential for the excited-state half reaction:

$$P^+ + e^- \longrightarrow P^* \quad (4)$$

The excitation energy $E(P/P^*)$ is the 0–0 energy for the lowest excited singlet state, usually approximated as the average of the absorbance and fluorescence energies:

$$P + h\nu \longrightarrow P^* \quad (5)$$

Table 3 Ground and excited singlet state redox potentials of photosynthetic pigments in vitro and in vivo[a]

	E (P/P*)	E_m (P^+/P)	E_m (P*/P^+)	E_m (P/P^-)	E_m (P*/P^-)
Chlorophyll *a*	1.85	+0.78	−1.07	−0.87	+0.98
Bacteriochlorophyll *a*	1.58	+0.64	−0.94	−0.84	+0.74
P700	1.75	+0.49	−1.26		
P680	1.80	~1.1	~−0.7		
P870	1.39	+0.45	−0.94		
P840	1.46	+0.25	−1.21		
P800	1.54	+0.25	−1.29		

[a]Most values taken from Reference 16, which contains original references. E(P/P*) = 0−0 excitation energies (eV); all other values are midpoint redox potentials of ground and excited states (V), versus NHE, calculated as described in text.

Finally, the midpoint redox potential for the oxidation of the ground state is given by equation (6):

$$P^+ + e^- \longrightarrow P \qquad (6)$$

This quantity is easily measured by a standard redox titration. Values for the excited-state redox potentials of chlorophyll *a* and bacteriochlorophyll *a* in vitro, as well as in a number of photosynthetic reaction centers are given in Table 3. The large negative values testify to the fact that the excited states are extremely strong reductants. Also shown are the potentials for the excited state acting as an oxidant $E_m(P^*/P^-)$ for the two isolated pigments, calculated analogously from the redox potential of the pigment anion $E_m(P/P^-)$. However, current evidence strongly suggests that the reaction center pigment excited state acts as a reductant in all reaction centers, as well as in most chlorophyll photoreactions in vitro.

3.2 Electron Transfer Schemes for Reaction Centers

The electron transfer patterns shown in Figure 2 can be combined with information on ground-state redox potentials of known electron carriers and the excited-state redox potentials given in Table 3 to construct detailed electron transfer schemes for photosynthetic systems. Schemes for the major classes of photosynthetic reaction centers are shown in Figure 6. A more in-depth discussion of some of these complexes is given below. In Figure 6, the electron carriers are placed at their midpoint redox potentials and the vertical arrow denotes energy input by a photon, thereby changing the redox potential of the reaction center photoactive pigment from that of the ground state to that of the excited state.

3.3 The Efficiency of Photosynthetic Energy Storage

It is not possible to give a single value for the energy storage efficiency of photosynthesis. Almost any value from 0 to 100% can be cited, depending on exactly how the question is formulated and where in the process the calculation is made. For example, the free energy stored in the initial radical pair products in isolated purple bacterial reaction centers is at least 90% of the photon energy. However, at each stage of the stabilization process a significant amount of energy is lost. This energy loss makes the process irreversible, and allows the energy to be stored in a form that can be utilized for cellular processes.

The overall thermodynamics of the photochemical energy storage also depend on the concentrations of the various forms of the redox carriers, and can be somewhat different from the midpoint potentials illustrated in Figure 6, which assume equimolar concentrations of oxidized and reduced forms. This point has been considered in detail by several authors with reference to viewing the photosynthetic system as a power converter.[20–23]

Using the midpoint redox potentials for the reductant H_2O (+0.82 V) and oxidant $NADP^+$ (−0.32 V) substrates in oxygen-evolving photosynthesis, the in situ measured maximum quantum yields for each photoreaction of essentially unity, and the excitation energies given in Table 3, the overall energy storage by the oxygenic photosynthetic system can be easily calculated to be approximately 41% of the energy in the photons. (Four turnovers of each photosystem are required to produce one molecule of O_2 and two molecules of NADPH.)

If the calculation is made instead using the ultimate electron acceptor CO_2, and measured whole plant quantum yields in dim monochromatic light, then the energy storage drops to about 27%. Further losses are incurred if white light is utilized as an energy source, as photochemistry takes place only from the lowest excited singlet state, and the energy difference between a blue and a red photon is lost as heat. A value of 5% has been estimated for an average energy conversion efficiency for sunlight falling on a leaf.[23] This number also includes losses due to growth and wasteful processes such as photorespiration.

If one takes the global view of the energy stored in biomass compared to the total solar energy incident on the Earth, then the estimated overall efficiency is about 0.05%.[24] This includes losses due to reflection, absorption by nonphotosynthetic pigments, the fact that much of the solar output is in the near-infrared region, which is not efficiently used by abundant organisms, and various cellular processes.

4 ANTENNA STRUCTURE AND FUNCTION

4.1 Mechanism of Excitation Transfer[25,26]

The photosynthetic antenna system is organized to collect and deliver excited-state energy to the reaction center complexes. The delivery of energy is by means of excitation transfer. Excitation transfer in photosynthetic systems is

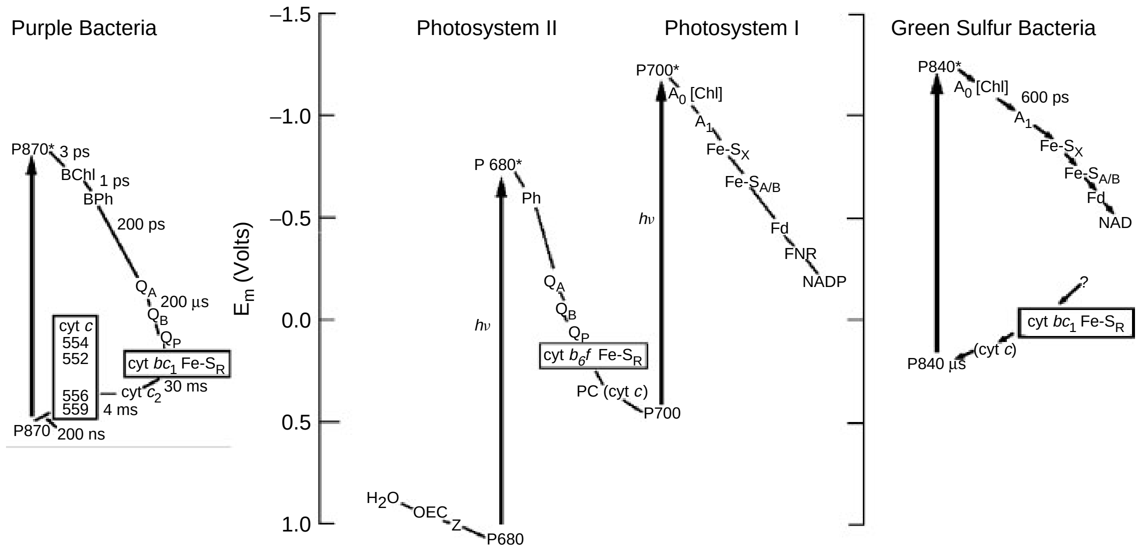

Figure 6 Electron transfer schemes for photosynthetic reaction centers. Heavy vertical arrows indicate energy input by photon absorption, thinner arrows indicate preferred electron transfer pathways. Carriers in parentheses indicate alternate species in some organisms. Question marks indicate carriers or electron transfer steps that are likely but have not been unambiguously established. The cytochrome bc_1 and b_6f complexes are boxed, and the details of the electron flow in these complexes are omitted. All redox potentials are referenced to the normal hydrogen electrode. Abbreviations: AC auracyanin; BChl, bacteriochlorophyll; BPh, bacteriopheophytin; Chl, chlorophyll; cyt, cytochrome; Fd, soluble ferredoxin; Fe-$S_{A/B}$, iron-sulfur centers contained on a low-molecular-weight peptide peripheral to the reaction center core; Fe-S_R, Rieske iron-sulfur center; Fe-S_X, iron-sulfur center contained in the reaction center core; FNR, ferredoxin-NADP reductase; $h\nu$, photon; NAD(P), nicotinamide adenine dinucleotide (phosphate); OEC, oxygen-evolving center; P870, P680, P700, P840, P800, reaction center photoactive pigment with absorption maximum in nanometers at the indicated wavelength; PC, plastocyanin; Ph, pheophytin; Q, quinone (subscript indicates a specific quinone); Z, tyrosine radical donor to Photosystem II

generally considered to take place by means of the Förster resonance transfer mechanism. If two pigments are separated by more than several Angstroms and the transitions are allowed, the transfer between energy donor and energy acceptor occurs primarily via a Coulomb (dipole-dipole) mechanism, with rate constant given by equation (7):

$$k_e = k_f \left(\frac{R_o}{R}\right)^6 \qquad (7)$$

where k_f is the rate constant for fluorescence, R is the distance between energy donor and acceptor and R_o is the ‘‘critical distance’’ at which energy transfer is 50% efficient. R_o is given by equation (8) (in units of nm^6):

$$R_o^6 = \left(\frac{8.785 \times 10^{17}\kappa^2}{n^4}\right) \int \frac{F(\nu)\varepsilon(\nu)\,d\nu}{\nu^4} \qquad (8)$$

where $\varepsilon(n)$ is the molar extinction coefficient on a wavenumber scale, $F(n)$ is the normalized emission spectrum of the energy donor, n is the refractive index and κ^2 is an orientation factor, given by equation (9):

$$\kappa^2 = (\cos\alpha - 3\cos\beta_1\cos\beta_2)^2 \qquad (9)$$

where α is the angle between the two transition dipoles and the β’s are the angles between each dipole and the line joining them. The values of κ^2 can range from 0 to 4. For a random orientation of the transition dipoles, the average value of κ^2 is 2/3.

Typical values of R_o between chlorophylls and bacteriochlorophylls are 60–100 Å (assuming $\kappa^2 = 1$). Excitation transfer is therefore a longer range process than is electron transfer (see below). In fact, the structures of antenna complexes have undoubtedly been fine tuned by evolution to minimize excited-state electron transfer processes, while at the same time efficiently delivering energy to the reaction center.

If the pigments are very close to each other, then the simple picture described above breaks down. Electron exchange terms can contribute to the energy transfer process. This is thought to be the case particularly for carotenoid to chlorophyll energy transfer, where forbidden transitions are involved, so that the Coulomb terms are zero. In the case of strongly interacting pigments, exciton coupling results, in which it is most useful to view the system as a supermolecule rather than as individual chromophores. Currently a large amount of structural data is available for photosynthetic antenna complexes. The structures of many of them will be discussed below. It is clear from a variety of evidence that in certain cases the very weak coupling case described by equation (7) is

probably adequate, while in others the exchange mechanism may be important. Excitonic effects are clearly apparent in many photosynthetic complexes.[25]

4.2 Structure of Photosynthetic Antenna Complexes[4]

A remarkable variety of antenna complexes have been identified from various classes of photosynthetic organisms. There seems to be little doubt that there have been multiple evolutionary origins of antenna complexes, as there is no common structural theme evident. Figure 7 shows a rogue's gallery of various types of photosynthetic antenna complexes. These include the cyanobacterial phycobilisome type antennas that act as light guides, large multimeric circular complexes integral to the membrane found in proteobacteria, enormous chlorosome structures in green sulfur bacteria containing rods of self-assembled bacteriochlorophyll with relatively little protein. Many antenna complexes, like the chlorophyll a/b Light-harvesting complexes, are integral membrane complexes in which pigments (chlorophylls and carotenoids) are associated with proteins to form well-defined pigment-protein complexes that span the photosynthetic membrane and probably interact directly with the reaction centers, which are also integral membrane proteins. Others are only peripherally attached to the membrane and are easily removed by gentle treatments. The phycobilisome and the chlorosome complexes are examples of *peripheral* antenna complexes. The phycobilisomes are large complexes containing bilins, which are open-chain tetrapyrroles, as pigments that are covalently attached to proteins.[27,28] Chlorosomes contain specialized bacteriochlorophyll pigments (bacteriochlorophylls c, d, or e), which form large pigment aggregates with relatively little involvement of protein.[29–31]

Phycobilisomes are large supramolecular aggregates attached to the stromal side of the thylakoid membrane in cyanobacteria, red algae, and cryptomonads.[32] The size of phycobilisomes varies amongst species and growth conditions and can easily reach sizes of 2 MDa. All pigment binding protein species show a first level quaternary arrangement of α and β subunits forming an $\alpha\beta$-dimer. This further arranges into second level round disklike structures of $(\alpha\beta)_3$ or $(\alpha\beta)_6$ units. On this core are arranged six additional rodlike structures made up of phycocyanin. Also associated with the phycobilisome are colorless linker proteins. High-resolution X-ray structures are available for several of the bilin-containing proteins of the phycobilisomes.

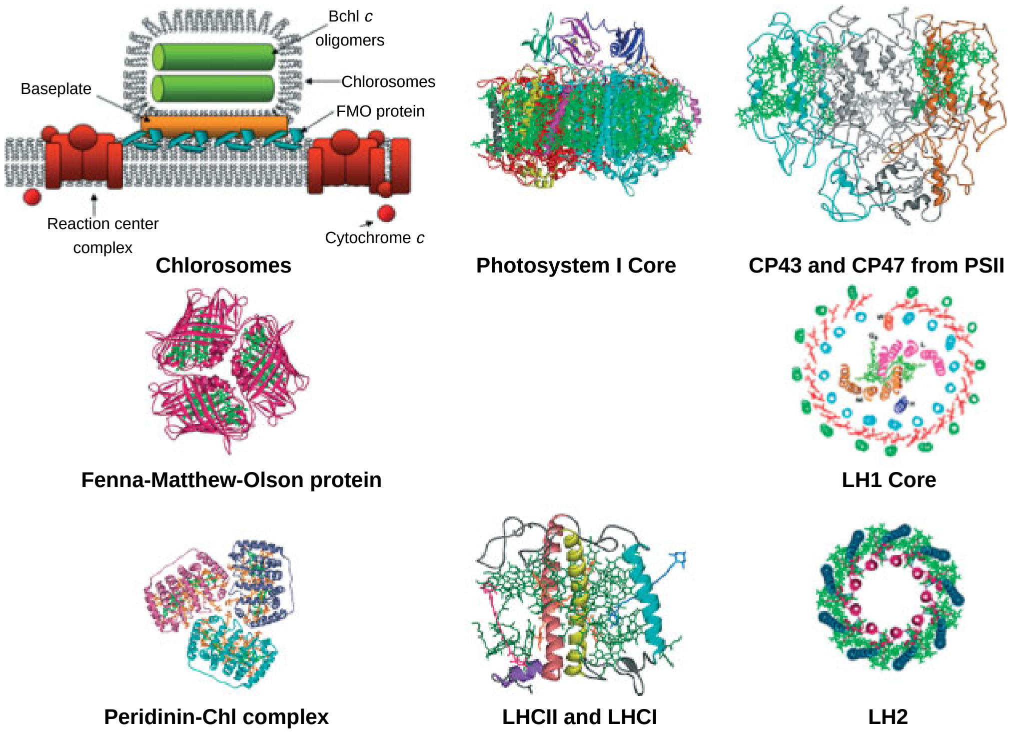

Figure 7 Rogue's gallery of structures of peripheral antenna complexes. As labelled these include Chlorosomes from green sulfur bacteria, fused antenna domains of the Photosystem I core, the CP43 and CP47 proteins of Photosystem II, the Fenna-Matthew-Olson (FMO) protein associated with chlorosomes, LHI proteins surrounding a purple bacterial photosynthetic core, the peridinin-chlorophyll a protein of dinoflagellate algae, the LHCI and LHCII proteins found in plants and many algae, and the LHII protein complex that is associated with LHI in purple bacteria

These include structures of phycoerythrin, C-phycocyanin and allophycocyanin. From the known high-resolution structures of the component proteins, in conjunction with biochemical, spectroscopic, and electron microscopic measurements, structures for the phycobilisome have been proposed. Figure 8(a) shows a recent proposed structure for the arrangement of the proteins in a phycobilisome from *Thermosynechococcus vulcanus*.[32] A tricylindrical allophycocyanin core is surrounded by three pairs of phycocyanin rods (R1, R2, R3). It is proposed that the bilin-containing core and the rods are connected by protein connecters in the phycobilisome-like phycocyanin 622. Other structures include structure of allophycocyanin a and allophycocyanin b,[33] C-phycocyanin from the red algae *Porphyra yezoenis*,[34–38] and the structures of phycoerythrin,[39–41] R-phycocyanin.[42] Figure 8(b) shows the energy pathway within the phycobilisome. It can be seen that some of the pigments are very close together, while others are separated by much longer distances. Thus, for some energy transfer processes the simple Förster dipole-dipole mechanism described in the previous section is probably inadequate. Figure 8(c) and 8(d) show the ribbon representation of the allophycocyanin α-subunit and β-subunits, respectively. Three $\alpha\beta$ monomers are arranged around a 3-fold axis to form a hexameric disc shaped $(\alpha\beta)_3$ trimer, shown in Figure 8(e). Hexamers like these are stacked to form the rods of the phycobilisome (Figure 8(a) and 8(b)).

Another antenna complex where high-resolution structural information is available is the bacteriochlorophyll *a* binding protein (also known as the Fenna-Matthews-Olson or FMO protein) from green sulfur bacteria.[43] This complex serves as the bridge between the peripheral chlorosome complex and the membrane-bound reaction center complexes. In this

case, the pigments interact moderately strongly, at distances of approximately 10 Å. Because this was the first chlorophyll protein complex to have its detailed structure determined, it has been the subject of intense spectroscopic and theoretical analysis.[44]

4.3 Supercomplexes

4.3.1 The Structure of the Light-harvesting LH1 and LH2 Complexes of Purple Photosynthetic Bacteria[45]

The basic structure of all the component proteins making up the Light-harvesting (LH) complexes of purple photosynthetic bacteria is similar.[46,47] It consists of two polypeptides (α- and β-subunits) that fold into transmembrane α-helices and form a heterodimer that noncovalently binds bacteriochlorophyll and carotenoids. Several of these heterodimeric units group together to form ring structures. The size of these ring structures differs between LH1 and LH2, with LH1 being much larger (about 120 Å in diameter) and encircling the reaction center complex. The smaller LH2 rings (60–70 Å diameter) group around the LH1-reaction center complex, but their exact arrangement is unclear (Figure 9).

Electron and atomic force microscopy has shown that the LH2 complexes from *Rhodopseudomonas acidophila*, *Rhodovulum sulfidophilum*, and *Rhodobacter sphaeroides* are all monomers of the basic $\alpha\beta$-subunits. Crystal structures of the LH2 complexes from *Rps. acidophila* and *Rs. molischianum* have also been reported. Each $\alpha\beta$-unit binds 3 bacteriochlorophyll and two carotenoid molecules, although in the crystal structure only one carotenoid electron density was clearly defined. The arrangement of the $\alpha\beta$-subunits is

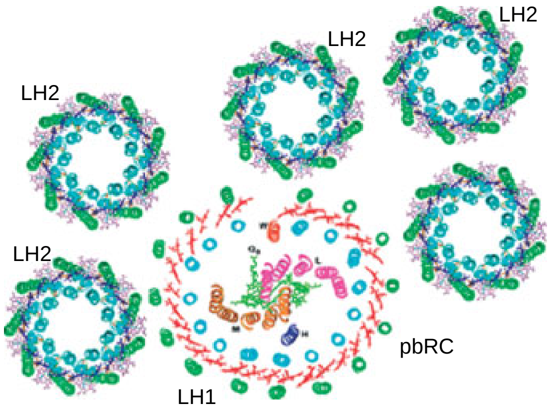

Figure 9 The bacterial supercomplexes found in purple bacteria (*Rhodopseudomonas palustris*). A single reaction center complex is surrounded by a nearly circular ring of LHI. In close proximity are additional smaller rings of LHII. A gap exists in the LHI ring in some but not necessarily all cases, presumably for the entry of PufX or some other protein

that of a double row of α-helices, with the α-protein inside and the β-protein outside. Once again the bacteriochlorophylls are stacked in two layers, one near the cytoplasmic side of the inner membrane and the other to the periplasmic side. The bacteriochlorophyll rings of the top portion of LH2 are nearly parallel to each other, with a Mg-Mg distance of around 9 Å. The ring of nearly parallel bacteriochlorophylls is nearly perpendicular to the plane of the bacteriochlorophylls in the other ring when overlapping (as they do at B850$\alpha\beta$ and B800) facilitating faster electron transfer.

While the structure of LH2 is well resolved, the structure of LH1 remains less well understood. Because of the sequence similarity of LHI $\alpha\beta$-subunits of *Rhodobacter sphaeroides* to the LH2 $\alpha\beta$-subunits of *Rhodospirillum molischianum*, the structure of the LH1 subunits was modeled versus the crystal structure of *Rs molischianum* LHII.[48,49] The crystal structure of *Rhodobacter sphaeroides* Rb RC was then modeled into the center of a ring of LHI $\alpha\beta$-subunits. Using this method, the resultant modeled ring contained 16$\alpha\beta$-subunits, binding 32 bacteriochlorophyll molecules. The general size and helix positions generally agreed with an 8.5 Å electron microscopy projection map of *R. rubrum* LH1 (which was done without *R. rubrum* RC present). However, it is now clear that in many (but not necessarily all) cases in vivo there is a break in the ring, so that it is not a perfect circle, but has an opening. In some cases this has been proposed to be the site where a photosynthetic regulatory protein PufX resides. PufX has been shown to copurify with the LH1-RC complex from *Rhodobacter sphaeroides*. A structure of the RC-LH1 complex from *Rhodopseudomonas palustrus* is shown in Figure 9.[50] In this case, PufX is not present and an as yet unidentified protein interrupts the ring.

4.3.2 *Superstructures of PSI or PSII in some Organisms in cases of Iron Stress or Low Light*[51–53]

In cyanobacteria under conditions of iron limitation leading to iron stress, the phycobilosomes are deconstructed, and a macromolecular supercomplex is synthesized. Iron stress induces the expression of a protein that is very similar in structure to CP43, only lacking the large hydrophilic loop that joins the ends of transmembrane helices 5 and 5′, and is called C43′.[54] CP43′ is encoded by the *isiA* gene. Another gene, *isiB*, encodes a flavodoxin, which replaces the iron-containing ferredoxin as the electron acceptor for PSI during iron stress.[53,55–57] Electron microscopy of the PSI/CP43′ supermacromolecular complex shows that in *Synechocystis* PC 6803 under iron stress 18 subunits of CP43′ form a well-structured ring around the cloverleaf of PSI, thereby increasing the light-harvesting capacity of PSI by 70% (Figure 10(a)). Each CP43′ subunit binds between 12 and 13 chlorophyll a molecules, based upon modeling calculations and comparisons to the CP43 subunit of PSII.

Prochlorophytes are cyanobacteria that do not contain phycobiliproteins, but rather contain chlorophyll a/b binding Pcb proteins. Pcb sequences are homologous to the sequences of IsiA and CP43. It was shown that in low-light adapted strains of the prochlorophyte *Prochlorococcus marinus* SS120, similar to the case with CP43′ of *Synechocystis* PC 6803, Pcb forms an 18-subunit ring around the trimeric PSI, even under conditions of Fe sufficiency. Another prochlorophyte,

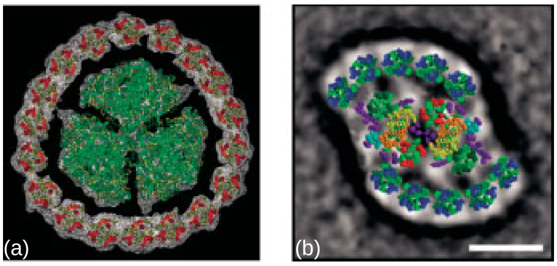

Figure 10 Bacterial supercomplexes found under conditions of light starvation or iron stress. (a) Modeling of the Cα backbone and chlorophylls (yellow) of the PSI trimer (green) and CP43″ helices (red) using data from X-ray diffraction studies of the PSI complex of *Synechocystis* PCc 6803 induced during iron stress (deficiency). (Reprinted with permission from Ref. 54. © 2003 American Chemical Society) (b) Structure of the Pcb-PSII supercomplex isolated from *prochloron didemni*, incorporating the X-ray structures of the PSII core dimer and the Pcb homolog CP43 from *synechocystis elongatus*. CP43 was used to model Pcb. The CP43 transmembrane helices are shown in blue, with the chlorophyll a molecules in green. Other colors are for the transmembrane helices of the PSII core, with D1 = yellow, D2 = orange, CP47 = red, CP43 = dark green, cytochrome b_{559} = cyan, and the low-molecular-weight subunits = purple. (Reproduced from T.S. Bibby, J. Nield, M. Chen, A. W. Larkum, and J. Barber, 'Structure of a photosystem II supercomplex isolated from Prochloron didemni retaining its chlorophyll a/b light-harvesting system' *Proc Natl Acad Sci U.S.A.*, 2003, **100**, 9050. © 2003 National Academy of Sciences, USA)

Prochloron didemni, is a symbiont that lives in a layer under the body of a marine ascidian. An 18-subunit ring structure is not formed around PSI, but rather a separate macromolecular complex of ten Pcb subunits and two PSII complexes form a supercomplex.[51,58,59] As shown in Figure 10(b), two complexes of PSII make up the core of the supercomplex. Five Pcb subunits line in a row on either side of the core. It is assumed, based upon sequence and structural homology to CP43, that thirteen chlorophylls bind to each Pcb subunit.

The integral membrane chlorophyll a/b antenna complex from higher plants forms two-dimensional crystals, which have been analyzed using electron diffraction and electron microscopy, and also by three dimensional crystals by X-ray crystallography.[46,50,53,57]

4.4 Kinetics and Energetics of Excitation Transfer

Excitation transfer must be fast enough to deliver excitations to the photochemical reaction center and have them trapped in a time short compared to the excited-state lifetime in the absence of trapping. Excited-state lifetimes of isolated antenna complexes, where the reaction centers have been removed, are typically in the 1–5 ns range. Observed excited-state lifetimes of systems where antennas are connected to reaction centers are generally on the order of a few tens of picoseconds, which is sufficiently fast to ensure that under physiological conditions that almost all the energy is trapped by photochemistry.

In many antenna complexes, an energy gradient or funnel is present, in which a series of pigments is found with progressively more red-shifted Q_y absorption maxima (and consequently progressively lower excited-state energies). In most known cases, the lowest energy antenna pigments are physically closest to the reaction center, and the higher energy pigments are the farthest. This gradient provides a funneling effect for the excitations, and imparts a directionality and irreversibility to the energy transfer process, although at the cost of the difference in energy levels of the pigments. This funneling effect is particularly apparent in large peripheral antenna complexes such as phycobilisomes and chlorosomes, where there may be up to several thousand antenna pigments per reaction center. In this case, it is clear from the structural data shown in Figure 8 that the shorter wavelength absorbing pigments are located toward the ends of the rods and the longer wavelength absorbing one are toward the core, which is in turn attached to the membrane where the reaction center is located. The energy flow is therefore downhill energetically while at the same time moving the excited state physically closer to the reaction center where photochemistry will eventually take place.

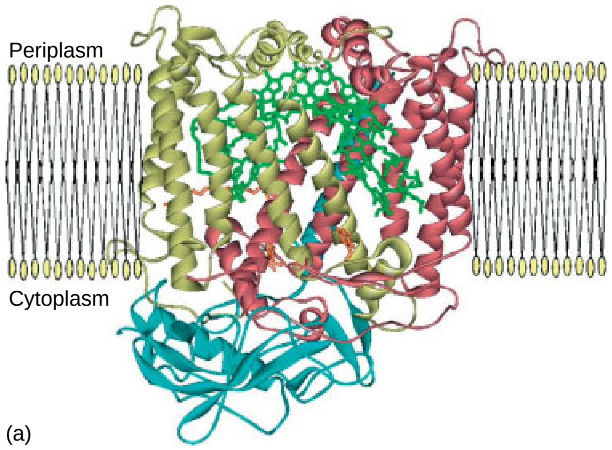
5 STRUCTURE AND MECHANISM OF THE TYPE II RC FROM PURPLE BACTERIA[45,60]

The structure of the purple bacterial Type II RCs (PbRCs) have been known for nearly 20 years, and as such are very well characterized spectroscopically, biochemically, and structurally.[61–64] These were the first reaction center complexes to be purified, and the first to be studied by picosecond kinetic methods. The chemical composition of the reaction centers from selected purple bacteria and the functionally related reaction center from the green bacterium *Chloroflexus aurantiacus* is summarized in Table 4. The RC from *Rb. sphaeroides* contains three protein subunits, known as L (light), M (medium), and H (heavy). PbRC is a stripped down version of PSII, with its subunits L and M similar structurally to D1 and D2 and representing an ancient duplication. H is a cytoplasmic subunit, and in some species a periplasmic cytochrome subunit C is present. The PbRC has no internal antenna and thus must harvest light using external antennas. The internal electron transfer chain is almost identical in layout to PSII. There are some important differences, however, the most glaring of which is that PbRC utilizes bacteriochlorophyll rather than chlorophyll. The structure of the reaction centers from two organisms are known, *Rhodobacter sphaeroides* and *Rhodopseudomonas viridis*. All of the reported crystal structures of RCs and LHs (circular antenna complexes discussed earlier) except that of *Rv* are from bacteriochlorophyll a-containing species. The RC from *Rv* contains bacteriochlorophyll b. The structure of the *Rhodopseudomonas viridis* PbRC is shown in Figure 11. The reaction center protein forms a scaffolding upon which the cofactors are arranged. The part of the protein that crosses the lipid bilayer is almost purely alpha helical in

Table 4 Chemical composition of bacterial reaction centers

Organism	BChl *a*	BChl *b*	BPheo *a*	BPheo *b*	Protein Subunits[a]	Ubiquinone	Menaquinone	Metal	Carotenoid
Rhodopseudomonas viridis	–	4	–	2	LMHC	1	1	Fe	1
Rhodobacter sphaeroides	4	–	2	–	LMH	2	0	Fe[b]	1
Chromatium vinosum	4	–	2	–	LMHC	1	1	Fe	1
Chloroflexus aurantiacus	3	–	3	–	LM(C)[c]	0	2	Mn	0

[a]Molecular masses (from gene sequences) of the subunits are approximately L-31, M-34, H-28, C-41 kDa. [b]Certain strains of this organism contain Mn. [c]This organism contains a cytochrome subunit, although it is lost during preparation.



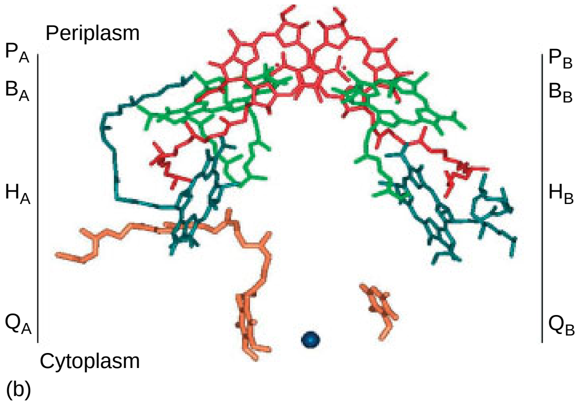


Figure 11 (a) Crystal structure of the *Rhodopseudomonas viridis* reaction center. Coordinates taken from the Protein Data Bank and visualized using Accelrys DSViewer Pro. (b) Arrangement of the chromophores in the *Rhodobacter sphaeroides* reaction center. The red pigments at the top labeled D_A and D_B are the bacteriochlorophyll *a* special pair, known as P870. The light green pigments labeled B_A and B_B are the accessory bacteriochlorophyll *a* molecules and the azure pigments labeled H_A and H_B are bacteriopheophytin *a* molecules. The orange molecules labeled Q_A and Q_B are the ubiquinone acceptors. The blue ball is an Fe atom

secondary structure, and contains predominantly nonpolar amino acids, with almost no charged amino acids. There are 11 transmembrane helices, with 5 each from L and M, and one from the H subunit. The L and M proteins have a pseudo-2 fold axis of symmetry, running approximately perpendicular to the plane of the membrane. The symmetry is broken by the H subunit, which has no symmetry-related counterpart, and also by the fact that the L and M subunits have only about 60% sequence identity. In addition to the protein complement, these reaction centers contain several additional *cofactors*, most of which are not covalently attached to the protein. These include bacteriochlorophyll *a* (in some cases *b*), the corresponding metal-free bacteriopheophytins, two quinones (either ubiquinone or menaquinone), a nonheme Fe, (replaced by Mn in some species) and in most cases a molecule of carotenoid. The cytochrome subunit contains four heme *c* groups, covalently bound to cysteine residues. As in the other RCs, the electron transfer chain is comprised of two branches: two accessory BChls in close proximity to the special pair (B_A, B_B), two bacteriopheophytins (H_A, H_B), and a pair of quinones (Q_A, Q_B) (Figure 11(b)). The primary electron donor in the PbRC is called a ''special pair'' because of strong excitonic coupling. This is primarily due to perfect stacking of the chlorin rings of the two bacteriochlorophyll *a*'s (P_A and P_B) of the special pair. The Mg–Mg distance is 7.6 Å, but there are strong $\pi - \pi$ interactions between the two chlorin rings. The special pair is called P870, after the wavelength maximum of their Q_y absorbance band. This pair of pigments together form the photoactive pigment whose excited state loses an electron to form the primary ion pair state. The EPR and ENDOR spectra of the oxidized special pair and acceptor complex have been studied extensively.[65,66] The unpaired electron in the primary donor is approximately equally shared between the two pigments, resulting in a reduction of the hyperfine coupling constants by a factor of two, compared to the cation radical of the monomeric pigment in solution. A variety of evidence indicates that electron transfer proceeds only down the pigments on the A branch, and then crosses over from the A to the B branch at the quinones. The function of the pigments in the B branch is not yet clear, and may be primarily structural.

It has been established that the electron flow in Pb is cyclic (see Figure 2). Upon absorption of a photon by the special pair (P_A/P_B), an electron is promoted to an excited state, whereupon it is transfered through B_A to H_A in 2–3 picoseconds. The reduced bacteriopheophytin ($H_A{}^-$) donates an electron to Q_A in 200 ps. Within 200 µs, the electron is transfered to Q_B, forming Q_B semiquinone. After a second round of excitation, transfers, and reduction of Q_B semiquinone, QH_2 is released after taking up two protons from the cytoplasmic side of the inner membrane. This is quite similar to the case with PSII of cyanobacteria and the chloroplasts of higher plants. In Pb, the QH_2 is used to reduce cytochrome bc_1 oxidoreductase (to be discussed later), which in turn reduces cytochrome c_2. Cytochrome bc_1 pumps two protons across the inner membrane into the periplasm, resulting in a proton gradient that is used by ATP synthase to make ATP. Cytochrome c_2 completes the cyclic electron flow by rereducing the RC special pair. As opposed to anoxygenic photosynthetic bacteria, cyanobacteria and chloroplasts utilize a cytochrome b_6f in place of cytochrome bc_1.

5.1 Kinetics and Pathways of Electron Transfer within Reaction Centers[66,67]

A tremendous number of different techniques have been brought to bear on the bacterial reaction center system, including almost every imaginable kind of spectroscopy, as well as a wide range of biochemical and genetic manipulations. Here it is only possible to give a brief summary of some of

the results. The focus will be on the first few reactions following excitation of the special pair, either directly by photon absorption or indirectly by excitation transfer from antenna or other reaction center pigments. The technique of picosecond absorbance transient difference spectroscopy has been especially informative with respect to elucidating the pathway of electron flow in these complexes, and will therefore be emphasized. Figure 12 summarizes the photochemical and early secondary reactions that take place in isolated reaction centers. A variety of evidence indicates that the electron transfer pathway and kinetics in isolated reaction centers are not significantly altered from their behavior in vivo.

Following excitation of the special pair, the excited state of P870 (P960 in organisms that contain bacteriochlorophyll *b*, such as *Rps. viridis*) has a lifetime of about 3 ps at room temperature, decreasing to about 1 ps at cryogenic temperatures. This excited state (P870*) is conveniently monitored by measuring stimulated emission in the 900 nm region. As P870* decays, absorbance bands bleach at 535 nm and 760 nm, assigned to Q_x and Q_y transitions of the bacteriopheophytin on the A branch, while at the same time a broad new band appears in the 650 nm region. The new state formed is the radical ion pair state $P870^+$ BPh_A^-, in which an electron has been transferred from the excited special pair to the bacteriopheophytin on the A branch. The A branch bacteriopheophytin is implicated largely by the spectra in the Q_x region. The two bacteriopheophytin molecules have slightly different spectral signatures, owing to differences in the amino acid polarities in their immediate environments.

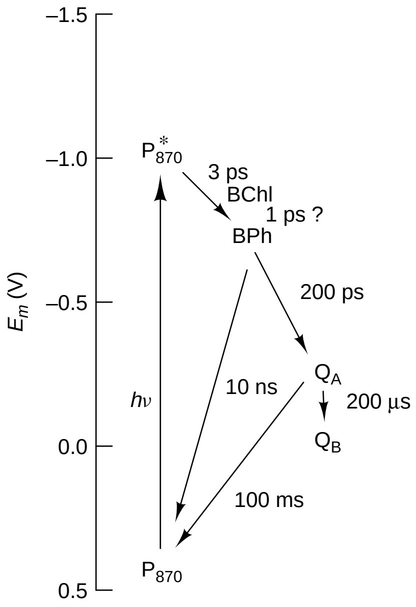

Figure 12 Energy-kinetic diagram for electron transfer in purple bacterial reaction centers at room temperature. Numbers given are typical for several species of purple bacteria

The $P870^+$ BPh_A^- ion pair state decays in 200–300 ps to form the $P870^+$ Q_A^- state. The electron is then transferred to Q_B in 100–200 μs finally to form the state $P870^+$ Q_B^-. The $Q_A^- \rightarrow Q_B^-$ reaction is thermally activated, while all the others are nearly independent of temperature, actually speeding up slightly at cryogenic temperatures. The implications of this are discussed in the next section.

The arrangement of cofactors shown in Figure 11 suggests that an earlier charge-separated state may precede the $P870^+$ Bph_A^- state, namely $P870^+$ $BChl_A^-$, where $BChl_A$ is the accessory bacteriochlorophyll labeled B_A. This state is generally considered to be involved in the primary electron transfer process, although the nature of its involvement has been a matter of intense debate.[67–69] The data clearly indicate that the rate constant for its decay is faster than that of its formation, thereby precluding buildup of substantial amounts of the state. The energy of the $P870^+$ $BChl_A^-$ state is close to that of P870*. The distances and calculated electronic couplings between the special pair and BPh_A are sufficiently long and weak, respectively, that it is extremely unlikely for the electron transfer process to take place directly from P870* to BPh_A. Electrochromic effects of the newly created charges on the electronic properties of the nearby pigments further complicate the picture.

Perhaps the most striking aspect of the comparison of the structural and kinetic data on reaction centers is the apparent two-fold symmetry of the structure, contrasted with the clear evidence for asymmetry in the electron transfer pathway. Estimates of the branch ratio for electron transfer down the A branch in Figure 11, compared to the B branch are as high as 200:1.[70] A considerable effort, including analysis of many site-directed mutants, has gone into trying to understand the factors that facilitate electron transfer down the A branch instead of the B branch. Surprisingly, excitation with blue light causes a significant fraction of B side electron transfer.

Another interesting feature of the electron transfer times shown in Figure 12 is that the rates of recombination processes, in which the electron simply returns from one of the acceptors directly to the oxidized special pair, are invariably a factor of fifty or more slower than are the rate constants for the forward reaction. It is because of this kinetic control of the rates of wasteful processes that the quantum yield for photochemistry is so high. One of the major factors thought to be involved in the slow recombination rates is the large energy gap involved. This is best understood by considering some theoretical aspects of biological electron transfer reactions.

5.2 Theoretical Analysis of Electron Transfer Reactions (*see Long-range Electron Transfer in Biology*)[71–73]

Biological electron transfer reactions have been the subject of a great deal of both experimental and theoretical analysis in a wide range of systems. Of these systems, the bacterial

photosynthetic reaction center is attractive, because it exhibits in a single complex a number of unusual features, including the ability to follow the reactions from liquid helium temperatures to above room temperature, and the ability to modify the free energy of the process by chemical, genetic and electrical methods. The structure of the complex is known at high resolution, diffusion processes are not involved, and a wealth of kinetic and other spectroscopic data are available. No other biological system possesses all these features.

The theoretical description of biological electron transfer has grown out of the pioneering work of Marcus on inorganic reactions in solution. The electron transfer process can be viewed as a nonradiative relaxation process from an initial state with the electron donor (D) reduced and the acceptor (A) oxidized to a final state with the donor oxidized and the acceptor reduced, according to equation (10).

$$D_{red} + A_{ox} \longrightarrow D_{ox} + A_{red} \qquad (10)$$

The Fermi Golden rule describes the first-order rate constant for the electron transfer process, according to equation (11), where the summation is over all the vibrational substates of the initial state i, weighted according to their probability P_i, times the square of the electron transfer matrix element in brackets. The delta function ensures conservation of energy, in that only initial and final states of the same energy contribute to the observed rate. This treatment assumes a weak coupling between D and A, also known as the nonadiabatic limit.

$$k_{et} = \frac{2\pi}{\eta} \sum_i P_i |\rangle \Psi_f | \tilde{V} | \Psi_i \langle|^2 \delta(E_f - E_i) \qquad (11)$$

Note that the wave functions for the initial and final states (Ψ_i and Ψ_f include both donor and acceptor. This equation is usually simplified by making the Born-Oppenheimer approximation for the separation of nuclear and electron wave functions, resulting in equation (12), in which $\tilde{V}$ is the electronic matrix element describing the coupling between the electronic state of the reactants with those of the product, and FC is the Franck–Condon factor.

$$k_{et} = \frac{2\pi}{\eta} \tilde{V}^2 FC \qquad (12)$$

The electronic coupling matrix element experimentally depends primarily on the distance and orientation of the reacting species. A variety of evidence indicates that this parameter depends exponentially on the distance between the reacting groups. The Franck–Condon factor depends on the overlap of the nuclear wave functions of the initial and final states, suitably weighted by the Boltzmann factor. This term includes effects of temperature and the free energy change of the reaction. Another parameter important to describe the electron transfer process is the reorganization energy λ, which can be considered to be the amount of energy required to distort the geometry of the reactants into that of the products without the electron transfer actually taking place. Three general regimes can be considered for the free energy dependence of the electron transfer rate constant, diagrammed schematically in Figure 13.[72]

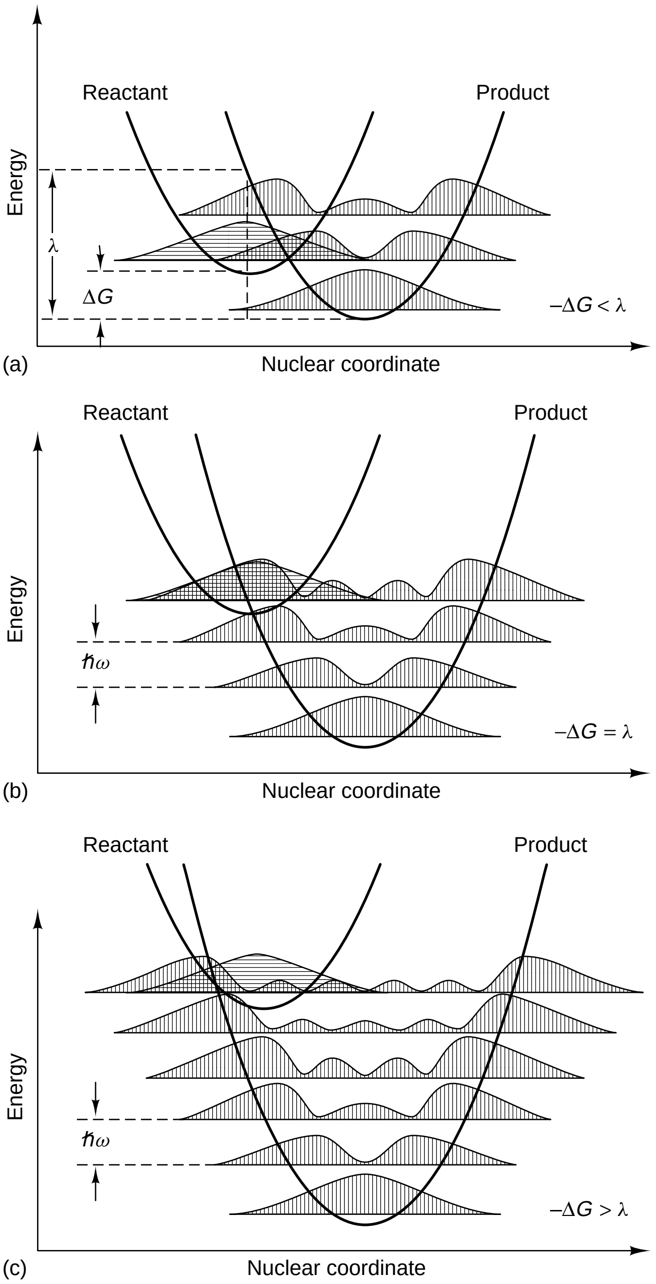

Figure 13 Potential energy surfaces for electron transfer reactions. Harmonic oscillator potential energy functions for reactants and product are shown, including the nuclear wave functions, which are shaded. The dark shaded region indicates the magnitude of overlap of the nuclear wave functions, which is the Franck–Condon factor. (a) is the ‘‘normal’’ region, (b) is the ‘‘activationless’’ region and (c) is the ‘‘inverted’’ region as defined in the text. (Ref. 72. Reproduced by permission of Nature Publishing Group. www.nature.com)

If $-\Delta G^{o} < \lambda$, the process exhibits normal activated behavior, illustrated by Figure 13(a). This is the case for endergonic to slightly exergonic reactions. If the reaction is significantly exergonic, so that $-\Delta G^{o} = \lambda$ then the potential energy curves for the reactants and products intersect near the bottom of the reactant potential well, and the reaction is in the ''activationless'' regime (Figure 13b). The Franck–Condon factor is at a maximum and the reaction is extremely fast with a very weak temperature dependence. Finally, for extremely exergonic reactions with $-\Delta G^{o} > \lambda$, the system is in the ''inverted'' regime, and the Franck–Condon factor and therefore the rate decreases again (Figure 13c).

The Marcus inverted region has been invoked as a major reason that the recombination reactions from the early charge-separated states in photosynthetic reaction centers are so slow compared to the forward reaction at the same point (Figure 11). This may indeed be the case, although many other factors are involved that have not been considered in this brief and oversimplified discussion. Readers should consult specialist reviews for more in-depth consideration of these issues.

5.3 Role of the Fe and Pathways of Proton Uptake

The nonheme Fe in the reaction center is centrally positioned between the two quinone molecules. It has a distorted octahedral geometry with four histidine nitrogen ligands and two oxygen ligands from a glutamic acid (Figure 14).[1] The Fe is low-spin Fe^{2+}, and exhibits no EPR spectrum unless one of the quinones is in the semiquinone state. Under these conditions, the Fe^{2+} and Q^{-} antiferromagnetically couple to give rise to a very broad EPR signal centered at $g = 1.8$. The magnetic and electronic properties of this Fe–quinone complex have been analyzed in detail by Feher and coworkers.[74]

The position of the Fe^{2+} between the two quinones has prompted suggestions that it may be directly involved in the electron transfer between the two quinones, or that the unpaired spins may somehow affect the electron transfer process. However, neither of these appear to be the case. Complexes in which the diamagnetic ion Zn^{2+} has been substituted for Fe^{2+} are essentially indistinguishable from the native complex in terms of electron transfer properties.[75] In addition, metal-free complexes still carry out the $Q_A^{-} \rightarrow Q_B$ reaction at nearly normal rates. In these latter complexes, the quantum yield of the formation of the Q_A^{-} state is reduced by approximately half, however.[76] It may be that the Fe^{2+} serves mainly a structural role to hold the two halves of the complex, as it is one of the few groups to be coordinated to both the L and M subunits.

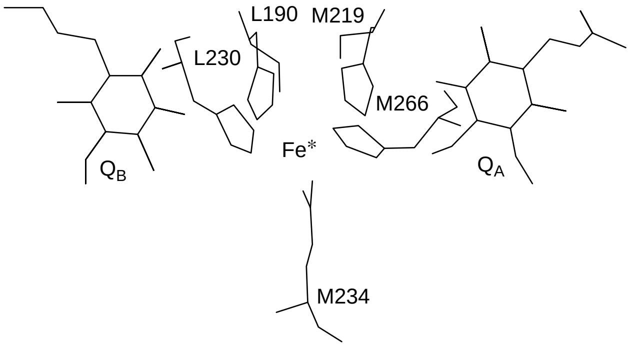

Figure 14 Structure of the photosynthetic reaction center from *Rhodobacter sphaeroides* in the region of the Fe^{2+} and quinones. The residue numbers refer to the L and M subunits of the reaction center

The photochemistry of the reaction center takes place one electron at a time. However, one of the products of the electron transfer process is a reduced ubiquinone, which has taken up two electrons as well as two protons. To form this species, the reaction center must turn over twice, with electrons entering the complex by donation of cytochrome c_2 with the oxidized special pair. The electrons accumulate in the quinone acceptors and protons are taken up from the surrounding medium. Finally, a fully reduced ubiquinol is formed, which is released from the complex into the hydrocarbon portion of the membrane. The quinol is subsequently reoxidized at the cytochrome bc_1 complex (described below).

A pathway of protonatable residues connects the Q_B binding site with the aqueous cytoplasmic compartment. The particular residues involved in the proton transport pathway have been identified in large part using site-directed mutants. Figure 15 shows the proposed pathway of H^{+} transfer in *Rhodobacter sphaeroides*.[77]

6 PHOTOSYSTEM I AND PHOTOSYSTEM II FROM OXYGEN-EVOLVING ORGANISMS

Only the cyanobacteria and prochlorophytes are capable of oxygenic photosynthesis. All other photosynthetic bacteria are anoxygenic. The oxygenic photosynthesis performed by algae and higher plants is essentially done by a endosymbiotic cyanobacteria. The membrane-bound proteins that perform photosynthesis are termed photosynthetic systems (or photosystems, (PS)). These photosystems are divided into groups depending upon their terminal electron acceptors. Type I reaction center (RC) complexes have high-potential Fe_4S_4– clusters as their terminal electron acceptors. This type includes PSs from anoxygenic heliobacter and green sulfur bacteria, as well as the PSI component of the oxygenic PS. Type II RCs have a quinone-type terminal electron acceptor. This type includes the RCs of green filamentous bacteria, purple bacteria, and the PSII component of oxygenic PS. All anoxygenic bacteria possess only one of either of these two types of RC, but oxygenic organisms use both PSI and PSII in concert and interdependently.

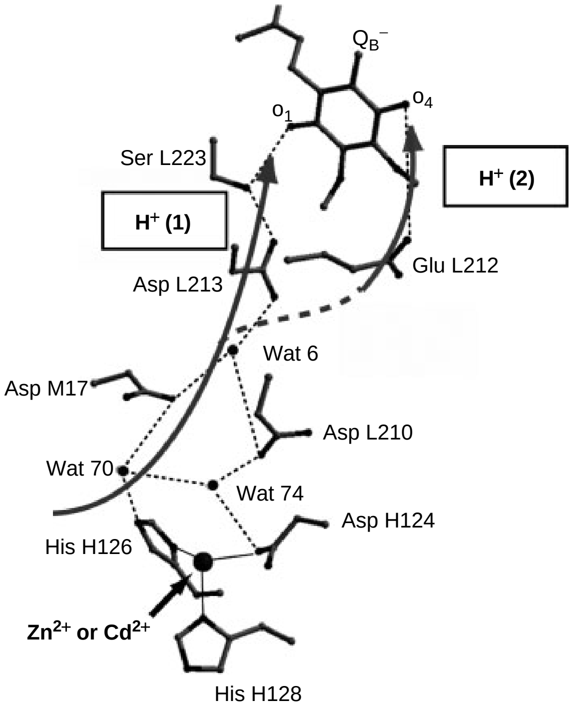

Figure 15 Pathway of H^+ uptake in *Rhodobacter sphaeroides*. The solid line is the pathway for the first H^+ to bind Q_B; the dashed line is the pathway to protonate the other oxygen by the second H^+. Binding of metal ions at the site indicated blocks proton transfer. (Reprinted from Okamura *et al*., *Biochim. et Biophys. Acta*, 2000, **1458**, 148. © 2000, with permission from Elsevier)

Type I and Type II RCs are related in sequence and structure, and they both possess a core (or internal) antenna system. One major difference between Type I and II RCs is that in Type II RCs the antenna proteins are separate peptide sequences, whereas in the Type I RCs the antenna peptide is fused to the core protein

All photosynthetic organisms that produce O_2 contain two photosystems connected in series, as shown in Figure 16. Four main protein complexes are embedded in the membrane, Photosystems I and II, the cytochrome b_6f complex and the ATP synthase or coupling factor. The two photosystems are entirely distinct entities, with different pigment and protein compositions and different genes coding for the proteins. All four of these complexes have been purified, extensively studied, and crystallized (see more below).

6.1 Structure and Mechanism of PSI[78,79]

In contrast to Photosystem II, which operates in a highly oxidizing regime, Photosystem I is much more reducing. The redox potentials of the early electron acceptors in Photosystem I are approximately -1 V, with the excited state of the photoactive chlorophyll P700, estimated to be -1.26 V (Table 3).

The crystal structure of photosystem I from the thermophilic cyanobacterium *Synechococcus elongatus* was published in June of 2001.[79] A cartoon diagram of PSI is shown in Figure 17(a). It was shown to be comprised of 12 protein subunits containing 127 cofactors comprising 96 chlorophylls, 2 phylloquinones, 3 Fe_4S_4 clusters, 22 carotenoids, 4 lipids, a putative Ca^{2+} ion and 201 water molecules. The crystal structure revealed PSI to be a trimer of multimers arranged in a cloverleaf pattern with a C3 axis of symmetry perpendicular to the membrane plane. PSI is comprised of nine protein subunits with transmembrane α-helices (PsaA, PsaB, PsaF, PsaI, PsaJ, PsaK, PsaL, PsaM and PsaX). On the stromal side are three subunits (PsaC, PsaD, PsaE). The core proteins PsaA and PsaB share sequence similarity to each other and to D1 and D2 proteins of PSII. The lumenal side of the PS is comprised largely of loops connecting the transmembrane helices, however there is a hollow near the center of the complex on the lumenal side that is believed to be the docking site for the electron carriers cytochrome c_6 and plastocyanin.

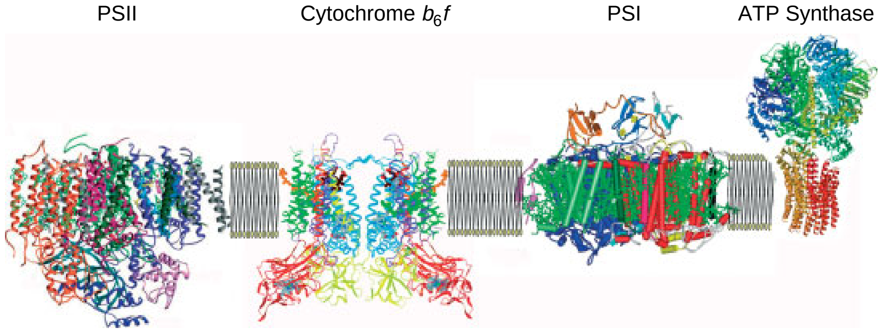

Figure 16 Membrane organization in oxygen-evolving photosynthetic systems. The four main complexes present in the membrane are (from left to right) Photosystem II, the Cytochrome b_6f complex, Photosystem I, and ATP synthase. All complexes now have published crystal structures, ribbon diagrams of which are shown in the Figure. Coordinates taken from the Protein Data Bank and visualized using Accelrys DSViewer Pro, or 2-D pictures were taken from the PDB website and modified

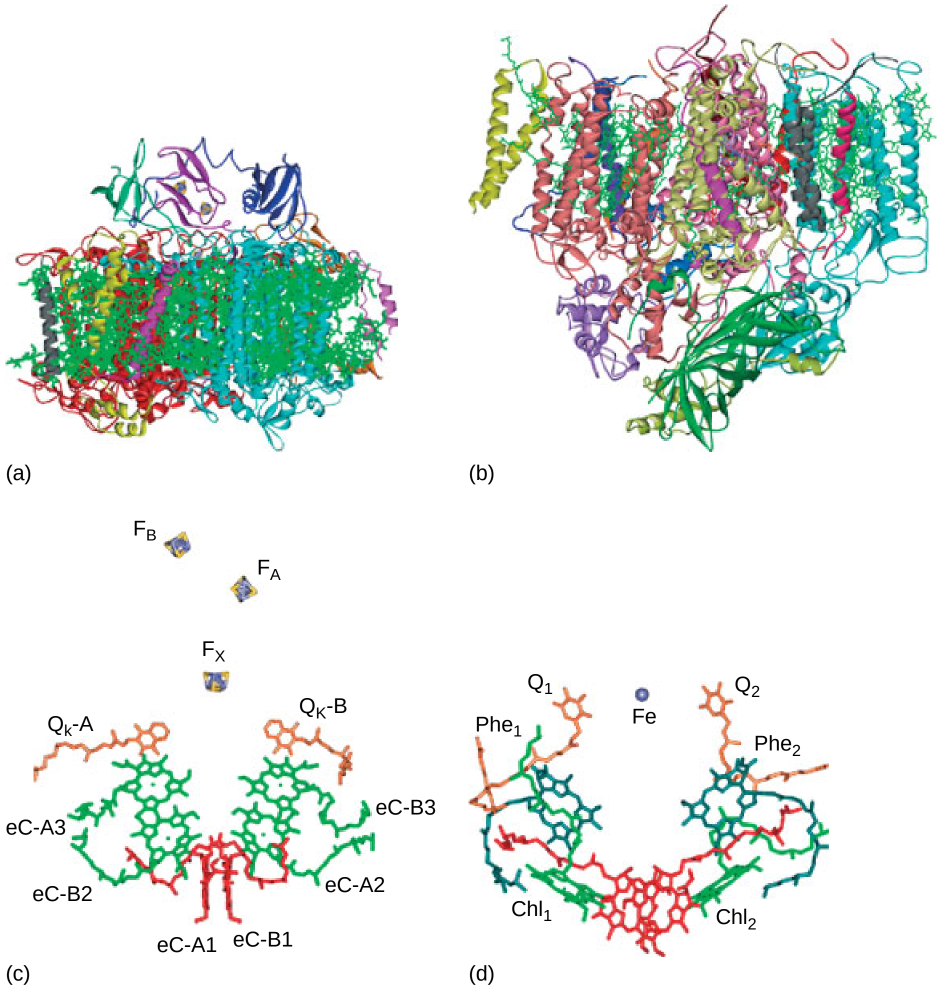

Figure 17 Crystal structures for (a) Photosystem I and (b) Photosystem II (code 1JB0 for PSI from the cyanobacterium *Thermosynechococcus elongatus*, and code 1S5L for PSII from *T. elongates*, respectively). Upper panel: Side views of the pigment-protein complexes in the reaction centers. Lower panel: cofactors of electron transfer in the reaction centers. Both models are shown at the same scale. A. For Photosystem I, PsaE is shown in green, PsaC in dark purple, PsaD in dark blue, PsaA in teal, PsaB in red. Other colored helices are from PsaK, M, F, J, L, and I. B. For Photosystem II, D1 and D2 are the core proteins of the Photosystem II reaction center. CP43 and CP47 are membrane-bound antenna complexes, MSP (dark green) is the ''Manganese Stabilizing Protein.'' C and D. Redox cofactors of electron transfer in two types of the photosynthetic reaction centers (c) The iron-sulfur (type I) RC. Two branches of potential electron carriers in the PSI include eC-A1-eC-B1, primary donor P700 (red); eC-A2 (eC-B2), accessory Chls; eC-A3 (eC-B3), primary acceptor A_0 and its symmetric counterpart; Q_K-A (Q_K-B), phylloquinones (secondary acceptors); F_x, F_A, F_B, iron-sulfur clusters (d) The two branches of the potential electron carriers in PSII. The branches include the primary donor P680 (red), accessory chlorophylls Chl_1 and Chl_2 (green), secondary acceptors pheophytin Phe_1 and Phe_2, and the quinones Q_1 and Q_2. The manganese cluster of the water-splitting protein is not shown. The coordinates were obtained from the Protein Data Bank and visualized using Accelrys DSViewer Pro

On the lumenal side, PsaC is shown to contain the two iron-sulfur clusters F_A and F_B. It also contains a putative binding site loop for interactions with ferredoxin or flavodoxin (the terminal electron acceptors). PsaD is primarily used for the proper positioning of the iron-sulfur clusters of PsaC with respect to F_x, as electrons must pass through F_x to F_A and then to F_B.

The electron transfer chain of PSI is shown in Figure 17(c). The primary electron transfer chain of PSI is split into two branches, as it is in PSII. The A branch contains the chlorophylls eC-A1, eC-B2, eC-A3 and phylloquinone QK-A, and the B branch contains chlorophylls eC-B1, eC-A2, eC-B3 and phylloquinone QK-B. There is a pair of chlorophylls (eC-A1 and eC-B1) that are parallel at a 3.6 Å interplanar distance and with a partial overlap of the chlorin rings. The Mg1-Mg2 distance is 6.3 Å. These two chlorophylls make up P700, the primary electron donor. Unlike the PbRCs, the pair of chlorophylls is not homodimeric. In RCI, eC-B2 is a chlorophyll *a*, but eC-A1 is a chlorophyll *a*', the $C13^2$ epimer of chlorophyll *a*. The asymmetry in P700 extends to the immediate binding pocket of the two chlorophylls, with eC-A1 being hydrogen bonded through water molecules to

transmembrane helices while eC-B1 has no hydrogen bonds. Hydrogen bonds generally increase the redox potential of the redox-active species the hydrogen bond contacts, therefore the $P700^+$ should be largely localized on the nonhydrogen bonded eC-B1. This has been confirmed to be true by ENDOR experiments.[80]

Before discussing the subject of which pathway the ejected electron from $P700^+$ follows, the general arrangement of the components of the pathway will be further discussed. The next pair of chlorophyll molecules in the pathway are labelled eC-A2 and eC-B2, although eC-B2 is closer to eC-A1, and eC-A2 is closer to eC-B1. Following these chlorophylls, are eC-A3 and Q_K-A in the eC-A1 pathway, and eC-B3 and Q_K-B in the eC-B1 pathway. One or both of the chlorophylls eC-A3 or eC-B3 may be the electron acceptor termed A_0 determined from picosecond transient absorption and ESR measurements. One or both of the phylloquinones (Q_K-A and Q_K-B) may represent the electron acceptor A_1 determined from nanosecond transient absorption spectroscopy. Following the phylloquinones, any electron travelling in either pathway must pass through the single Fe_4S_4 cluster F_x. From there, the electron passes through F_A to F_B and out of the RC to ferredoxin or flavodoxin.

At one time it was controversial as to whether both pathways of PSI were active. Subsequently, kinetic investigations have shown that the two sides of the pathway are active, but it was demonstrated that the rate of electron transfer from each pylloquinone to F_x was different ($35 \times 10^6 s^{-1}$ and $4.4 \times 10^6 s^{-1}$), but substantial. Mutational studies have shown the A branch is the slower one.[81–84] The asymmetry between the two pathways appears to be larger in cyanobacteria than in higher plant PSI.

PSI collects its energy through internal-antenna proteins, but ones that are fused with the core proteins, unlike those found in PSII. The N-terminal halves of PsaA and PsaB are similar to the PSII internal-antenna proteins CP43 and CP47. However, unlike in PSII there are a huge number of chlorophyll residues present in PSI. 90 Chl *a* and 22 carotenoid bind to the internal-antenna system of PSI, with 79 alone binding to PsaA and PsaB. The arrangement of the chlorophyll *a* molecules is generally like that found in PSII, in that they are stacked in two layers, one near the stromal side of the membrane and the other to the lumen side. The C-terminal domains of PsaA and PsaB cannot, unlike D1 and D2 of PSII, be considered pure RC domains, but rather RC/antenna hybrid domains.

The three Fe–S clusters have been studied extensively by EPR.[85,86] F_A has g values of 2.05, 1.94 and 1.86, F_B has values of 2.07, 1.92 and 1.89, and F_X2.04, 1.88 and 1.78. If both F_A and F_B are reduced at the same time, the clusters interact to give a composite spectrum with resonances at 2.05, 1.94, 1.92 and 1.89. When the electron transfer is interrupted, the recombination is from an earlier acceptor and is almost always faster than when a later acceptor is reduced.

6.2 Structure and Mechanism of Photosystem II[87–90]

Photosystem II is unique among photosynthetic reaction centers in that it has the capability to oxidize H_2O to O_2. This difficult chemistry is carried out in a Mn-containing complex, which accumulates four oxidizing equivalents from four photochemical turnovers of the photoactive pigments. The oxygen evolution system is described in detail in ***Manganese: The Oxygen-evolving Complex & Models***, so is not considered here. The redox potential of the oxidized reaction center photoactive pigment, $P680^+$, is not known precisely, but has been estimated to be approximately +1.1 V (Figure 6 and Table 3). These reaction centers are considerably more complicated than those found in purple bacteria, and include nearly two dozen distinct proteins, some of which are integral to the membrane, while others are associated on one side or the other of the membrane.

The 3.8 Å resolution X-ray crystal structure of Photosystem II from the thermophilic cyanobacterium *Thermosynechococcus elongatus* (formerly *Synechococcus elongatus*) was published in February 2001,[87] additional structures at higher resolution and with better crystallographic parameters were later published.[90] The most recent PSII structure is shown in Figure 17(b).

The crystals of PSII used were able to perform water oxidation, so it is assumed that the PSII was in the active and correct form. PSII from *Se* is comprised of 36 transmembrane helices, with 22 of them assigned to the PSII proteins CP47, CP43, D1 and D2. The remaining come from the low-molecular-mass subunits, which include the α and β subunits of cytochrome *b*-559. Extrinsic proteins evident in the crystal structure but not well defined were the 33 kDa protein and cytochrome *c*-550. The arrangement of the α helices D1 and D2 in PSII from *Se* resembles that of subunits L and M in the published structure of the purple bacterial reaction center and the five carboxy-terminal helices of PsaA and PsaB from photosystem I (PSI). CP47 and CP43 consist of six transmembrane α-helices arranged in trimers of dimers. They are structurally similar to the six amino-terminal transmembrane portions of PsaA an PsaB. D1 and D2 form a dimer at the reaction center core. The oxygen-evolving complex is bound to D1. CP43 and CP47 are related by pseudo-C2 symmetry and are present on opposite sides of the D1/D2 core. Other subunits present in the structure are largely present for their stabilizing effects and include the transmembrane α-helical proteins PsbI, PsbX, PsbH, PsbK, PsbL.

The internal-antenna proteins CP43 and CP47 contain 12 and 14 chlorophyll *a*, respectively, which are largely found in two layers near the stromal and lumenal ends of the transmembrane α-helices. Figure 17(d) shows the doubly branching electron transfer pathway of PSII. At the center of the D1/D2 dimeric interface lie two chlorophyll *a* molecules (PD1 and PD2) with Mg-Mg distance of 10 Å, the planes of which are aligned in parallel, with an interplanar distance of 5 Å. These probably represent P680. Since they are relatively

far apart, in comparison to PSI or the purple bacteria reaction center, they would not be called a special pair *per se*, and do not have the strongest of excitonic coupling. On either side of this pair and located at distances of 9.8 Å and 10 Å, respectively, from P_{D1} and P_{D2}, are two chlorophyll molecules (Chl_{D1} and Chl_{D2}) that form the first link in the bifurcating electron transfer chain. These are followed by two pheophytin molecules, and then bound quinone molecules (Q_A and Q_B, although in the crystal structure the mobile Q_B site was unoccupied). The Q_A site is occupied by a tightly bound plastoquinone molecule. The role of the nonheme iron molecule present in the structure is probably for stabilization. The nonheme iron perturbs the EPR spectra of Q_A^- and Q_B^- in a manner very similar to that observed in the bacterial system.

The mechanism of transfer of electrons out of PSII is as follows: ejection of an electron from the excited primary donor P680 produces a cationic radical $P680^+$. The ejected electron passes probably through Chl_{D1}, through pheophytin to the electron acceptor Q_A that is tightly bound at the stromal side of subunit D2, which accumulates two electrons. Four successive light-induced charge separating steps occur on P680, and after each charge separation event, $P680^+$ abstracts an electron from the nearby manganese cluster (described in greater detail in *see* ***Manganese: The Oxygen-evolving Complex & Models***) through the redox-active tyrosine residue labelled TyrZ (Tyr 161 of D1). After two charge separations, the now doubly reduced Q_A doubly reduces the dissociable Q_B bound in its binding site on D1. Q_BH_2 dissociates and drifts off into the membrane plastoquinone pool, to be replaced a new oxidized Q_B.[87,90] The four positive charges accumulated on the manganese cluster are used to oxidize two water molecules, producing O_2 and four H^+.

The similarity between Photosystem II and the purple bacterial reaction center breaks down on the oxidizing or donor side, as the bacterial complex does not evolve oxygen. Another aspect of Photosystem II that is unique among all photosynthetic reaction centers is the involvement of redox-active amino acids in the main path of electron transfer.[91] A tyrosine residue (almost certainly a tyrosinate ion) is the immediate electron donor to $P680^+$, the oxidized photoactive pigment in Photosystem II, donating an electron in tens to hundreds of nanoseconds. The neutral tyrosine radical formed by electron donation to $P680^+$ then extracts an electron from the Mn-containing complex in hundreds of microseconds to milliseconds, depending on how many oxidizing equivalents have previously been accumulated in the Mn complex. This radical species is therefore only observed transiently. A second tyrosine radical is also found in the Photosystem II complex. This radical is stable and is clearly not involved in mainstream electron transfer from H_2O to P680, and its function is not well understood. The tyrosine that gives rise to this radical is in a symmetry-related position to the tyrosine that is active in the normal pathway of electron flow, based on the proposed structures of Photosystem II.

Even though the two photosystems are functionally connected, they are not physically associated, and a variety of evidence indicates that they are predominantly found in different regions of the membrane. Photosystem II is located primarily in the stacked grana regions of the thylakoid membranes (Figure 1), while Photosystem I is found in the unstacked stroma membrane regions and at the edges or margins of the stacks. This places the two photosystems up to several hundred angstroms apart and requires that diffusible electron transfer intermediates couple them together. A large freely diffusible pool of plastoquinone is present within the membrane. Plastoquinone is reduced by Photosystem II and oxidized by the cytochrome b_6f complex, and is clearly involved in the coupling of the two photosystems, although it is probably not the only species involved. Another diffusible species is the blue copper protein plastocyanin,[92–95] which is located in the aqueous space inside the thylakoid membrane. There is evidence that plastocyanin also has substantial lateral mobility, connecting complexes that are physically quite distant. The fact that the two photosystems are spatially separated and that freely diffusible intermediates connect them suggests that there is not a one-to-one coupling of photosystems, in which a particular Photosystem II always reacts with a particular Photosystem I. Instead, reducing equivalents are deposited into a common pool by Photosystem II and withdrawn from the pool by Photosystem I. This arrangement does not require that the stoichiometries of the two photosystems be the same, and indeed the ratio of the abundance of photosystems is somewhat variable, depending on light intensity and light quality, or the spectral distribution of light.

A number of other electron carriers are present in various photosynthetic systems. These include soluble carriers such as the blue copper protein plastocyanin and auracyanin[96–99] (*see* ***Copper Proteins with Type 1 Sites***) and soluble cytochromes and ferredoxins (*see* ***Iron–Sulfur Proteins***), as well as additional membrane-bound complexes. The membrane-bound multisubunit cytochrome b_6f complex is discussed is Section 7.

6.3 Photosystems from Other Organisms

The photosystems found in some types of non-oxygen-evolving bacteria are structurally and functionally analogous to Photosystem I in the same way that the reaction centers from purple bacteria are analogous to Photosystem II.[1,5,67,100–103] These bacterial species include the green sulfur bacteria and the heliobacteria. Study of these systems may help to understand certain aspects of the structure and function of Photosystem I, as well as the evolution of photosynthetic reaction centers. Interestingly, in these systems the reaction center core appears to consist of a homodimeric complex instead of the heterodimeric protein complexes found in all other photosystems.[101,103] This might possibly represent a more primitive arrangement.

7 CYTOCHROME *bc* AND *bf* COMPLEXES

7.1 Structure and Mechanism of the Cytochrome bc_1 Complex[104–108]

As part of the cyclic electron flow of the photosystems of anoxygenic purple bacteria, cytochrome bc_1 is used. It is also a component of the eukaryotic (mitochondrial), and bacterial respiratory chain. In cyanobacteria and higher plants (chloroplasts), cytochrome bc_1 is replaced in the photosynthetic electron transfer chain with the analogous protein complex, cytochrome b_6f (see later). The cytochrome bc_1 complex is comprised of, minimally, three protein subunits: cytochrome *b*, cytochrome c_1, and a ''Rieske'' iron-sulfur protein (*see* ***Iron–Sulfur Proteins***). Additional subunits are found in some organisms, and in some cases the function of these subunits are not known. A schematic diagram of the catalytic core of the cytochrome bc_1 from bovine heart mitochondria is shown in Figure 18.[1] The structure of the complex from purple bacteria has a similar core structure. The cytochrome b portion of the complex was shown to be an integral membrane protein with 8 transmembrane helices. Cytochrome b binds two heme b cofactors, one near the periplasmic side of the inner membrane and the other near the cytoplasmic side. The heme near the periplasmic side has a relatively low redox potential of −100 mV and is thus termed ''b_L'', whereas the other has a potential of +50 mV and is termed ''b_H.'' The main function of cytochrome bc_1 in the cell is to participate in the so-called ''Q-cycle'' (to be described later). Within cytochrome *b* are two binding sites for ubiquinone/ubiquinol. The site of quinol oxidation is near b_L and is labelled Q_o, while the other binding site is that of quinone reduction, and is near b_H. It is labelled the Q_i site (for ''internal''). On the periplasmic side of the membrane, and anchored by a single N-terminal transmembrane α-helix, is the Rieske Iron-Sulfur Protein (ISP). A flexible loop connects the transmembrane helix of ISP to the periplasmic domain. Within the periplasmic domain is a single uniquely liganded Fe_2S_2 cluster. The cluster is unusual in that one iron is liganded by histidine residues, while the other is liganded by cysteine residues. Typically Fe_2S_2 clusters are liganded by four cysteine residues. This arrangement makes the histidine-liganded iron much more easily reduced, and localizes the reducing equivalents on that iron when reduced. The result is the raising of the cluster redox potential to +280 mV, a much higher value than cysteine-only liganded clusters.

Cytochrome bc_1 makes use of a modified Q-cycle, as shown overlaying the schematic in Figure 18. In this scheme, two molecules of ubiquinone are oxidized per one reduced. The net effect is the production of a proton gradient across the inner membrane. The reaction mechanism of this is described as follows:

(1) One ubiquinol molecule binds to the Q_o site and an electron is transferred to the nearby Rieske ISP, while a proton is released to the periplasm.

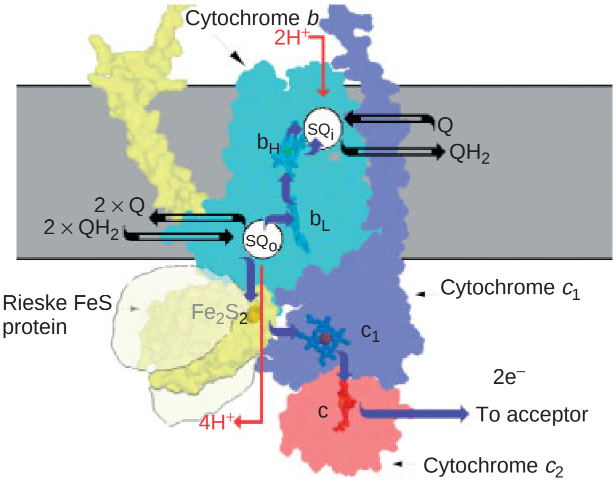

Figure 18 Schematic structure of the cytochrome bc_1 complex from mitochondria. The structure of the complex from purple photosynthetic bacteria is thought to be similar. The pathway of electron and proton transfer (modified Q-cycle) is overlaid on the schematic structure. Movement of the Rieske FeS protein is shown by the semitransparent yellow areas[1]

(2) The electron from the resultant ubisemiquinone is released to b_L, with the concurrent release of another proton to the periplasm. The electron is then transferred to b_H.

(3) There is a large movement of the Rieske ISP towards the cytochrome c_1, such that the Fe_2S_2 cluster is moved 20 Å closer to the heme cofactor.

(4) A ubiquinone molecule binds to site Q_i and is reduced to the semiubiquinone state by the now reduced b_H.

(5) The now oxidized ubiquinone at the Q_o site is released to the intermembrane space.

(6) The movement of the Rieske protein allows for the transfer of one electron to heme c_1, and subsequently to the soluble electron carrier cytochrome c_2, which is docked on the cytochrome c_1.

(7) A new ubiquinol molecule binds to the Q_o site and follows the same oxidation as the first molecule. This also results in two more protons being released to the periplasmic space.

(8) The now reduced b_H reduces the ubisemiquinone at the Q_i site, and two protons are taken up to produce a ubiquinol on the cytoplasmic side. There is thus a net uptake of two protons from the cytoplasm, and a net release of four protons to the periplasm, resulting in an overall net pumping of two protons from the cytoplasm to the periplasm. This results in a proton gradient, a protonmotive force, across the inner membrane, which is utilized by ATPase to synthesize ATP from ADP.

The hinge action of the Rieske ISP serves as a gating mechanism, preventing the double transfer of electrons through cytochrome c_1 to cytochrome c_2, which would short

circuit the whole process described above (resulting in no net protonmotive force being established).[1]

7.2 Structure and Mechanism of Cytochrome b_6f [109–112]

Cytochrome b_6f is used in place of cytochrome bc_1 in cyanobacteria and chloroplasts. Light energy utilized by PSII results in plastoquinol production from plastoquinone. Reducing equivalents carried by the plastoquinol are then transferred across b_6f, through cytochromes bound to b_6f, to plastocyanin or cytochrome c_6. Reduced plastocyanin or cytochrome c_6 is then used to rereduce PSI. The crystal structure of cytochrome b_6f at 3.0 Å resolution is shown in Figure 19. Cytochrome b_6f is a dimer of multimers. Cytochrome b_6f contains four large subunits. Cytochrome b_6 is a transmembrane helical protein that binds two cytochrome b hemes. It is homologous to the N-terminal domain of cytochrome b of the cytochrome bc_1 complex. The Rieske Iron-Sulfur Protein is similar to that found in cytochrome bc_1, with a helical tether connected through a flexible loop to a lumen domain. The helical tether of one multimer extends into the other multimer, serving to unify the complex. It contains a Fe_2S_2 cluster that is liganded with two cysteines and two histidines. Subunit IV is also a transmembrane helical protein, and is homologous to the C-terminal domain of cytochrome b of the cytochrome bc_1 complex. Cytochrome f is analogous to cytochrome c_1 of cytochrome bc_1, but is unrelated by

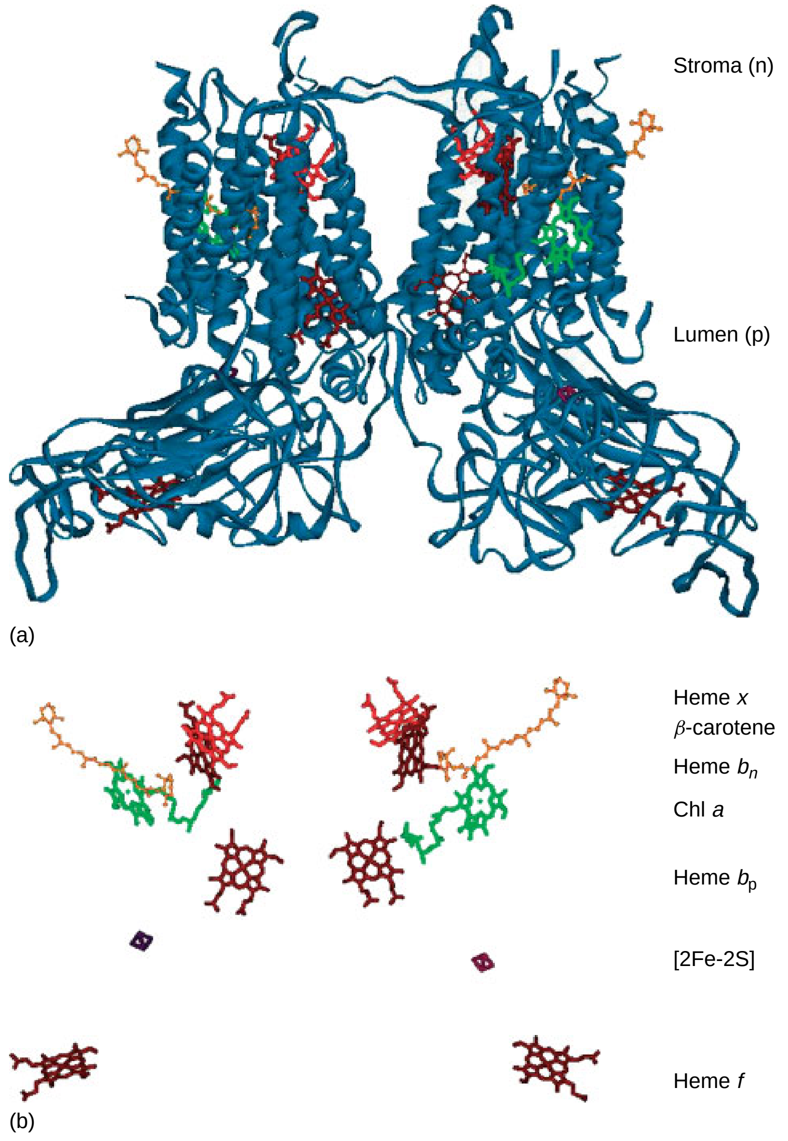

Figure 19 (a) Crystal structure of the cytochrome b_6f complex from *Mastigocladus laminosus* at 3.0 Å resolution. The coordinates were obtained from the Protein Data Bank and visualized using accelrys DSViewer Pro. (b) The electron and proton transfer chain of cytochrome b_6f with the protein stripped away

homology or structure. The heme of cytochrome f maps to 12 Å different position versus the heme of cytochrome c_1, both relative to the heme b position. Cytochrome f has two extrinsic domains. A large domain has a position analogous to the bc_1 extrinsic cytochrome c_1 domain. The small domain of cytochrome f maps to a position occupied by subunit 8 in bc_1. Cytochrome f also does not have the intermonomer contacts that cytochrome c_1 has. There are also four small transmembrane helical subunits (PetG, PetL, PetM, and PetN), which serve to stabilize the complex and generally form a ring around the inner subunits.[109]

Some of the structural elements of the cofactors are described below. A chlorophyll a molecule is bound between helices F and G of subunit IV with no direct protein-Mg bonds. The function of this chlorophyll is not known. The 9-cis-β-carotene is inserted near the center of transmembrane region between PetL and PetM. It is 14 Å from chlorophyll a, and thus cannot be there to quench the chlorophyll excited triplet state. The roles of these two elements are uncertain. As shown in Figure 19(b), two hemes (b_n and b_p, near the stromal and lumen sides of the membrane, respectively) are bound in cytochrome b_6. These are both bis-histidine liganded and are in analogous positions to heme b_L and b_H of the cytochrome bc_1 complex. One major surprise in the crystal structure is the presence of a hitherto unknown and unreported heme. This heme is not, based upon density maps, a member of any known heme family, and it is thus termed ''heme x.'' The heme is covalently linked through a thioether bond to cysteine 35, but there are no protein ligands to the iron. Rather, the iron is liganded to a water molecule that is hydrogen bonded to the propionate side chain of heme b_n and to the backbone amide of invarient Gly38 of cytochrome b_6. It is thought that heme x is a universal feature of cytochrome b_6f from other organisms because many residues in the binding pocket (both from subunit IV and cytochrome b_6) are invariant amongst different organisms based upon sequence comparisons. That the heme x and heme b_n are perpendicular to each other and in contact implies that electron flow through heme x is important. Heme x is located at the same position as the n-side ubiquinone and antimycin A binding site in the bc_1 complex. This is then why no inhibitors of n-side electron transfer in the cytochrome b_6f complex have been identified that are similar to antimycin. However, the exact role of heme x is unclear.[109]

In the crystal structure, an endogenous plastoquinone is found bound at the n side of each central cavity adjacent to heme x, clearly identifying it as the Q_n site. The Q_p site is inferred from structural elements and because in some crystals a quinone mimick is bound at the roof of the central cavity at the putative Q_p site. The mechanism of quinone oxidation and reduction is generally similar to that of cytochrome bc_1 (see above). As in cytochrome bc_1, it is probably necessary for the Rieske ISP lumen domain to rotate back and forth during turnover to gate electron flow.

As for the mechanism of the Q-cycle, the overall stoichiometry of protons translocated across the membrane to electrons is 2:1, rather than the 1:1 that would be predicted by a simple mechanism in which the quinone was reduced on one side of the membrane, picking up protons from the aqueous environment and then oxidized near the other side of the membrane, liberating the protons to the aqueous phase on the other side. A variety of evidence indicates that the two electrons that come from oxidation of a quinol do not follow the same pathway. One reduces the Rieske protein and then is transferred to cytochrome c_1, next to cytochrome c_2, and eventually rereduces the oxidized reaction center special pair. The other electron reduces the lower potential heme b, then the higher potential heme b. After two quinol oxidations, the electrons that went through the hemes b reduce an oxidized quinone at the quinone reducing site, in the process picking up two additional protons on the cytoplasmic side of the membrane. The net reaction is that for every two electrons that go through the Rieske protein branch, two quinols are oxidized and one is reduced. In the process, four protons are liberated to the periplasmic side of the membrane. The energy generated by the proton gradient, as well as an electrical potential gradient created by the electrogenic electron flow across the membrane through the b hemes, is then utilized to make ATP. This is thought to take place by a chemiosmotic mechanism, first proposed by Mitchell.

1 INTRODUCING CISPLATIN[1]

Cancer is one of the major causes of death in the western world. It refers to approximately 150 diseases that exhibit some common characteristics: an uncontrolled growth of cells and the ability to invade and damage normal tissues either locally, or at distant sites in the body. Nowadays, three classical approaches exist to treat cancer: surgical excision, irradiation, and chemotherapy. The role of each depends on the type of cancer and its development stage.

cis-Diamminedichloroplatinum(II) (**1**, Figure 1), generally referred to as cisplatin, is widely used as a chemotherapeutic agent. Its anticancer properties remained unnoticed until 1964, when Barnett Rosenberg investigated the effects of electric fields on the growth of *Escherichia coli* bacteria. He observed a strong filamentous growth, but an arrest of cell division. Rosenberg and coworkers subsequently found that the electric field was not responsible for the cell division arrest, but that this effect had to be attributed to traces of platinum compounds such as *cis*-$Pt(NH_3)_2Cl_2$ and *cis*-$Pt(NH_3)_2Cl_4$. These compounds were formed by the slow reaction of the platinum electrodes with the electrolyte NH_4Cl solution. Soon a number of compounds were tested, and only the ones having cis geometry were found to block cell growth. The most active complex, cisplatin, was found to have antitumor activity, while its trans isomer (transplatin, **2**) did not show antitumor activity.

After this serendipitous discovery, clinical trials were performed to investigate the efficacy of cisplatin against a variety of solid tumors. Cisplatin entered Phase I clinical trials in 1971, was approved by the U.S. FDA in 1978, and was developed into one of the most widely used drugs in cancer chemotherapy. Cisplatin is especially effective against solid tumor types, such as testicular, ovarian, head and neck, and small-cell lung cancer.[2] For testicular cancer, when recognized in an early stage, curing rates exceed 90%.

2 MECHANISM OF ACTION OF CISPLATIN

2.1 Introduction

The activity of cisplatin is generally accepted to originate from its binding to DNA.[3] Most conclusive evidence for this is the observation that cells deficient in DNA-repair ability are hypersensitive to cisplatin. Cisplatin and other platinum drugs are thus categorized as DNA-binding drugs. A molecule bound to DNA may interfere with transcription and/or DNA replication mechanisms, triggering processes, such as apoptosis, that lead to cell death.

2.2 Cellular Uptake of Cisplatin

Cisplatin is administered by intravenous injection. In blood and extracellular body fluids, the physiological chloride concentration is about 100 mM, which strongly suppresses cisplatin hydrolysis. Thus, cisplatin reaches the outer surface of cancer cells mainly as a neutral molecule. The precise mechanism of cellular uptake of cisplatin remains unclear. However, it is generally believed that passive diffusion is the main mechanism, although some evidence supports the involvement of active transport mechanisms.[4] After entering the cell, the chloride concentration drops to 4 mM and hydrolysis of cisplatin takes place. Although various hydrolysis products may form, the predominant species is the $[PtCl(H_2O)(NH_3)_2]^+$ cation,[5] which is in equilibrium with its deprotonated form $[PtCl(OH)(NH_3)_2]$. Since water is a far better leaving group than hydroxide or chloride, the cationic aqua form is the species that is most likely to react with DNA and other molecules in the cell. Inside the cell, many competitors for DNA binding are present.[6] Alternative targets include phospholipids and phosphatidylserine in the membrane, and RNA and sulfur-containing proteins in the cytosol.

2.3 Formation of Cisplatin-DNA Adducts

A schematic structure of a single-stranded DNA fragment with the four common nucleobases is depicted in Figure 2. Platinum is a soft metal and therefore coordinates preferentially to the N atoms in DNA. At physiological pH, the N3 atoms of thymine are protonated, the N3 of purines are sterically hindered, and aromatic sites without a σ-lone pair are also excluded from platinum coordination. Four binding sites are left for platination: the N7 atoms of guanine and adenine, the N1 of adenine, and the N3 of cytosine. All four can be platinated, but the first binding step shows a strong preference for the N7 atom of guanine.[7] This preference can be explained by its strong basicity, and by the possibility of hydrogen bonding between ammine protons of cisplatin with the O6 atom of guanine (during the approach and also after binding).

Following activation via intracellular aquation reactions, cisplatin forms a variety of stable bifunctional adducts with DNA, as depicted in Figure 3. Cisplatin mainly forms 1,2-intrastrand cross-links on adjacent purine bases. It has been found that 60–65% of the platinum bound to DNA is in the form of 1,2-d(GG) intrastrand cross-links and 20–25% in intrastrand 1,2-d(AG) cross-links.[8,9] Other adducts formed are the 1,3-d(GXG) and 1,4-d(GXXG) cross-links, accounting for at most 6%. Only a small percentage of cisplatin (1.5%) was found to be involved in interstrand adducts. It remains

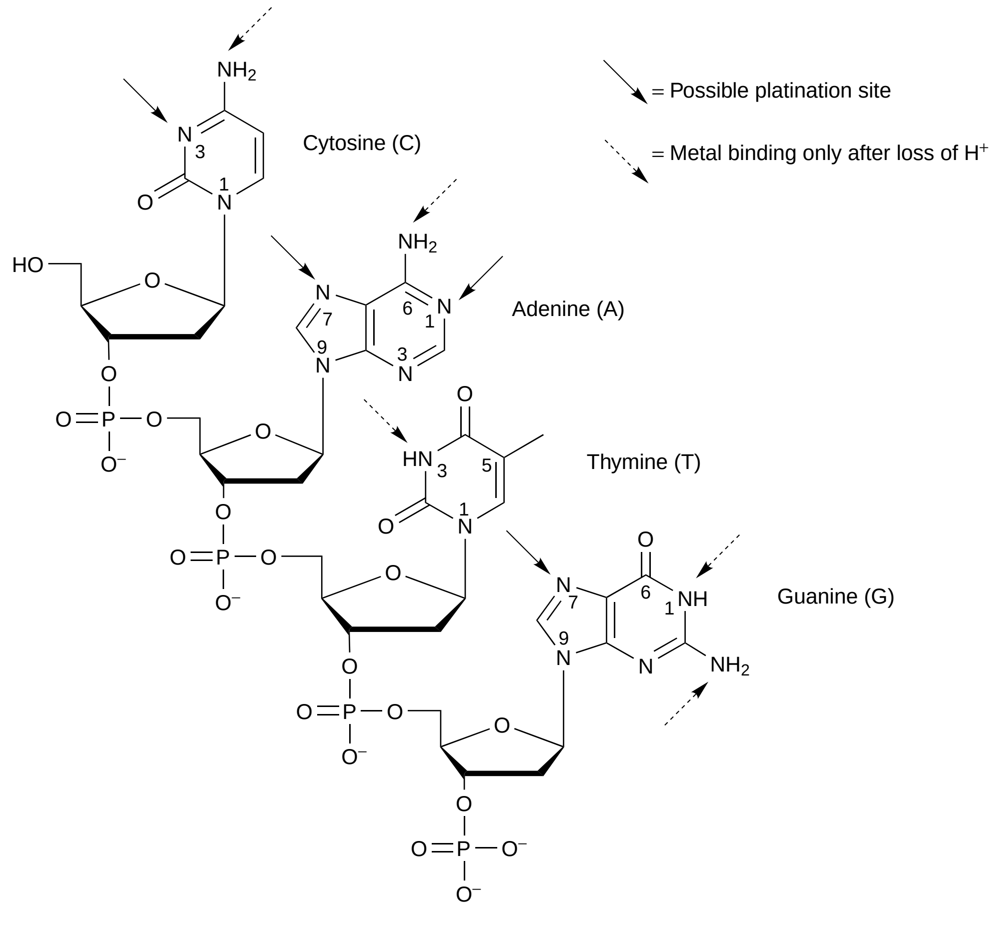

Figure 2 Possible platinum binding sites on DNA bases

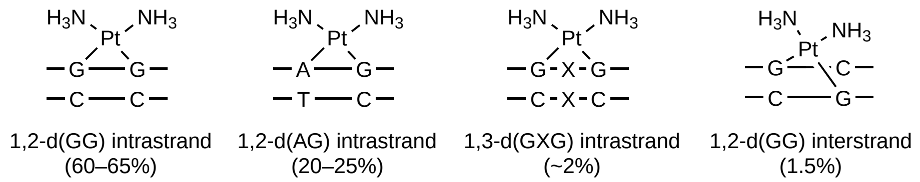

Figure 3 Various types of cisplatin-DNA adducts and their frequency

unclear which of the above described platinum-DNA adducts are responsible for the cytotoxic effect. Because of the high prevalence of the 1,2-intrastrand adduct and the inability of the inactive transplatin to form this cross-link, a pivotal role has been suggested for the 1,2-d(GG) adduct. This assumption is supported by the finding that nucleotide excision repair (NER), an important DNA-repair system, repairs 1,3-intrastrand adducts more efficiently than 1,2-intrastrand adducts, while the 1,2-d(GG) adducts are repaired the least effectively. However, the minor adducts have been suggested to play an important role as well.[8]

2.4 3-D Structure of the Major Cisplatin-DNA Adduct

The binding of cisplatin to DNA induces structural distortions in the double helix. The structural features of DNA oligomers containing the 1,2-d(GG)-cisplatin adduct have been studied using X-ray crystallography and NMR spectroscopy.[3,4] In a recent theoretical study, many similarities in the structures of various 1,2-intrastrand adducts have been discussed.[10] Common distortions that are found are the kinking of the helical axis toward the major groove (55–79°) and the partial unwinding (∼20°) of the double helix. An example of an NMR solution structure is given in Figure 4.

2.5 Protein Recognition of Cisplatin-DNA Adducts[3,9]

The altered structure of the DNA duplex attracts proteins involved in DNA damage recognition and high-mobility group domain (HMG) proteins, which have been postulated to mediate the antitumor activity of cisplatin.

Cells deficient in DNA repair are hypersensitive to cisplatin and some cisplatin-resistant cell lines show increased DNA repair and increased expression of the DNA. Platinum-induced DNA lesions are primarily repaired by the NER system. This system involves more than 20 proteins responsible for damage recognition, incision of the DNA strand on both sides of the lesion, removal of the damaged bases, and finally ligation by a DNA ligase.

A different class of proteins that specifically recognize cisplatin-damaged DNA is the so-called HMG proteins. The HMG domain is a DNA-binding motif that comprises about 80 amino acids. This domain is found in a variety of chromosomal proteins and transcription factors. Binding to DNA is associated with recognition of structural distortion of the DNA helix. Several HMG domain proteins have been shown to selectively bind to 1,2-d(GG) and 1,2-d(AG), but not to the less kinked 1,3-d(GXG) adducts. A crystal structure of a cisplatin-1,2-d(GG) adduct in an oligonucleotide complexed with a HMG domain has been reported and is schematically depicted in Figure 5.[12] Binding of HMG proteins to damaged DNA has been suggested to shield the platinum-DNA complex from repair enzymes, thus enhancing the cytotoxicity of cisplatin. Another hypothesis for the role of HMG proteins in the mechanism of cisplatin is that Pt-DNA adducts highjack proteins away from their normal binding sites, thus disturbing normal DNA transcription. These two mechanisms are not mutually exclusive and might mediate cisplatin's activity altogether.

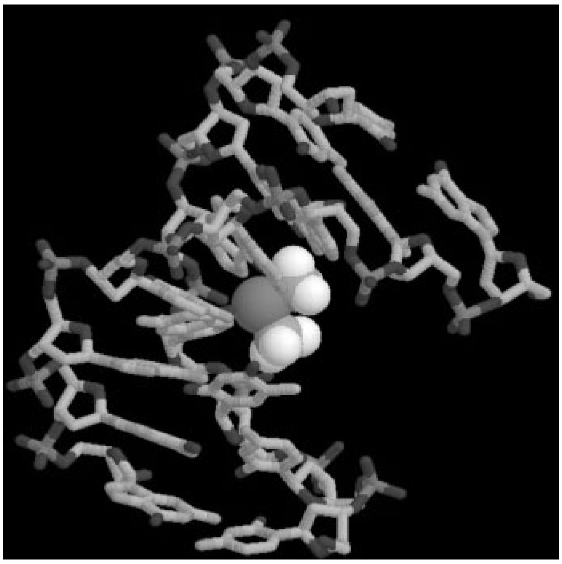

Figure 4 NMR solution structure of d(CCTG*G*TCC)·d(GGA CCAGG) with the cisplatin 1,2-(GG) intrastrand cross-link showing bending of the double helix toward the major groove.[11]

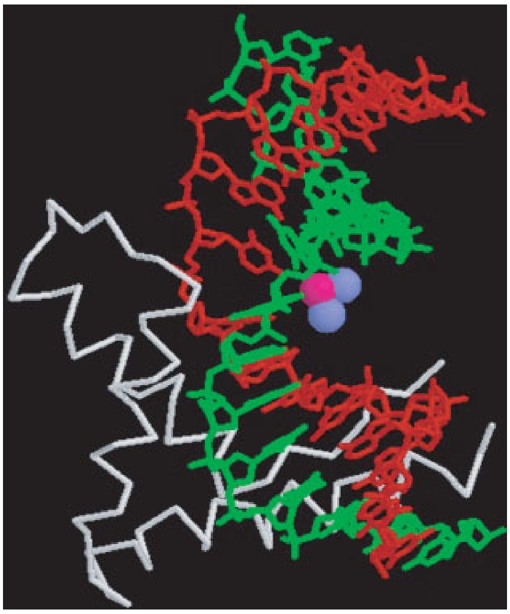

Figure 5 Schematic X-ray structure of the complex of HMG1 domain A with a 1,2-d(GG) intrastrand adduct of cisplatin with d(CCTCTCTG*G*ACCTTCC)·d(GGAAGGTCCAGAGAGG)[12]

3 PROBLEMS WITH CISPLATIN

There are some serious drawbacks to the use of cisplatin in anticancer therapy. Severe toxicity problems occur, such as failure of the kidneys and bone marrow (nephrotoxicity and hematoxicity), nausea, intractable vomiting (emesis), peripheral neuropathy, deafness (ototoxicity), and seizures.[13] These toxic side effects of cisplatin limit the dose that can be administered to patients; typical doses are 100 mg day^{-1} for up to five consecutive days.[14] The nephrotoxicity can be reduced by hydration and diuresis. 5-HT3-receptor blockers control nausea and emesis. Much effort has been devoted to the development of chemoprotective agents, which alleviate the side effects on normal tissues without compromising antitumor activity – mainly sulfur-containing agents such as sodium dithiocarbamate (Naddtc), 2-mercaptoethanesulphonate (mesna), and amifostine (WR-2721). Amifostine has recently been approved for coadministration with cisplatin, which reduces nephro- and neurotoxicity.[13]

The major clinical problem encountered is the resistance against cisplatin. Some types of cancer are intrinsically insensitive to cisplatin treatment, whereas other cancers develop resistance during chemotherapy. This phenomenon limits the applicability of cisplatin to a relatively narrow range of tumors. The cisplatin-resistance mechanism seems to be multifactorial. Several main factors have been identified as potential modulators of cellular resistance, and are discussed below.

Decreased uptake leads to lower intracellular drug concentrations. In many cisplatin-resistant cell lines, reduced accumulation was observed.[4,8] The cisplatin membrane transport system is poorly understood, but studies on cisplatin-resistant cells with decreased drug accumulation have identified two membrane proteins that may be involved in uptake and efflux respectively: a 48-kDa protein with decreased expression and a 200-kDa glycoprotein with increased expression.

Another mechanism is increased intracellular detoxification. Cisplatin is scavenged by intracellular thiol-containing molecules, especially glutathione (GSH), which is present in cells at high concentrations (0.5–10 mM).[15] Glutathione reacts with platinum drugs to form deactivated conjugates, which are readily excreted by a glutathione S-conjugate export pump.[8] Raised intracellular concentrations of GSH often correlate with cisplatin resistance. Another intracellular thiol that could play a role is metallothionein. This protein consists of 62 aminoacids, 20 of which are cysteine, and is presumed to take part in the detoxification of heavy metal ions in cells. Thiol-containing biomolecules have primarily been associated with resistance and toxicity, however, it has been suggested that cisplatin binding to GSH may serve as a drug reservoir modulating the kinetics of DNA platination.[15]

Increased DNA repair was observed in some cisplatin-resistant cell lines.[8] For the 1,2-intrastrand adducts of cisplatin, the NER system is of particular importance. It has been shown that several DNA-repair proteins such as the Xeroderma Pigmentosum Group A (XPA) protein, which is involved in damage recognition in NER, can be overexpressed in resistant cell lines, resulting in efficient repair and therefore reduced toxicity.

Enhanced tolerance to DNA adducts has been found in some cisplatin-resistant cells.[13] Mechanisms that are involved are enhanced postreplicative bypass – the ability of the replication complex to synthesize DNA downstream a cisplatin-induced lesion – and defects in the repair process named mismatch repair (MMR).

Another mechanism of resistance that has recently been suggested is the failure of apoptotic pathways.[8]

4 CISPLATIN DERIVATIVES AND NEW APPROACHES

4.1 Cisplatin Analogs Used in the Clinic

The clinical drawbacks associated with cisplatin therapy stimulated the search for other antitumor-active platinum complexes with improved pharmacological properties. Over 3000 platinum compounds have been synthesized and tested in vitro in the past 30 years.[1,3] However, less than 1% of these have entered clinical trials and very few have as yet emerged as clinically acceptable. The most successful of these second-generation platinum compounds is carboplatin (**3**, Figure 6). Since its introduction in 1986, it has largely replaced cisplatin in the treatment of patients that suffer from toxic side effects. Although less antitumor-active, carboplatin is also less toxic than cisplatin, allowing the use of higher doses in order to achieve a comparable level of clinical efficacy. The decreased toxicity is achieved by the substitution of the chloride-leaving groups by a didentate dicarboxylate,

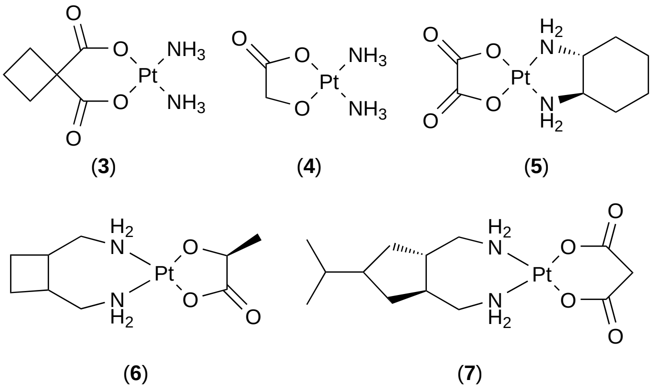

Figure 6 Cisplatin analogs used in the clinic. Numbers refer to: carboplatin (**3**), nedaplatin (**4**), oxaliplatin (**5**), lobaplatin (**6**), and SKI 2053R (**7**)

lowering the rate of aquation and thereby the reactivity of the compound.[13] The kinetics of DNA damage by carboplatin, mainly the initial binding step leading to monofunctional adducts, are much slower compared to cisplatin. Interestingly, it seems possible that nucleobases attack carboplatin directly without prior aquation of the drug, leading to long-lived ring-opened species.

Nedaplatin (**4**) is a drug similar to carboplatin and has been clinically used in Japan since 1995. Unfortunately, both drugs are cross-resistant with cisplatin, which implies that they are affected by the same resistance mechanisms. This may be related to the fact that the drugs cause the same type of DNA damage as cisplatin.

Oxaliplatin (**5**) (recently renamed Eloxatin) has been approved for the secondary treatment of metastatic colorectal cancers.[13] It appears to have a different spectrum of activity compared to cisplatin, and has been shown to circumvent cisplatin resistance. The MMR protein complex binds to DNA globally modified by cisplatin, but not to that by oxaliplatin. Furthermore, MMR-deficient cells are slightly more resistant to cisplatin, but not to oxaliplatin. It has been proposed that steric effects caused by the 1,2-diaminocyclohexane ring may prevent the MMR complex from recognizing the lesion.

Lobaplatin (**6**) exhibits a lower reactivity toward isolated DNA and serum proteins compared to cisplatin. Preclinical data suggested a lack of cross-resistance to cisplatin. However, as yet no clear evidence is available of clinical activity in cisplatin-resistant tumors. Lobaplatin has recently gained approval in China.[13]

SKI 2053R (**7**), containing an even bulkier amine ligand than (**6**), was shown to be active in murine leukemia with acquired resistance to cisplatin. Clinical activity in cisplatin-resistant tumors has not yet been reported. On the basis of studies in gastric cancer patients, SKI 2053R has received approval in South Korea.[13]

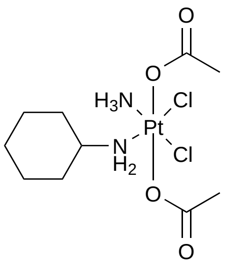
4.2 Structure–Activity Relationship (SAR)

The majority of the vast amount of platinum complexes synthesized fit a set of structure−activity relationships (SARs).[1] For a platinum drug to exhibit antiproliferative activity, the Pt(II) or Pt(IV) complex should have a cis geometry and the general formula of *cis*-$[PtX_2(Am)_2]$ or *cis*-$[PtX_2Y_2(Am)_2]$, where X is the leaving group and Am is an inert amine with at least one N–H functionality. Monofunctionally binding cationic complexes are inactive. The leaving group should be an anion with intermediate binding strength to platinum and should have a weak trans effect to avoid labilizing the amine. Complexes with labile leaving groups such as ClO_4^- or NO_3^- are highly toxic, probably because of the high reactivity toward intracellular biomolecules other than DNA. Complexes with rather inert leaving groups, such as I^- or SCN^- are generally inactive. In recent years, however, a large number of new compounds that do not satisfy the classical SARs have been reported to show antitumor activity. The demonstration of antitumor activity for these complexes indicates that cisplatin-like DNA lesions are not the only cause of cytotoxicity. Some examples are presented below.

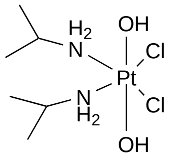
In the search for a more successful drug, numerous alternative concepts in the design of new platinum drugs emerged. Requirements that have influenced the search for new complexes include: reduction in toxicity, increased spectrum of activity, circumventing resistance, and oral activity to facilitate outpatient treatment.[4] The remainder of this section will give an overview of the various approaches used, classical and novel. Platinum complexes with appended functionalities will be discussed in more detail.

4.3 Platinum(IV) Complexes[16]

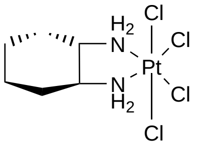
One of the advantages of Pt(IV) complexes is that some of them can be administered orally, expanding chemotherapy to ‘outpatient treatment’. Furthermore, Pt(IV) complexes show a reduced toxicity as they are octahedrally coordinated, resulting in slower ligand-substitution reactions than their Pt(II) analogs. It is generally believed that platinum(IV) complexes are reduced to platinum(II) by extracellular and intracellular agents prior to reaction with DNA, and thus act as a prodrug. The stability of the complexes depends on both the axial and equatorial ligands: carboxylato or hydroxo axial ligands lead to more inert complexes than axial chloride. The reduction potential of platinum(IV) complexes has been found to correlate with DNA binding and in vitro cytotoxicity. Recently, Hall *et al.* were able to monitor the fate of Pt(IV) drugs in situ using X-ray Absorption Near Edge Spectroscopy (XANES).[17] One of the most successful Pt(IV) complexes is satraplatin (**8**, Figure 7), also known as JM216, which



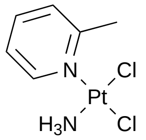
(**8**)



(**9**)



(**10**)



(**11**)

Figure 7 Pt(IV) complexes satraplatin (**8**), iproplatin (**9**), and ormaplatin (**10**) and the sterically hindered Pt(II) complex ZD0473 (**11**)

entered clinical trials in 1992. Satraplatin possesses in vivo oral antitumor activity against a variety of murine and human subcutaneous tumor models, and has a relatively mild toxicity profile with myelosuppression being dose limiting. However, Phase III trials were abandoned because of variability in drug uptake. Two other compounds, iproplatin (**9**) and ormaplatin (**10**) entered clinical trials as well, but were abandoned because of the lack of superior performance and neurotoxicity, respectively.[16]

4.4 Sterically Hindered Platinum(II) Complexes

As mentioned in Section 3, one of the main mechanisms of cisplatin-resistance is an increased intracellular thiol-mediated detoxification. ZD0473 (**11**, Figure 7), *cis*-[$PtCl_2(NH_3)$(2-methylpyridine)], is currently in Phase III trials and is a highly promising lead in which the replacement of an ammine ligand by a 2-methylpyridine ligand induces a marked decline in the reactivity of the platinum toward thiourea, methionine, Guanosinemonophosphate (GMP), and pyridine compared to cisplatin and *cis*-[$PtCl_2(NH_3)$(pyridine)].[13,18] The methyl group is nearly perpendicular to the platinum plane, sterically hindering an axial approach to the platinum. Preclinical evaluation shows significant activity of ZD0473 on a variety of cell lines, including several that possess acquired resistance to cisplatin and carboplatin. Across a panel of cisplatin-sensitive and resistant human ovarian carcinoma xenografts, ZD0473 shows improved or comparable activity to that observed for cisplatin. Furthermore, it is the first platinum(II) drug to demonstrate good oral availability and activity.

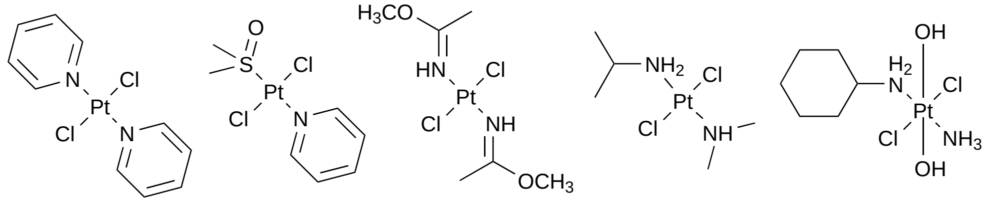
4.5 Trans-Platinum(II) Complexes

Although the trans isomer of cisplatin, *trans*-$PtCl_2(NH_3)_2$ or transplatin, is inactive, substitution of the ammine ligands resulted in a number of antitumor-active trans complexes (Figure 8).[19] The inactivity of transplatin is thought to be the result of its inability to form 1,2-intrastrand adducts. However, deactivation by binding to proteins and other cellular components has also been suggested to play a role.[20] Sterically demanding ligands, as in ZD0473 (**11**, Figure 7), may reduce the detoxification reactions that prevent binding to DNA. The antitumor-active trans complexes can be divided into four series: (1) *trans*-Pt(II)Cl_2 complexes with planar aromatic ligands (**12** and **13**, Figure 8); (2) *trans*-iminoether complexes (**14**); (3) *trans*-Pt(II)Cl_2 complexes with asymmetric aliphatic amines (**15**); and (4) *trans*-Pt(IV) mixed amine complexes (**16**). The complexes with planar ligands show reduced DNA-binding kinetics compared to transplatin and enhanced interstrand cross-linking compared to cisplatin. The cytotoxicity is higher than for their cis isomers and transplatin and, presumably as result of the altered DNA-binding mode, no cross-resistance with cisplatin was observed. The iminoether complexes also exhibit reduced DNA-binding kinetics, are more cytotoxic than their cis counterparts, and lack cross-resistance with cisplatin in vitro. Compound (**14**) inhibits DNA synthesis even though it preferentially forms monofunctional adducts. Complexes with asymmetric aliphatic amines mainly form interstrand adducts and exhibit a cytotoxic activity in cisplatin-sensitive cells comparable to cisplatin. In some cases, a lack of cross-resistance was found. The Pt(IV) mixed amine complexes promote DNA interstrand cross-links and are active against cisplatin-resistant tumors. Interestingly, the corresponding *trans*-Pt(II) complexes without the axial hydroxo groups are inactive.

4.6 Polynuclear Complexes[21]

Dinuclear and trinuclear compounds represent a new class of platinum anticancer complexes and are among the most studied platinum compounds in antitumor chemistry. Many of these complexes circumvent cisplatin-resistance mechanisms.[22] In contrast to cisplatin, the polynuclear complexes predominantly form interstrand cross-links. The dinuclear complex $[\{trans\text{-}PtCl(NH_3)_2\}_2\{\mu\text{-}(H_2N(CH_2)_nNH_2)\}]^{2+}$ (1,1/*t*, *t*) (**17**, Figure 9) is antitumor-active and shows no cross-resistance in cisplatin-resistant cell lines. Binding studies showed that DNA binding for this compound is different from that for cisplatin, as illustrated by the increased interstrand cross-linking. However, clinical testing was abandoned because of severe neurotoxicity.

The trinuclear platinum(II) complex, $[\{trans\text{-}PtCl(NH_3)_2\}_2\{\mu\text{-}trans\text{-}Pt(NH_3)_2(H_2N(CH_2)_6NH_2)\}]^{4+}$ (1,0,1/*t*,*t*,*t*, BBR-3464, **18**) was found to be very cytotoxic and effective against



(**12**) (**13**) (**14**) (**15**) (**16**)

Figure 8 Antitumor-active trans complexes. Numbers are explained in the text

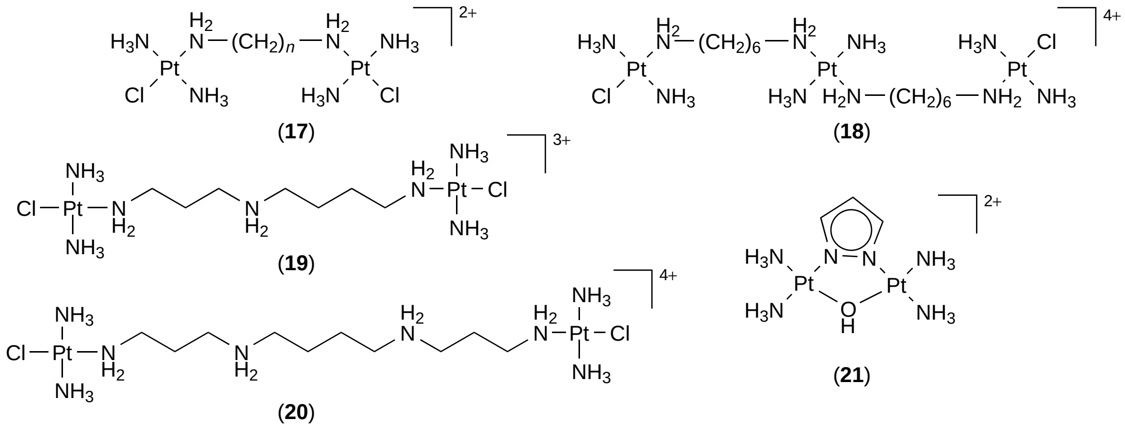


Figure 9 Selection of polynuclear platinum complexes. Numbers are explained in the text

cisplatin-resistant tumor cells. The overall +4 charge greatly enhances the affinity for DNA and the complex mainly forms long-range interstrand cross-links.

Dinuclear complexes formed with polyamines have attracted attention since polyamines are known to interact with the DNA backbone. Dinuclear cationic trans complexes that use the naturally available polyamines spermine (**19**) and spermidine (**20**) as linkers have been shown to be very active and to circumvent cisplatin resistance in L1210 murine leukemia cells in vitro. The internal charge, from an incorporated amine (**19**) and (**20**) or a platinum atom (**18**), featured in the diamine linker, seems to contribute significantly to the anticancer activity of the complexes.

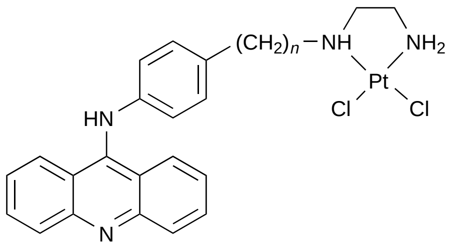
Recently, a new type of dinuclear platinum(II) complex, $[\{cis\text{-Pt}(NH_3)_2\}_2(\mu\text{-OH})(\mu\text{-pyrazolate})]^{2+}$ (**21**), was developed and found to have a very high activity. The bridging ligand in this complex is the rigid pyrazole, which was designed to induce minimal distortions when chelating at two neighboring G bases of DNA. It is anticipated that in this way the adduct is not, or hardly recognized by repair mechanisms. The crystal structure of the complex with two ethylguanine model bases has been resolved and shows that the orientation of the nucleobases is similar to the normal configuration of nucleobases in DNA.[23] Furthermore, a reaction with a double-stranded oligonucleotide containing a GG sequence resulted in hardly any distortion.[5]

4.7 Platinum Drugs with Extra Functionalities

To develop platinum drugs with improved properties compared to cisplatin, a plethora of cisplatin analogs have been designed with appended additional functionalities. The rationale is that these incorporated moieties could lead to a host of favorable pharmacokinetic properties, such as: targeting to cancer cells, improved transport into the cell, and increased affinity for DNA. Furthermore, to overcome the problem of resistance, pendant DNA interacting moieties have been incorporated in platinum drugs to induce an interaction with DNA distinct from that of the parent drugs. A selection of the myriad of approaches toward platinum drugs with altered properties is given below.

Chottard[24] prepared a large series of dichloro(ethylenediamine)platinum ($Pt(en)Cl_2$) derivatives, bearing a side chain with various functional groups, with the aim to examine how charge, polarity, and steric features of the side-chain affect the antitumor activity. The expectation was that compounds bearing an electropositive side chain, such as one or more ammonium groups, would be driven to the polyanion DNA and therefore exhibit the highest activity. However, the highest activity was obtained for complexes with appended bulky hydrophobic groups.

Intercalators are planar compounds that bind reversibly to DNA by π-stacking between base pairs. DNA intercalators have been attached to platinum complexes to increase the localization of the drug in the vicinity of its target and to reduce the exposure of platinum to deactivating intracellular nucleophiles such as thiols. Denny and McFadyen prepared a series of these complexes by conjugating $Pt(en)Cl_2$ to anilinoacridine (**22**, Figure 10) and acridinecarboxamide (**23**).[1] These complexes exhibited improved activity in cisplatin-resistant cell lines compared to cisplatin, but there was no improvement relative to the carrier ligands. Murray[25] recently demonstrated a similar cytotoxicity profile for 9-aminoacridinecarboxamide appended platinum complexes (**24**). However, these complexes displayed an altered sequence specificity compared to that of cisplatin and the above-mentioned acridinecarboxamide platinum complexes (**23**). Furthermore, the presence of the intercalating group greatly increased the rate of reaction with DNA. Phenazinecarboxamide-platinum conjugates (**25**) also exhibit[26] enhanced rates of DNA platination when compared to unfunctionalized $Pt(en)Cl_2$. Furthermore, they were shown to be significantly more cytotoxic against murine P388/W than either cisplatin, $Pt(en)Cl_2$, or the metal-free ligands. Other intercalators that have been conjugated to



(**22**)

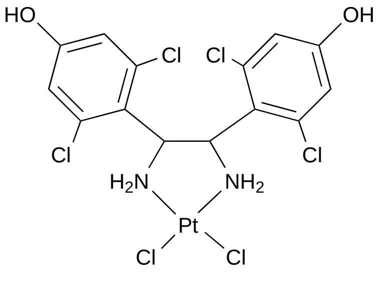
b: $n = 2$

Figure 11 A cisplatin analog conjugated to netropsin (**26a**) and distamycin (**26b**)

platinum drugs include quinolones, phenanthridinium, and anthraquinones.

Cisplatin analogs have also been linked to the DNA minor groove binders netropsin (**26a**) and distamycin (**26b**) with the aim to alter the interaction of the platinum moiety with the DNA (Figure 11).[9] These two oligopeptides are potent antibacterial, antiviral, and antineoplastic agents whose pharmacological activity has been correlated with their ability to bind to DNA. These nonintercalative compounds form noncovalent complexes with double-helical DNA in the minor groove and exhibit a preference for AT-rich domains. Kelland[27] found a strong and irreversible binding to AT regions in the minor groove for the platinum-peptide conjugates. Unfortunately, the antitumor activities found were much lower than cisplatin. In contrast, Brabec[9] showed that the distamycin-platinum conjugate coordinates to DNA with similar base-sequence preferences as the untargeted platinum drug, and concluded that not distamycin, but the platinum moiety acts as a targeting agent.

A number of researchers have used carrier groups that bind targets other than DNA, such as estrogen analogs, targeting platinum to some breast and prostate cancer cells that are known to overexpress estrogen receptors (**27** and **28**, Figure 12).[13,28] The antitumor activity of these complexes has been confirmed in estrogen-positive tumors, whereas estrogen-negative tumors did not respond. Keppler used ligands containing amino phosphonic acid groups in order to produce platinum drugs with selective activity in bone tumors (**29**) and (**30**).[13] Others have used carbohydrates[29] and bile acid.[30] Okuno developed an example of a carrier



(**27**)

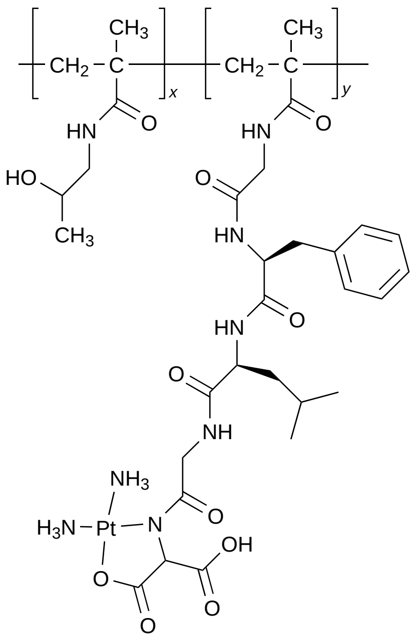
that is released after delivery of the platinum drug (**31**).[31] A lipophilic alkyl ester is attached to Pt(en)Cl_2, increasing platinum membrane transport, after which the ester is cleaved inside the cell by enzymatic hydrolysis.

Evidence that interactions between platinum drugs and peptides play a role in toxicity and resistance mechanisms in chemotherapy stimulated the investigation of platinum complexes with amino acids and small peptides.[32] A large variety of complexes have been described, coordinated in a mono-, di-, tri- or tetradentate fashion. The amino acids with aliphatic side chains or hydroxyl groups usually form chelated complexes through NH_2 and COO^- groups, but monodentate coordination through NH_2 is also possible. Amino acids with a carboxylate residue react in the same way, although the carboxylate can coordinate as well. In the sulfur-containing amino acids, the sulfur is the preferred coordination site. The amide N and O atoms are also coordination sites for platinum in peptide complexes. Although the majority of the numerous platinum–peptide and platinum–amino acid complexes described in the literature serve as models for cisplatin–peptide interactions in the cell, a few amino acid and dipeptide platinum complexes have been developed as potential anticancer drugs.[32–34] The idea behind this is based on the possibility for selective and increased transportation of the platinum moiety through membranes into cancerous cells, since amino acids are essential for cell growth.

Peptides and proteins have found tremendous use in tumor imaging and therapy when used as receptor-targeting moieties conjugated to radioactive metals. Likewise, a few groups have targeted platinum drugs to specific cancer cells using peptides or proteins as carriers. Wilchek[35] conjugated cisplatin to carboxyl groups of carboxymethyl dextran, which was targeted to the liver by the trinitrophenyl-functionalized streptavidin protein. Schally[36] synthesized a series of hexapeptide and heptapeptide analogs of the luteinizing hormone–releasing hormone (LH-RH) containing pendant $PtCl_2$-diaminopropionic and $PtCl_2$-diaminobutyric moieties. These analogs showed a wide range of receptor-binding affinities to cell membranes of human breast cancer and rat Dunning prostate cancer, as well as cytotoxic activity against human breast cancer and prostate cancer cell lines in vitro.

A promising concept is attaching multiple drug molecules to water-soluble polymers. These conjugates are attractive as a means of increasing drug solubility, reducing toxicity, and localizing more of the drug in the tumor via the Enhanced Permeability and Retention effect (EPR effect).[13,37] This phenomenon is due to the increased permeability of tumor vasculature that permits large macromolecules to enter the tumor tissue, where they are retained because of poor lymphatic and capillary drainage. Eventually, the polymer conjugates are taken up by the cell by endocytosis. Macromolecular agents have long plasma half-lives, because they are too large to pass through the normal vessel walls. After endocytosis, the conjugated drug is released by hydrolytic or enzymatic cleavage. The concept of polymeric anticancer agents has been established clinically in Phase I studies with HPMA copolymers conjugated to doxorubicin.[38] The macromolecules used as carriers for platinum drugs are numerous, and include the HPMA-peptide copolymer (**32**)



(**32**)

Figure 13 HPMA copolymer platinate AP5280 (**32**); $x = 90$ mol%, $y = 10$ mol%

(Figure 13), known as AP5280, which is a very promising potential anticancer drug now undergoing Phase I clinical trials. The amidomalonate-platinum chelate can be released inside the cell through enzymatic cleavage of the Gly-Phe-Leu-Gly peptide tether by lysozomal enzymes. In preclinical studies, (**32**) was shown to have similar or higher anticancer activity than cisplatin and carboplatin at only a fraction of its maximum tolerated dose (MTD). Moreover, increased tumor cell uptake and DNA adduct formation, and diminished toxicity compared to the parent compounds was observed.

4.8 Combinatorial and Parallel Synthesis Approaches

An alternative to traditional therapeutic drug development, the sequential synthesis and testing in a labor-intensive manner, is combinatorial chemistry. Combinatorial methods constitute tools with which large libraries of compounds can be synthesized through the combination of only a few building blocks, and subsequently screened for a desired property within a short period of time (high-throughput screening). Application of this method for inorganic compounds, with the exception of solid-state materials, has been demonstrated only in a few laboratories and has mainly dealt with (immobilized) catalyst design and enzyme mimetics. Interestingly, Lippard demonstrated that the platinum drug discovery process can be significantly accelerated by the preparation and mechanism-based screening of solution-phase platinum drug libraries.[33,39,40] In one case, roughly 3600 reactions were run and the products screened for their ability to inhibit transcription of β-lactamases in HeLa cells. The so-obtained library generated 14 hits, which were subsequently evaluated with respect to their cytotoxicity. Four compounds displayed good activity, of which three had been previously identified as potential drug candidates.

Solid-phase synthesis has been shown to be ideal for the preparation of libraries of potential drugs, and the advantages involved are likely to pertain to platinum drugs. In this respect, our group reported the solid-phase synthesis of dichloroplatinum(II) tripeptide complexes and dinuclear platinum(II) complexes.[41,42] Using this technique, a library of complexes was generated in an automated synthesizer and conveniently screened for cytotoxicity via an adapted MTT assay.[43]

5 SUMMARY AND OUTLOOK

Out of all the platinum compounds synthesized the last few decades, only a handful has emerged as clinically acceptable. Reduction of toxicity, increased spectrum of activity, and circumventing resistance are still main goals in platinum drug development. To this end, the field has moved toward the exploration of unconventional platinum compounds with often new modes of binding. The creation of functionalized platinum drugs with a higher target selectivity, or better cellular uptake in general, has received a lot of attention. Another promising strategy is the protection against inactivating reactions by using bulky nonleaving ligands. Alternatively, combinatorial methods could accelerate the search for the needle in the haystack through the rapid enrichment and evaluation of the collection of available platinum complexes known to date.

Platinum 'blue': blue oligomeric mixed valent Pt complex with Pt–Pt bonds

1 INTRODUCTION

Platinum is the best known of the platinum group metals (PGMs), which are Ru, Rh, Pd, Os, Ir, and Pt. The PGMs are both rare and very useful for their catalytic activity and their resistance to chemical attack. Platinum has been found in ancient Egyptian artefacts, and the pre-Columbian indigenous peoples of the Americas were familiar with the metal.[1a] The first European description of the element comes from Ulloa, who accompanied the French expedition of 1736 to measure the length of a degree of latitude at the Equator. His report[1b] concerned an unworkable metal called platina found in the Columbian gold mines. In 1741, a South American sample was brought to Europe and investigated scientifically. Only in 1783 did Lavoisier succeed in melting platinum for the first time. By 1805, Woolaston was producing and fabricating platinum by powder metallurgy in quantity from South American sources. It was sometimes called 'white gold' although this term is now used for Au–Pd alloys. The metal has now been found in many countries and it is currently produced in Russia, Columbia, Australasia, the US, Borneo, Burma, and Canada.[2a] The element can be recovered from many cupronickel ores, from anode sludge in electrolytic Cu refining, and from the residues in the Mond process for Ni refining. Useful reviews of the element and its chemistry have appeared.[2]

2 PROPERTIES AND EXTRACTION OF THE ELEMENT

The main properties are listed in Table 1.[1a] The best methods of platinum refining remain trade secrets, but general descriptions have been published.[1,2] In the Ni ores from Sudbury, Ontario, the Pt metals concentrate in a metal fraction formed by controlled oxidation of a sulfide ore; this can be magnetically separated and refined to produce relatively pure PGM. An aqua regia treatment dissolves most of the Pd and Pt, and the Pt is precipitated with NH_4Cl as the salt $(NH_4)_2[PtCl_6]$. This is pyrolyzed to give the metal, followed by purification via cycles of redissolution-reprecipitation. Resins containing certain macrocyclic ligands, which can selectively bind and release a number of metals, including Pt, are becoming commercially available, and their availability may change the refining process in the future. Procedures for recovering

Table 1 Some properties^a of elemental Pt

At. no.	78
At. wt.	195.08(3)
Density	21.45 (20 °C)
Mp	1769
Bp	4170
Electronegativity (Pauling)	2.28
Metallic radius	1.39 Å
Covalent radius	1.31 Å
Isotopes (abundance %, I, half-life)^a	190 (0.01, 0, 7×10^{11} y)
	192 (0.8, 0, ca. 10^{15} y)
	194 (32.9, 0, –)
	195 (33.8, 1/2, –)^b
	196 (25.3, 0, –)
	198 (7.2, 0, –)
Ionization potentials (eV)	
$Pt^0 \rightarrow Pt^I$	9.0
$Pt^I \rightarrow Pt^{II}$	18.56
$Pt^{II} \rightarrow Pt^{III}$	28.5
$Pt^{III} \rightarrow Pt^{IV}$	41.1
Electron affinity (eV)	2.12
Oxidation potentials (V)	
$Pt \rightarrow Pt^{2+} + 2e^-$	−1.2
$Pt + 4Cl^- \rightarrow PtCl_4{}^{2-} + 2e^-$	−0.75
$Pt + 4I^- \rightarrow PtI_4{}^{2-} + 2e^-$	−0.40
Sublimation energy (kcal mol^{-1} at 20^{0}C)	121.6
Common oxidation states and geometries	Pt^0, tetrahedral^c
	Pt^{II} square planar^d
	Pt^{IV}, octahedral

^{a}There are also a number of short-lived artificially produced isotopes with at. wts from 184 to 200. The longest lived is ^{193}Pt with $t_{1/2} < 500$ y. ^{b}Nuclear magnetic moment (μ): 0.6. ^{c}Planar three coordination rare. ^{d}Trigonal bipyramidal five coordination rare.

Pt from laboratory wastes have been described.[3] Platinum can be successfully electroplated, at least in thin films. Many of the Pt alloys follow the Hume-Rothery[4] structural rules, in which the structure adopted can be related to the average valence electron number for the alloy. Pt–Ir alloy (80–20) is especially useful for its ductility.

The use of the element in many industrially important catalysts is a measure of its exceptional catalytic activity. The important applications are: petroleum reforming; hydrogenation of unsaturated substrates; hydrosilation of unsaturated substrates; oxidation of SO_2 to give SO_3; oxidation of NH_3 to give HNO_3; and the oxidation of hydrocarbons in fuel cells. Platinum catalysts have important environmental applications in removing pollutants from power generator, internal combustion, and gas turbine engine effluents.[5] Autocatalysts convert over 90% of hydrocarbons, carbon monoxide, and oxides of nitrogen from gasoline engines into less harmful carbon dioxide, nitrogen, and water vapour.

Apart from the massive form, the element is most often encountered as ‘platinum black’, a finely divided and highly reactive material that has some catalytic activity. It can be prepared by reducing chloroplatinic acid with any of a variety of reductants, such as alkaline formaldehyde.[6] For practical applications, the metal is often deposited in colloidal form on an oxide, graphite, or other support, so that it better retains its high surface area and therefore its catalytic activity. Supported colloidal Pt has some advantages as a catalyst in organic synthesis.[7]

Sensors based on platinum are used in temperature measurement because of the substantial change of electrical resistivity with temperature. CO detectors are common safety features in homes and industrial buildings. Oxygen sensors, known as Lambda or Exhaust Gas Oxygen (EGO) sensors, use platinum and are a central component of the engine control system in a catalyst-equipped vehicle.

Zirconia grain stabilized Pt has advantages in practical applications of platinum by giving longer useful life at high temperature;[8] ACT™ coatings are useful in thermocouples and other high-temperature components.[9] The metal has the same coefficient of thermal expansion as soda glass and so an excellent glass-metal seal can be obtained. Platinum and platinum alloys are used in the fabrication of vessels that hold, channel, and form the molten glass because platinum’s high melting point, strength, and resistance to corrosion allow it to withstand the abrasive action of molten glass.

The use of platinum in jewelry is a result of its high strength and resistance to chemical attack (tarnish). It is estimated that over 90% of all hard disks produced contained platinum in their magnetic layers.

Besides numerous biomedical metallic devices, platinum is now used clinically in several important antitumor drugs notably Cisplatin (*cis*-$[PtCl_2(NH_3)_2]$), Carboplatin (*cis*-$[Pt(1,1\text{-ciclobutanedicarboxilato})(NH_3)_2]$), and Oxaliplatin ([Pt(oxalato)(*trans*-L-diaminocyclohexane)]), which are known to bind to DNA and inhibit cell division (*see* ***Platinum-based Anticancer Drugs***).

Platinum is not attacked by any of the mineral acids, but does dissolve in aqua regia, an HCl–HNO_3 mixture. The nitric acid provides the oxidizing power and the HCl provides the chloro ligands that stabilize Pt^{IV} in solution. The metal is also attacked by fused alkalis, by fused sodium peroxide and, at red heat, by chlorine and fluorine, especially in the presence of NaCl or other halide ion sources.

Platinum is found in compounds having a smaller range of oxidation states than is the case for many of the earlier elements in the periodic table. The differences between it and Pd are somewhat more marked than for analogous pairs of earlier elements. The coordination numbers (*see* ***Coordination Numbers & Geometries***) tend to be lower than for earlier elements: a CN of six is rarely exceeded and a CN of four is common. Many important concepts in coordination chemistry, such as square-planar coordination and the *trans* effect, were first discovered in Pt complexes. The high electronegativity of the element is reflected in a poor π-basic character, which helps account for the lack of a binary carbonyl.

3 BINARY COMPOUNDS

3.1 Halides

PtF_6 can be prepared from the elements as a red vapor which condenses at 69 °C and freezes at 61.3 °C; it shows a Jahn–Teller distortion, appropriate for its d^4 configuration. It is one of the molecules with the highest experimentally determined electron affinity[10] and therefore one of the strongest oxidants known and even gives $[O_2]^+$ $[PtF_6]^-$ and Xe^+ $[PtF_6]^-$ or Xe^{2+} $[PtF_6]^{2-}$ with O_2 and Xe;[11] the latter was the first noble gas compound (*see* ***Noble Gases: Inorganic Chemistry***). Dark red PtF_5 is tetrameric with four Pt–F–Pt bridges. The diamagnetic yellow–brown PtF_4 is formed from BrF_3 and Pt. All these species are hydrolytically unstable. An oxyfluoride, $PtOF_3$ is also known. The compound, once thought to be $[PtOF_4]$, was later shown to be $[O_2]^+$ $[PtF_6]^-$.[2] The molecular structures of the platinum fluorides have been determined.[12]

The highest chloride is $PtCl_4$, which is obtained as a red–brown solid from the elements at 300 °C or from heating chloroplatinic acid. Heating the tetrachloride gives the dichloride, which comes in a monomeric α-form as well as a hexanuclear form containing discrete $[Pt_6Cl_{12}]$ clusters. Br and I also form black $[PtX_4]$ as the highest binary halides. On heating, these convert to the dihalides. Rather unstable mono- and trichlorides have also been reported; the first may well be a cluster compound and the second probably contains both Pt^{II} and Pt^{IV}.

3.2 Chalcogen Compounds and Related Derivatives

Platinum is not oxidized when heated in air. PtO, linear PtO_2 and trigonal PtO_3 have been studied in argon matrices.[13] The brown trioxide which has been obtained in impure form by anodic oxidation probably contains Pt^{VI}, but the dioxide, PtO_2, is far better known. It is obtained as a red–brown hydrous material from hot Pt^{IV} solutions and sodium carbonate, but it loses most of the associated water to give the black anhydrous dioxide on heating to 200 °C. The amphoteric yellow trihydrate dissolves in NaOH to give $Na_2[Pt(OH)_6]$ and in HCl to give $H_2[PtCl_6]$. The monohydrate is a precursor of Adam's catalyst,[14] used extensively for the hydrogenation of organic compounds, when it is activated by reduction to finely divided Pt with H_2. Fusion of ammonium chloroplatinate and sodium nitrate has been recommended[14] for the preparation of Adam's catalyst. Chloroplatinic acid and sodium borohydride also gives a useful catalyst. Platinum sulfide on carbon is also available as a hydrogenation catalyst; it is less sensitive to poisons and does not reduce haloarene groups. A black, air-unstable hydrous Pt^{II} oxide is also known.

On heating, elemental Pt can also combine with elements such as B, Si, Ge, Pb, P, As, Sb, S, and Se, especially under reducing conditions. The phase diagrams are quite complex and several solid compounds are formed.[15] PtQ and PtQ_2 are known for Q = S and Te. For Se, $Pt_{10}Se_8$ and $PtSe_2$ are known. The PtQ_2 phases have the CdI_2 structure and are relatively easily oxidized. Pt_2Si and PtSi are both known, as well as PtP_2 and $PtAs_2$. PtO and PtS have square-planar Pt and tetrahedral Q. PtTe is a superconductor below 4 K.[16]

3.3 Hydrides

Platinum is able to absorb hydrogen gas, although not to the extent found for Pd (*see* ***Palladium: Inorganic & Coordination Chemistry***).

4 ZEROVALENT COMPLEXES

Complexes of Pt^0 can be tetrahedral, planar three-coordinate, or linear two-coordinate. Soft ligands and π-acceptor ligands are required to stabilize this low oxidation state. Acetylenes ($[Pt(\eta^2\text{-PhC}{\equiv}\text{CPh})_2]$),[17] olefines (($[Pt(\eta^2\text{-PhCH}{=}\text{CH}_2)_3)]$),[17] and especially phosphines are the most common ligands found in zerovalent complexes of platinum. Compounds with mixed ligands, including p-block elements donor ligands, are also known.

4.1 Phosphine Complexes

The most important zerovalent complexes are the phosphine derivatives of which the best known is the tetrahedral tetrakis(phosphine) $[Pt(PPh_3)_4]$, formed by reducing $[PtCl_2(PPh_3)_2]$ with hydrazine or alcoholic KOH in the presence of excess phosphine. A very wide range of similar complexes with alkyl-, alkaryl-, and fluorophosphines as well as with phosphites is now known. $[Pt(PPh_3)_4]$ dissociates readily in solution by sequential loss of PPh_3 (see equation 1).

$$[Pt(PPh_3)_4] \rightleftharpoons [Pt(PPh_3)_3] \rightleftharpoons [Pt(PPh_3)_2] \rightleftharpoons [Pt(PPh_3)]_n \quad (1)$$

The tris(phosphine) complex is planar, and the bis(phosphine) seems to be linear, by analogy with the isolable $[Pt(PCy_3)_2]$ species, for which a structure has been obtained.[18] The latter reacts with H_2 to give $[PtH_2(PCy_3)_2]$ and with X–H to give $[PtHX(PCy_3)_2]$ (X = C_6F_5, C_6F_5O, C_6F_5NH, and C_4F_4N). Water will protonate the very basic $[Pt(PEt_3)_3]$ to give $[PtH(PEt_3)_3]^+ OH^-$. The phosphite and fluorophosphine $[PtL_4]$ complexes are not dissociated in solution, as might be expected from their stronger π-acceptor power and smaller *Cone Angle*. Patterned Pt coatings can be deposited on silica via thermal decomposition of $[Pt(PF_3)_4]$.[19]

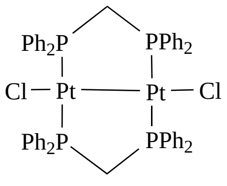
These complexes are important catalyst precursors and synthetic precursors in Pt chemistry. For example, oxidative addition of a variety of species XY to $[Pt(PPh_3)_4]$ normally gives $[PtXY(PPh_3)_2]$ (XY = Cl_2, MeI, Cl–Cu$(PPh_3)_3$, HCl, etc.).[20] In the case of HX addition, the Pt–H bond is sometimes sensitive to subsequent protonation and the final product can be $[PtX_2(PPh_3)_2]$, as is the case for X = Cl. Hydrogen does not react with $[Pt(PPh_3)_4]$, however.

The reaction with molecular oxygen gives an η^2-peroxy complex, $[Pt(\eta^2\text{-O}_2)(PPh_3)_2]$, in which the oxygen is reactive, and the complex can oxidize PPh_3, RNC, and alkenes to $OPPh_3$, RNCO, and the epoxide. SO_2, NO_2, NO, and CO_2 react to give the sulphato, dinitrato, dinitro, and carbonato complexes. The dioxygen complex is planar and seems to have substantial Pt^{II} character.[21]

Ligand exchange of $[Pt(P(OR)_3)_4]$ with free phosphite is dissociative, as expected for an 18-electron complex (*see Eighteen Electron Compounds*). $[Pt(PF_3)_4]$ is very stable and does not react with potential substrates for oxidative addition.

5 COMPLEXES OF 'MONOVALENT' PLATINUM

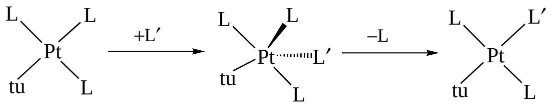
A number of species with Pt–Pt bonds have the +1 oxidation state. For example, the reaction of $[PtCl_4]^{2-}$ with $Ph_2PCH_2PPh_2$ under reducing conditions gives complex (**1**).[22] Treating $Pt^{IV}O_2$ with carbon monoxide in concentrated H_2SO_4 affords the homoleptic, dinuclear, cationic Pt^I carbonyl complex $[\{Pt(CO)_3\}_2]^{2+}$.[23] The apparently irregular behaviour of $^1J(^{195}Pt\text{–}^{195}Pt)$ in this class of compounds seems to be caused by an interplay between the influence of the ligands, relativistic effects on Pt–Pt and Pt-ligand bonds as well as 'atomical orbital contributions' to the nuclear spin–spin coupling constants.[24]



(**1**)

6 COMPLEXES OF DIVALENT PLATINUM

Pt^{II} is almost always 16-electron and square planar, as expected for a d^8 metal, although rare five-coordinate complexes are sometimes formed. This is the most stable oxidation state. Substitution reactions usually go by an associative pathway via an 18-electron five-coordinate intermediate. A high *trans* effect ligand such as thiourea (tu) favors substitution *trans* to itself by its preference for the equatorial site in the intermediate (see equation 2).



(2)

6.1 Hydride Complexes

One of the first hydride complexes, discovered by Chatt *et al.*, was *trans*-$[PtHCl(PEt_3)_2]$.[25] This and similar complexes can be formed by oxidative addition of HX to $[PtL_4]$ or by the action of a reducing agent such as hydrazine, alcoholic base, or $NaBH_4$ on $[PtCl_2L_2]$.[26] Some reductants, for example, trialkylgermanes, react with $[PtX_2(PPh_3)_2]$ to give $[PtHX(PPh_3)_2]$ by a radical chain pathway.[27] Hydrogen is also effective in the hydrogenolysis of Pt–X bonds (X = Cl, SiR_3, Ph, $SnCl_3$); for example, hydrogenolysis of $[PtCl(SiMe_3)(dppe)]$ at 60 °C and 1 atm produces the corresponding *cis* dihydride, rare for platinum. Another useful reagent is formic acid, which loses CO_2 and delivers hydride to a variety of $[PtHX(PPh_3)_2]$ species. Hydrolysis of the carbonyl $[PtX(CO)(PPh_3)_2]^+$ also gives $[PtHX(PPh_3)_2]$, probably via decarboxylation of a Pt–COOH intermediate.[28] Unusual dinuclear hydrides with Pt–H–Pt bridges, such as $[Pt_2H_3L_2]^+$ or $[(dppe)Pt(\mu\text{-}H)_2PtH(dppe)]^+$, which has both square planar and trigonal bipyramidal Pt,[29] are also known. Elemental sulfur (S_8) insert only one sulfur atom into the Pt hydride bonds of [PtHRL] (L = diphosphine) forming [Pt(SH)RL].[30] Proton NMR is very useful for studying Pt hydrides, where the ^{195}Pt–H coupling constants can be in the range of 700–1400 Hz. The Pt–H chemical shifts, J(Pt–H) coupling constants, and ν(Pt–H) IR stretching frequencies show a correlation with the nature of the *trans* ligand, as is also true for Ir.[31]

6.2 Pt–TM Bonds

Platinum forms an unusually large range of Pt–E bonds where E can be almost any element. A number of Pt–M species are known, where M is a transition metal; for example, $[Pt(PPh_3)_4]$ reacts with $[NiI_2(PPh_3)_2]$ to give $[I(PPh_3)_2Pt\text{–}NiI(PPh_3)_2]$. Square-planar Pt can also stack readily in the solid in such a way that weak Pt–Pt bonds are formed along the stack direction. Typical is Magnus' Green Salt, $[Pt(NH_3)_4][PtCl_4]$ (Pt–Pt = 3.23 Å); this complex and species like it show unusual colors as well as semiconducting and photoconducting properties.[32] A striking temperature dependance of the luminescence properties have been noted for several linear-chain platinum complexes[33] Some of these compounds show interesting vapochromic and vapoluminiscence properties.[34] The structure of the cluster $[Pt_3Ru_6(CO)_{21}(\mu\text{-}H)_3(\mu_3\text{-}H)]$ shows that the close-packed metals are segregated by layers in a bioctahedral arrangement ($Ru_3Pt_3Ru_3$); the complex is a hydrogenation catalyst for alkynes.[35]

6.3 Pt-Group 13 and Pt-Group 14 Bonds

Boryls are known via equation (3), which seems to occur by oxidative addition of the B–Cl bond followed by loss of HCl. The same type of complex is formed by oxidative addition of Ph_2BCl to $[Pt(PPh_3)_4]$.[36]

$$[PtHCl(PEt_3)_2] \xrightarrow{BClPh_2} [Pt(BPh_2)Cl(PEt_3)_2] \qquad (3)$$

Complexes bearing Pt–Si and Pt–Ge bonds have been invoked as potential intermediates in the formation of polysilanes ans polygermanes. The metallacycle $[(Et_3P)_2Pt(\mu\text{-}\eta^2\text{-}H_2CO)Ge(N(SiMe_3)_2)_2]$ takes part of a photochemical cycloreversion reaction with Pt hydride formation, releasing CO.[37]

Among group 14 elements, Sn is perhaps the most important. Pt^{II} solutions form intense colors in the presence of $SnCl_2$, and reaction of $SnCl_2$, with chloroplatinic acid gives a hydrogenation catalyst which is stable against colloid formation.[38] Although five coordination is rare for Pt^{II}, unusual species such as the trigonal bipyramidal $[Pt(SnCl_3)_5]^{3-}$ have been isolated from $SnCl_2$/chloroplatinic acid solutions. $SnCl_3$ groups are probably strongly π-accepting via their Sn–Cl σ^* orbitals.

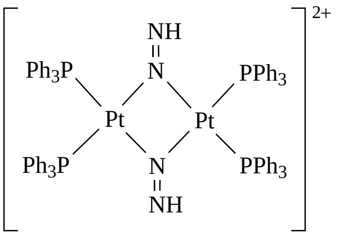
6.4 Complexes with Amines and N-donors

Pt^{II} amine complexes were very important in Werner's early studies in coordination chemistry (*see* ***Coordination Chemistry: History***).[39] The *cis* and *trans* bis(amine) complexes $[PtCl_2(NH_3)_2]$ have taken on special importance with the discovery that they bind to DNA, and the *cis*-form is in clinical use as an antitumor drug that has led to sharp falls

in mortality from a variety of organ cancers.[40] In accord with the expectations of the *trans* effect, the *trans* compound is formed from chloride ion attack on $[Pt(NH_3)_4]^{2+}$, while the *cis* complex is formed from NH_3 attack on $[PtCl_4]^{2-}$. The ionic isomers $[Pt(NH_3)_4]^{2+}$ $[PtCl_4]^{2-}$ are also known. In connection with the DNA problem, a large number of complexes between *cis*-$[PtCl_2(NH_3)_2]$ and the nucleic acid bases, nucleotides, and nucleic acid oligomers have been studied. In DNA, Pt probably chelates to the N(7) atoms of two guanines.[41] Halo-bridged complexes of the type $[(amine)XPt(\mu\text{-}X)_2PtX(amine)]$ are known, which undergo bridge-splitting reactions with amines and other ligands to give the *trans*-$[PtX_2L_2]$ species. The aromatic chelating ligands bipy and phen form an important series of completes of the $[PtX_2L]$ type (L = bipy or phen; X = halides, alkyls, aryls). The dimethylglyoximate complex $[Pt(dmg)_2]$ has N–O···H–O–N hydrogen bonds between the two planar ligands. Monoximes also form similar complexes.[42] Phthalocyanine and porphyrin complexes are also known.

The strong tendency toward forming planar complexes is shown by the reaction of $K(BH(pz)_3)$ (pz = pyrazolyl = $C_3H_3N_2$) with $[PtBr_2(PEt_3)_2]$, which gives the dinuclear species $[LBr_2Pt(pz)BH(pz)_2PtBrL]$ (L = PEt_3) where the normally *facial* tridentate $(BH(pz)_3)^-$ ligand is monodentate to one Pt and bidentate to the other in order to maintain planar four-coordination at both metals.[43]

Hydrazine reacts with Pt^{II} halides to give hydrides but intermediates with unusual structures have also been isolated from the solutions, for example (**2**).



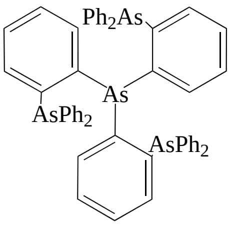
(**2**)

Azide forms the $[Pt(N_3)_4]^{2-}$ anion which reacts with PPh_3 (L) to give $[Pt(N_3)_2L_2]$, which in turn reacts with CO to form $[Pt(NCO)_2L_2]$ with loss of N_2.[44] The nitrile complexes $[PtCl_2L_2]$ (L = RCN), formed from the halide salt and the nitrile, are useful soluble precursors for synthetic chemistry. An unusual five-coordinate adduct, $[PtI(MeCN)_2(PPh_3)_2]I$, is formed from $[PtI_2(PPh_3)_2]$ and MeCN; reflux in benzene leads to loss of the methyl group to give $[Pt(MeCN)(CN)(PPh_3)_2]I$. Several NO derivatives are known, such as $K[Pt(NO)Cl_3]$ from $K_2[PtCl_4]$ and NO. Polymers with side-chain cyanobiphenyl groups give nematic phase liquid crystalline Pt complexes.[45]

6.5 Complexes with P-Donors and Related Ligands

The two most important classes of compounds are $[PtX_2L_2]$, from $[PtX_4]^{2-}$ and 2L, and $[LXPt(\mu\text{-}X)_2PtXL]$, made from $[PtX_2L_2]$ and PtX_2 (X = halide; L = phosphines, arsines, and stibines). Both *cis* and *trans* forms of the mononuclear species can usually be isolated. The dinuclear species easily undergoes bridge-splitting reactions with a variety of ligands to give substituted mononuclear derivatives. They are usually air stable and soluble in organic solvents. A detailed account of the syntheses of this class of compound has been given.[1a] The solvent-free mechanochemical synthesis of *cis*-$[PtCl_2(PPh_3)_2]$ and *cis*-$[PtCl_2(CO_3)]$ have been described.[46] The ^{31}P NMR spectra of the phosphine and phosphite complexes commonly show ^{31}P–^{195}Pt coupling constants of 3000–6000 Hz.

Five coordination is rare but sometimes seen with polydentate ligands such as (**3**), which gives a trigonal bipyramidal derivative [PtClL], where the Cl is axial.

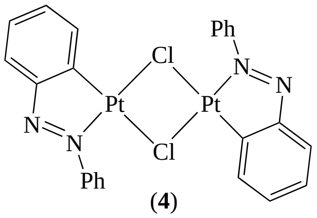


(**3**)

$[Pt(diars)_2]^{2+}$ gives five-coordinate adducts in solution with a variety of ligands X^-, such as X = N_3, Cl, SCN, Br, and I (equation 4); in the solid state the I compound has two equivalent long bonds to I (3.52 Å), however.

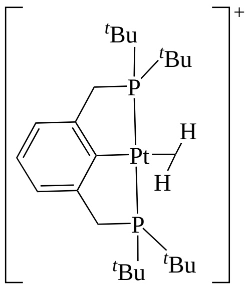
$$[Pt(diars)_2]^{2+} + X^- \longrightarrow [PtX(diars)_2]^+ \qquad (4)$$

Cyclometalation is a common reaction of Pt^{II} complexes of suitable N- and P-donor ligands; this gives organometallic derivatives with a Pt–C bond. For example, the product from azobenzene and $[PtCl_4]^{2-}$ is the chloro-bridged dinuclear species (**4**).



(**4**)

Tridentate 'pincer' ligands,[47] $(2,6\text{-}(CH_2ER_n)_2C_6H_3)^-$E = N (NCN), P (PCP), $n = 2$ or E = S (SCS), $n = 1$, form relatively stable complexes with Pt. Protonation of [PtH(PCP)]



(**5**)

($R = t$Bu) gives the Pt^{II} dihydrogen complex $[Pt(PCP)(H_2)]^+$ (**5**).[48]

6.6 Complexes with O-, S-, and Related Donors

Aqua ions are known but not very stable. Substitution of Pt^{II} in aqueous solution is sometimes zero-order in the added ligand, L, or can have both L-dependent and L-independent contributions to the rate, probably because intermediate formation of an unstable aqua complex is the rate-determining step for the L-independent pathway. A large number of O-donors, particularly anionic ones, give stable complexes, for example, carbonato, acetate, oxalate, acetylacetonate, and alkoxide. Tetrameric platinum(II) acetate is formed by formic acid reduction of Pt^{IV} solutions in acetic acid. It does not appear to be a very useful synthetic precursor for Pt^{II} chemistry. The acetylacetonate $[Pt(acac)_2]$ is monomeric and square planar.

Thiolates form stable complexes, almost always bridged, as in $[LClPt(\mu\text{-}SR)_2PtClL]$, obtained from $[LClPt(\mu\text{-}Cl)_2PtClL]$ and thiolate. Rare monomeric forms can be made by adding RSH to [PtL4] to give *trans*-$[Pt(H)(SR)L_2]$.[49] Thioether complexes such as $[(R_2S)ClPt(\mu\text{-}Cl)_2PtCl(SR_2)]$ are synthetically useful because the thioether can casily be displaced by other ligands. Monomeric *trans*-$[PtX_2L_2]$ (X = halide; L = thioether) are also known.[50] Thiourea (tu), which binds via S, has a very high *trans* effect, leading to rapid substitution in the position *trans* to S. The Krnakov test for distinguishing *cis*- from *trans*-$[PtX_2L_2]$ derivatives relies on this property of tu.[51] in its reaction with *cis*-$[PtX_2L_2]$ derivatives, tu labilizes the Pt–Cl bonds and ionic $[Pt(tu)_4]^{2+}$ is formed. In *trans*-$[PtX_2L_2]$ derivatives, on the other hand, tu substitutes for L only, and *trans*-$[PtX_2(tu)_2]$ is formed. A series of dithiolene complexes $[Pt(S_2C_2R_2)_2]$ is known; the one-electron redox activity of these species is thought to be ligand centered. Thiocyanate and selenocyanate form a large series of compounds, some of which are S- (Se-) and others N-bound.[1a] $[Me_2Et_2N][Pt(dmit)_2]$ (dmit = 4,5-dimercapto-1,3-dithiole-2-thione) is a superconductor with $T_c = 4\,K$ at 2.4 kbar.[52]

6.7 Complexes with Halides

The yellow $K_2[PtF_4]$ is known but the ion is hydrolyzed in aqueous solution and F complexes in general are very rare for Pt^{II}. The red crystalline $K_2[PtCl_4]$, formed from dissolving $PtCl_2$, in HCl and adding KCl, is one of the most important Pt^{II} complexes and an important starting material in much Pt^{II} chemistry. Slow solvolysis occurs in water to give $[PtCl_{4-n}(OH_2)_n]^{(2-n)+}$. The brown $K_2[PtBr_4]$ is also well known, but black $K_2[PtI_4]$ is rather unstable. $[X_2Pt(\mu\text{-}X)_2PtX_2]^{2-}$ salts are also known for Cl, Br, and I. Many of the complexes described in this article have halides as coligands. Bridged halo species of the type $[LXPt(\mu\text{-}X)_2PtLX]$ are particularly common. $[PtI_2(PMe_3)_3]$ is a rare example of a five-coordinate halo complex.

7 COMPLEXES OF 'TRIVALENT' PLATINUM

Pt^{III} complexes have been reviewed.[53] These are often mixed Pt^{II}/Pt^{IV} complexes; many have a chain structure[54] with M···M interactions or even M–M bonds. Others have $Pt^{II}-Hal-Pt^{IV}-Hal-Pt^{II}$ chains. An example of the latter has $\{Pt^{IV}L_4Cl_2\}^{2+}$ units alternating with $\{Pt^{II}L_2Cl_2\}$ units. Many analogs are now known.[55] The related platinum blues are oligomeric mixed valence compounds with Pt···Pt interactions and formed from $[PtCl_2(NH_3)_2]$ and pyrimidines, of which examples have now been crystallized.[56]

Few mononuclear complexes of the Pt^{III} oxidation level are known, and it is always hard to tell if a $Pt^{II}(L^{+\bullet})$ description is more appropriate. The paramagnetic blue $[Pt(C_6F_5)_3]^-$ is known, formed from $[Pt(C_6F_5)_4]^{2-}$ and Cl_2.[57] Thiamacrocycles, such as 1,4,7-trithiacyclononane (= L), can stabilize Pt^{III} in $[PtL_2]^{3+}$, a square pyramid in which one S of the ligand remains unbound.[58]

The bridging ligand POP $\{= (HO)(O^-)POP(O^-)(OH)\}$ forms dinuclear Pt complexes $[Pt_2(POP)_4]^{4-}$ that can be oxidized to the (III, III) ($[X_2Pt_2(POP)_4]^{4-}$) level with halogens. The most interesting property of these systems is the ability of $[Pt_2(POP)_4]^{4-}$ on irradiation to promote homolytic C–H bond scission of organic compounds, which can either result in dehydrogenation or dehydrodimerization of the organic compound.[59] The primary process is abstraction of an H atom by the excited state triplet, which has Pt–Pt σ^* radical character, to give a Pt hydride intermediate.

The structure of the dimeric Pt^{III}–Pt^{III} complex $[Pt_2(CN)_{10}]^{4-}$ has been studied in aqueous solution by EXAFS. A nonsupported Pt–Pt bond (2.73(1) Å) connects two $Pt(CN)_5$ entities in the dimer.[60]

8 COMPLEXES OF TETRAVALENT PLATINUM

Unlike Pd, which only reluctantly forms M^{IV} complexes, the tetravalent state is common for Pt. The lower ionization energy and higher M–L bond strengths for Pt are probably

responsible for the difference. As a d^6 ion, octahedral coordination is the rule and complexes are diamagnetic and low spin. Substitution reactions in these 18-electron species usually go by a dissociative pathway via a 16-electron five-coordinate intermediate. They can be catalyzed by Pt^{II}, in which case electron transfer becomes important.[61]

8.1 Hydride Complexes

Platinum(IV) hydride chemistry has been reviewed recently.[62] These are usually formed by oxidative addition to a Pt^{II} species and are rather unstable. The reaction shown in equation (5), for example, is readily reversible, because the product easily loses HCl. Hydrido complexes are often involved as intermediates in reactions in which the first step is oxidative addition of an H–X species to Pt^{II}.

$$trans\text{-}[PtHCl(PEt_3)_2] + HCl \longrightarrow [PtH_2Cl_2(PEt_3)_2] \quad (5)$$

8.2 Complexes with Pt–TM Bonds

Mixed Pt^{IV}–Pt^{II} species having a metallic luster are known in which the metals are stacked with close Pt–Pt distances. For example, $K_{1.6}[Pt(C_2O_4)_2]$ $2.5H_2O$ has a distance of only 2.75 Å, and the system seems to be fully delocalized. 'Trivalent' $K_2[Pt(CN)_5]$ $3H_2O$ is of the same type.

8.3 Complexes with Group 14 Donors

These can be isolated from R_3E–H (E = Si, Ge, Sn) additions to Pt^{II} complexes. They are usually rather unstable, and lose the group 14 ligand and the group that lies *trans* to the highest *trans* effect group (see equation 6).[1a]

$$trans\text{-}[PtI_2(PEt_3)_2] + H\text{–}SiH_2Cl \longrightarrow [PtHI_2(SiH_2Cl)(PEt_3)_2] \quad (6)$$

8.4 Complexes with Group 15 Donors

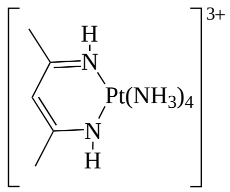
These constitute a very large group of compounds. For example, all the $[Pt(NH_3)_nCl_{6-n}]^{(n-2)+}$ complexes are known except that in which n is one. They are usually made either by substitution of a Pt^{IV} species or by oxidation of a Pt^{II} precursor (see equations 7 and 8).

$$[PtCl_6]^{2-} + 6NH_3 \longrightarrow [Pt(NH_3)_6]Cl_4 + Cl_2^- \quad (7)$$

$$[PtBr_2(NH_3)_2] + Br_2 \longrightarrow [PtBr_4(NH_3)_2] \quad (8)$$

$[Pt(NH_3)_6]^{4+}$ reacts with acacH to give (**6**) in which a diimine complex has been formed by loss of water.[63] The Pt^{IV} amido complex $K_2[Pt(NH_2)_6]$ is also known.[64]

An azide $K_2[Pt(N_3)_6]$ is known, and $[PtCl_2(NCMe)_2]$ reacts with Cl_2 to give $[PtCl_4(NCMe)_2]$. Many phosphine and arsine complexes undergo oxidative addition to give Pt^{IV}



(**6**)

derivatives, as was shown in equation (5), but phosphines and other reductants can also reduce Pt^{IV} to Pt^{II}, so some of the products can be unstable. Attempts to substitute Cl for I in $[PtCl_4(PR_3)_2]$, for example, led to formation of $[PtI_2(PR_3)_2]$ and free I_2.

8.5 Complexes with Group 16 Donors

$[PtCl_2(NH_3)_2]$ reacts with H_2O_2 to give the Pt^{IV} bis(hydroxy) species $[PtCl_2(OH)_2(NH_3)_2]$.[65] An interesting S-donor example is $(NR_4)_2[Pt(S_5)_3]$, in which three chelating dianionic $S_5{}^{2-}$ ligands are present. The compound has been resolved into its optical isomers, one of the very few purely inorganic species for which this has been accomplished.[66] A related species, $[Pt(Se_4)_3]^{2-}$, has also been isolated from a Pt^{II} salt and the $Se_5{}^{2-}$ ion; since the product is Pt^{IV} this involves redox steps.[67] The thioether complexes $[PtBr_4(SR_2)_2]$, formed via oxidation of the Pt^{II} species, are also known.

8.6 Complexes with Group 17 Donors

The very soluble hexachloroplatinic acid, $H_2[PtCl_6]{\cdot}nH_2O$, is the most useful precursor for synthetic and catalytic work. For the hydrosilation of unsaturated substrates, the catalyst of choice is chloroplatinic acid, because of its very high activity. There is currently some doubt as to whether the true catalyst is homogeneous or colloidal metal and therefore heterogeneous (*see* ***Hydrosilation Catalysis***). Nearly all halides and pseudohalides (= X) form salts of the $[PtX_6]^{2-}$ ion and of the $[PtX_4(NH_3)_2]$ type.

1 INTRODUCTION

As with diverse progress in other chemical frontiers, organometallic chemistry in the last decade exhibits tremendous change from the traditional appearance. Similar to the trend in coordination and organometallic chemistry of other metals, the quest for new ligands not only extends the territory for conventional organoplatinum chemistry, but also opens up new areas for this field.

Ligand evolution has been substantially advanced in two aspects, the broadened motif as well as the growing synthetic power. Delicate design and syntheses for ancillary ligands (*see Ancillary Ligand*) are often exhausting but can be rewarding for the invention of new organometallic functionality and reactivity. The bidentate (*see Bidentate Ligand*) and tridentate (*see Tridentate Ligand*) ligands can exert a more powerful influence on the complexes of group 10, which prefer four-coordinate square-planar geometry for the most common 2+ valence, than on the metals of other groups. From the viewpoint of the ligand usage in organometallic chemistry, phosphines and the cyclopentadienyl ligands (*see Cyclopentadienyl*) represent the periods of the 1970s and 1980s respectively. Then, the nitrogen-donating ligands experienced a renaissance in the 1990s and the carbon-donating ligands caught the succeeding tide at the end of the twentieth century. Among them, cyclometallated (*see Cyclometalation*) polydentates, aminocarbenes, and diimines are the most successful examples. The modern ligands are required to fine-tune electronic and steric influence on the metal center by varying the substituents, in addition to their intrinsic character. Fortunately, rapidly developing synthetic knowledge enables acquisition of the ligand variety and optimizes the desired properties for the complexes.

One of the major landmarks in organometallic chemistry has to be the discovery of the unprecedented organometallic bonding modes or functionalities. On the other hand, the chemistry of many conventional organometallic species has been advanced substantially. In addition to simply seeking new compounds and structures, the quest for new substances that possess specific properties and applications has become an essential issue in research. For instance, the organic π-conjugates bring abundant photophysical properties to organoplatinum. The rigid linear alkynyl units are the most favored building blocks for molecular architecture (*see* ***Self-assembled Inorganic Architectures***) of large skeletons.

Proceeding with nano technology, nano sciences created immense waves in the late twentieth century. The concept of supermolecules was created for chemical composition beyond the covalent association of atoms.[1] The synthesis by means of assembling large building blocks through weak interactions entered the chemical arena. Because the coordination compounds intrinsically combine the geometry and molecular assembly through metal, they are naturally employed as cornerstones for preparing supermolecules and nano-materials.

Although the compounds containing the Pt–C bonds are legitimate organoplatinum members, the species with the Pt–Si and Pt–H bonds that show comparable reactivity are often adopted into organoplatinum chemistry. Studies in platinum(IV) chemistry have opened new windows for learning the C–H activation, the long-term Holy Grail in organometallic chemistry. Apparently, the electron-rich nitrogen-donor ligands can stabilize the highly valent Pt(IV) state. Some new chemical transformations developed

along with the discovery of the new platinum-alkyl and aryl compounds, affording insights into mechanistic and catalytic paradigms. Other new chemical transformations and mechanistic studies of the organoplatinum complexes concerning carbon–carbon as well as carbon–main group elements coupling reactions are discussed.

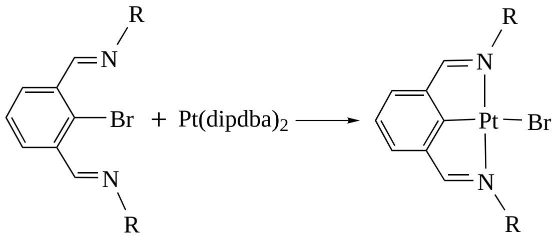
This review is selective and is prepared to provide the representative features and prevailing developments of organoplatinum chemistry, particularly in the last decade. The subjects that are closely related to coordination chemistry, luminescence behavior, catalysis, organic synthesis using transition metal complexes, and organometallic clusters, and so on, which are covered in articles in this volume, are not discussed in detail.

2 ORGANOPLATINUM COMPLEXES CONTAINING CONVENTIONAL BONDING

2.1 Ligands with Carbon Donor

Cyclometallation, which provides multidentate ligands containing carbon donors, has been known as a useful synthetic method for preparing organometallic complexes.[2] A noticeable extension in such a category, which substantially facilitates the recent development of organoplatinum chemistry, is the pincer-type ligands, which allow tridentate meridional chelation with various donor combinations to the metal.[3]

There are three typical synthetic routes for these complexes. The first way is with use of conventional oxidative addition (*see Oxidation Number*) of aryl halides to a Pt(0) precursor (Scheme 1). The second is via transmetallation (*see Transmetalation*) using anionic aryl salts (Scheme 2).[4] The third and perhaps the most convenient method for the

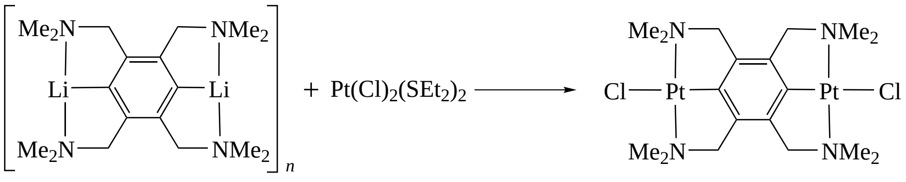


Scheme 1

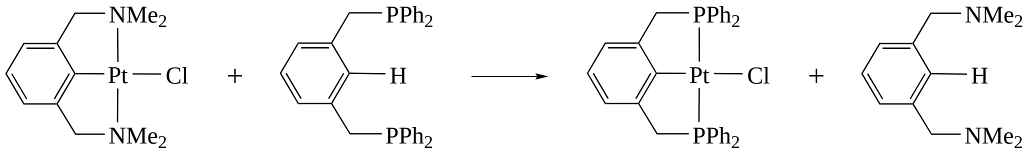
preparation of the cyclometallated ligands is through aryl C–H activation (Scheme 3).[5] It appears that the C–H activation may be facilitated by a pre-coordination that assists the orthometallation (*see Orthometalation*) in proximity.

Such pincer ligands have been expanded with all kinds of imaginable combinations and variations. They not only may serve as ancillary groups or be involved in the reactions, but also can result in novel reactivity or confer specific physical properties on the complexes. For instance, complexes with bifunctional ligands are used as building blocks for polymeric materials (Scheme 4).[6] The crystals of a pincer complex are found to show controlled and fully reversible crystalline-state change based on incorporation of SO_2 into the crystal lattice (Scheme 5).[7] Such transformation along with distinct color change is thought to afford gas-storage devices as opto-electronic switches. A complex (**1**) resulting from water-induced double cyclometallation with 2,6-diphenylpyridine shows [C-N-C] ligation.[8] Suitable arrangements such as [C-N-N] in (**2**) and (**3**) show photoluminescence.[9] The extension to macrocyclic derivatives leads to the synthesis of *N*-confused porphyrin complexes (Scheme 6).[10]

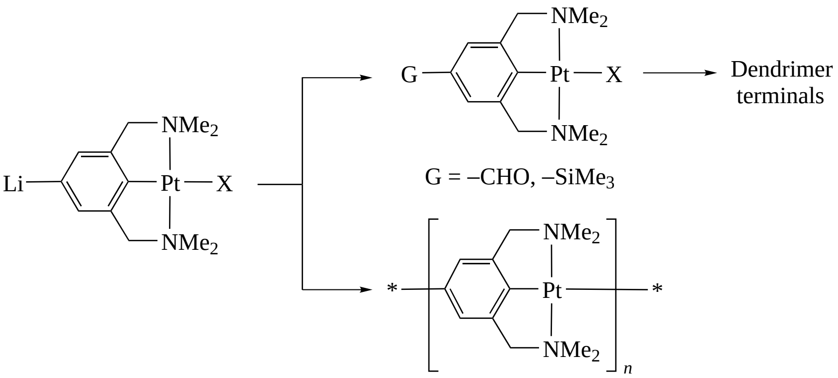
The amino carbene ligands open a new era of ancillary ligands in organometallic chemistry. One of the pioneering studies is the synthesis of 2-coordinate homoleptic (*see Homoleptic Compound*) complexes of low-valent noble



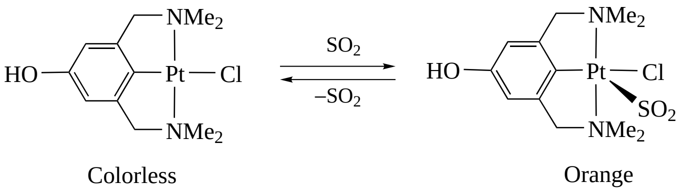
Scheme 2



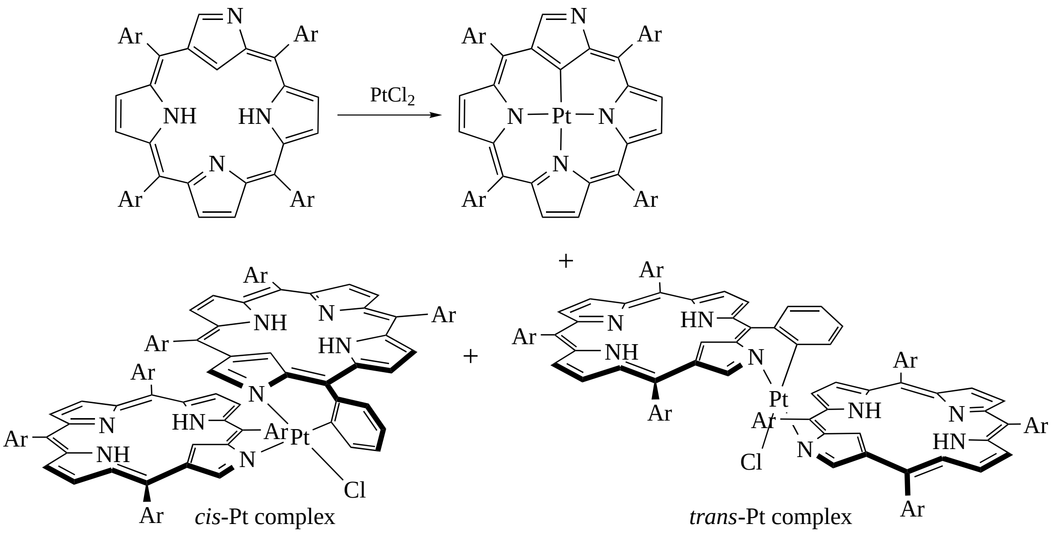
Scheme 3



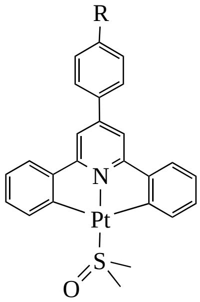
Scheme 4



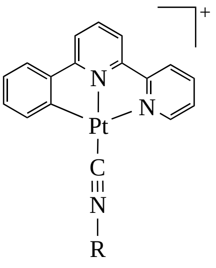
Scheme 5



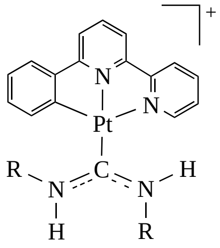
Scheme 6



(**1**)

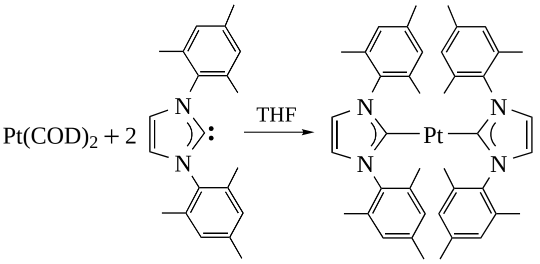


(**2**)



(**3**)

metals including platinum by ligand replacement, as shown in Scheme 7.[11] The NMR and X-ray crystallographic characterizations evidence the dπ-pπ back-donation (*see Back Bonding*) in the M–C bonds in the biscarbene platinum complex, which holds a linear geometry with the imidazole rings twisted 51°. The N,N'-di-*tert*-butyl biscarbene platinum derivative Pt[C{N(^{t}Bu)CH}$_2$]$_2$ could result from cocondensation of metal vapor with an excess of ligand. The geometry of the complex is still linear, but with a 90° twisting imidazole angle.[12] The ligand variation extends to the bidentates (**4**);[13] and a tridentate ligand



Scheme 7

of bis(pyridine) carbene provides the Pt(IV) species (**5**).[14] Recently, an anionic bis(phosphinidene) carbene gives a tris(carbene) pincer complex under CO atmosphere (**6**).[15]

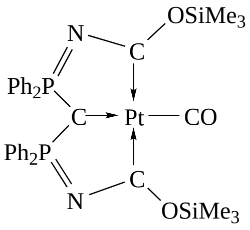
(**5**)

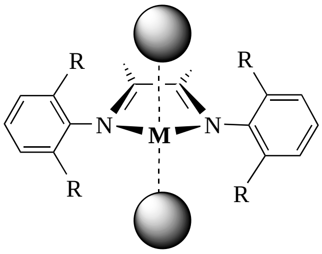


(**6**)

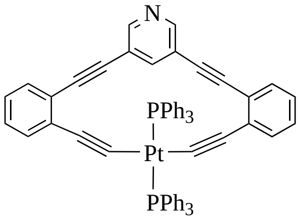
2.2 Ligands with Nitrogen Donors

Phosphines had been employed more in organometallic chemistry of soft late transition metals than had the ligands with nitrogen donors. An important development of exploiting new ligands in the latest decade has to be the usage of bidentate diimines. One reason for the renaissance of these long-time known species is the introduction of deliberate steric control in the proximity of metal. In a square-planar environment, the *ortho*-substituted aryls at the imino nitrogen likely dispose perpendicularly to the molecular plane as shown in (**7**). Such a configuration will have the aryl substituents at the *ortho*-carbons point to the axial coordinating sites. Bulky R group such as isopropyl thus can efficiently influence the reactivity that requires the axial vicinity.[16,17]

The diimine ligands with aryls containing different ortho substituents can generate the syn- and anti- isomers that



(**7**)



(**8**)

differ in orientation of the substituents with respect to the coordination plane as shown in Scheme 8.[18] Such a coordination arrangement confers further chemical selectivity on the complexes (Scheme 9).[19] The methyl groups on C_α atoms make the reduction of the metal center more difficult than the C_α-unsubstituted complexes. On the other hand, a change of the substituent at the aromatic ring has virtually no effect. The square-planar Pt(II) dialkyl complexes appear to undergo Pt–R homolysis upon oxidation. Oxidation by a one-electron process results in subsequent disproportionation (*see Disproportionation*) to (N-N)Pt^{II}(L)Me and (N-N)Pt^{IV}(L)Me_3 cations. The former species is an analog of the active species in C–H activation and alkene polymerization reactions (*see Alkene Polymerization*).[20]

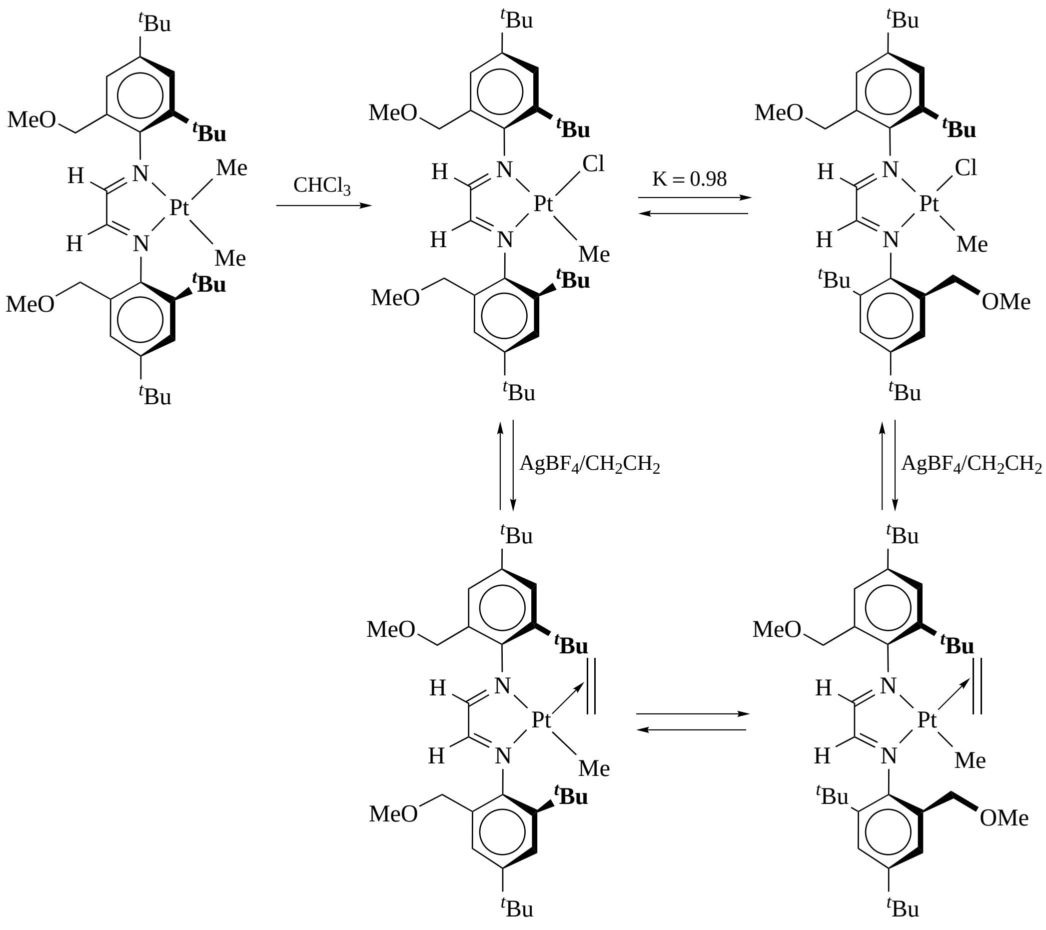
Shilov and coworkers discovered the oxidation of methane to methanol by mixtures of Pt^{II} and Pt^{IV}, and aroused the Holy Grail-pursuing for electrophilic C–H activation and subsequent alkane oxidation. The diimine complexes of Pt(II) methyl are indeed found to facilitate smooth benzene activation, resulting in formation of methane via Pt^{IV}(Me)(Ph)(H) intermediates (Scheme 10).[21] Such Pt(II)/Pt(IV) involved C–H activation reactions have been widely extended to a variety of nitrogen-donor ligands, whose electronic and steric effects shed light on the reaction mechanisms (see Section 7.1).

Chirality has been introduced into the diimine complexes to give rise to the reactivity control. For example, high stereoselective α-olefin coordination has been observed in a special di-exo-iminocyclohexane complex (Scheme 11).[22]

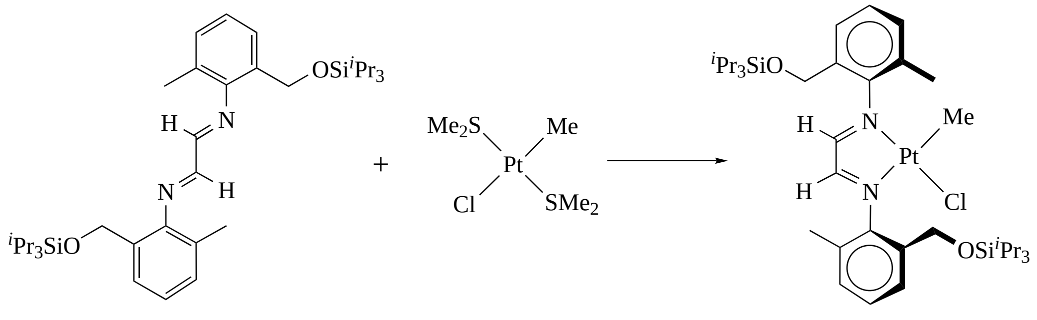
3 ORGANOPLATINUM COMPLEXES WITH NEW ORGANIC MOTIFS

3.1 σ-Donor Complexes

Metal carbonyls (*see* ***Carbonyl Complexes of the Transition Metals***) are extended to superelectrophilic cations, including square-planar $[Pt(CO)_4]^{2+}$ by reductive carbonylation of $Pt(SO_3F)_4$ or PtF_6 in super acid environment (Scheme 12).[23] Using a comparable approach, $[Pt(CO)_3]^{2+}$ in



Scheme 8



Scheme 9

S_4 symmetry of which two planar T-shape $Pt(CO)_3$ fragments are associated in perpendicular configuration through the Pt–Pt bond is obtained by the dissolution of PtO_2 in concentrated sulfuric acid (Scheme 13).[24] The vibrational stretching frequencies of carbonyl are over 2200 cm^{-1}, and the ^{13}C MAS NMR measurements are found below δ140.

The dialkyl complexes of platinum(II) with coordinating dimethyl sulfide typically like $Pt(SMe_2)_2Me_2$ and $Pt_2Me_4(\mu\text{-}SMe_2)_2$ have been known for certain period, and now are widely used as starting materials for the synthesis of new organoplatinum complexes with nitrogen donors.[25] Ligands with hybrid donors or special donating functionalities sometimes may assist the synthesis of new species. A platinum methylene complex was generated by treating lithium salt in CH_2I_2 (Scheme 14).[26] Thermolysis of a (perfluoroalkylphosphine)ethyl complex at 120 °C in CF_3CO_2H results in the formation of a μ-alkylidene (*see Alkylidene*) complex (Scheme 15).[27]

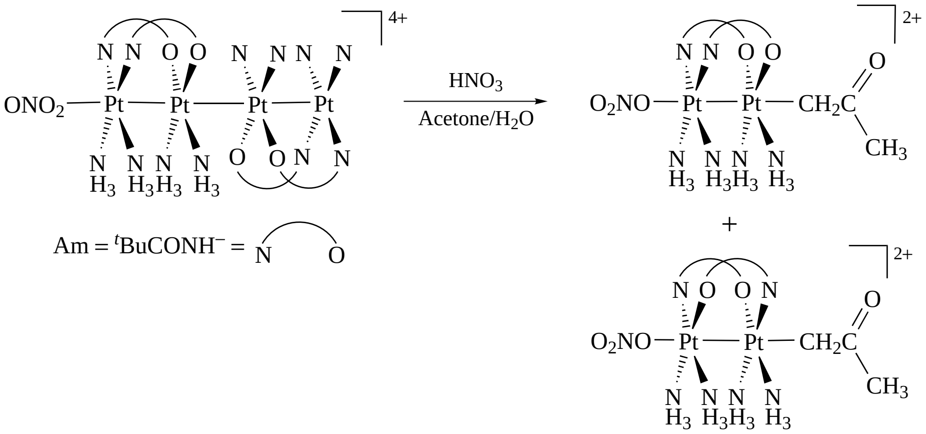
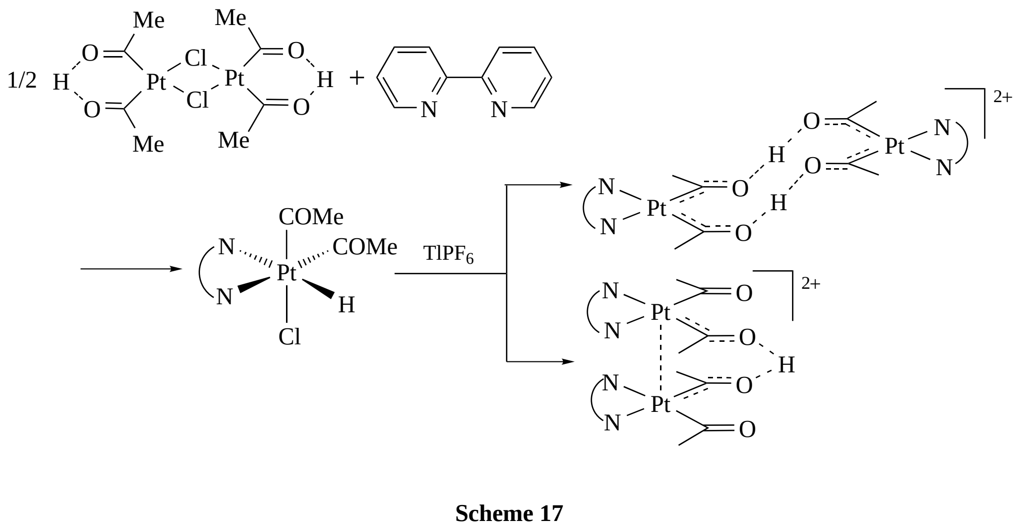


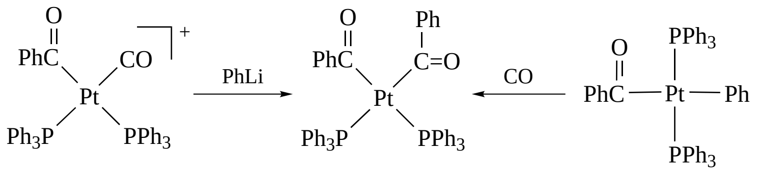
Scheme 16

The pivalamidate-bridged diplatinum^{III} ketonyl complexes may be prepared from the reaction of platinum blue complex and nitric acid in acetone.[28] Two isomers with the amidate configuration in head-to-head and head-to-tail modes and the ketonyl ligand at one axial end are characterized (Scheme 16). An alternative route is from catalyzed oxidation of olefins.[29]

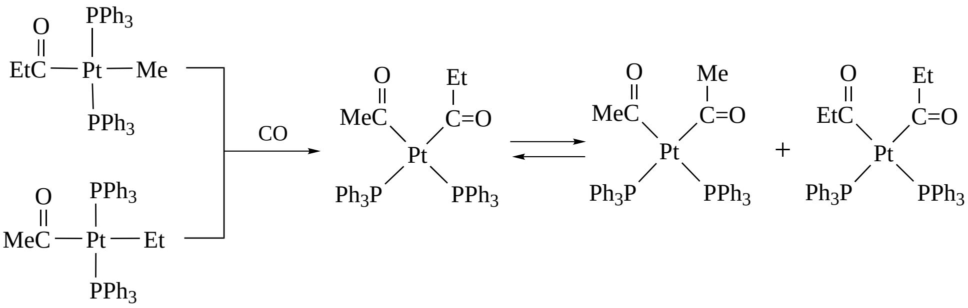
Transformation between platina-β-diketones, the metallo analogues of enol tautomers of 1,3-diketones, and platina-β-diketonates was previously studied in the 1980s.[30] Recent studies indicate the reaction of platina-β-diketone with bipyridines via oxidative addition yields the diacyl hydrido Pt(IV) complex. Further ligand abstraction may result in H–bond bridged dimer and a double-deck dimer through Pt–Pt interaction (Scheme 17).[31] On the other hand, the prototype of unsupported *cis*- diacyl platinum(II) species was obtained either via nucleophilic addition to cationic acyl carbonyl complexes or CO insertion into a trans acyl alkyl complex (Scheme 18). In the latter process for propionyl methyl or acetyl ethyl complex,



Scheme 17



Scheme 18

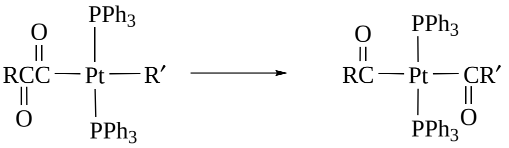


Scheme 19

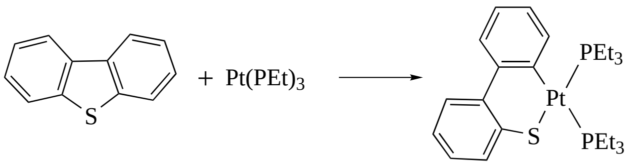
the insertion may result in acyl scrambling (Scheme 19). Trans-diacyl complex was obtained from a facile decarbonylative isomerization of an α-ketoacyl alkyl complex (Scheme 20). Such diacyl species are the legitimate models for Pd-catalyzed double carbonylation reactions (*see Carbonylation*).[32]

Metallacycles (*see Metallacycle*) are readily prepared via C–C bond activation, particularly in a strained ring. Insertion of Pt(0) into biphenylene leads to the formation of biphenyl complex. Following this strategy, the reaction of semibuckminsterfullerene ($C_{30}H_{12}$) with Pt(0) yields a buckybowl complex (Scheme 21).[33] Similar ring expansion via carbon–sulfur bond cleavage is also observed. Thiaplatinacycles derived from thiophenes and Pt(0) has been achieved (Scheme 22).[34] Such reactions may serve as good models for the homogeneous hydrodesulfurization processes. In one case, a platinum hydride complex (*see **Hydride Complexes of the Transition Metals***) was capable of generating the biphenyl product by sulfur extrusion (Scheme 23).[35]

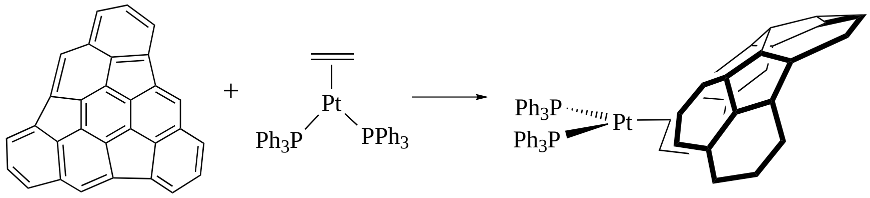
Alkynyl complexes, also known as metal acetylides, possess both rigid linear skeleton and π-conjugation. In the structural aspect, alkynyls make excellent linear bridging units. By means of the reactions of transmetallation (*see Transmetalation*), poly-Pt-acetylides are readily synthesized (Scheme 24).[36] Copper(I)-mediated oxidative coupling



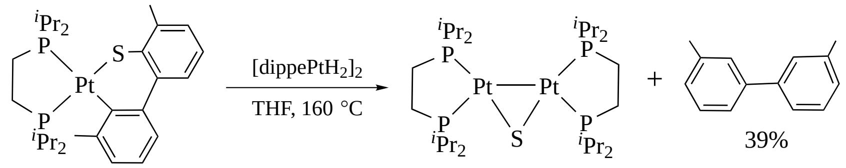
Scheme 20



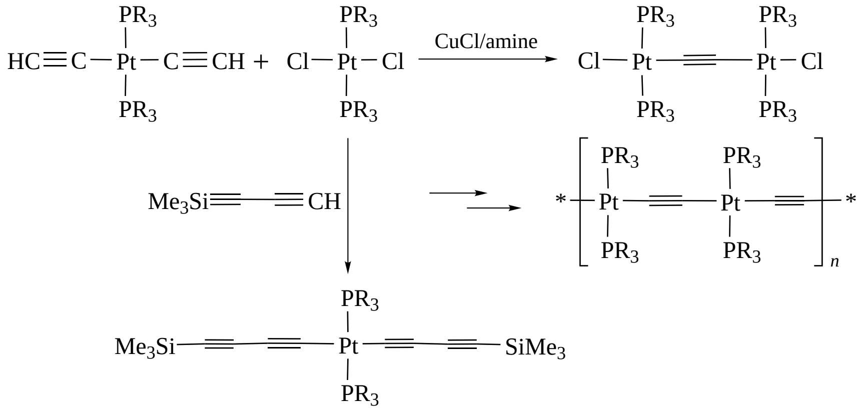
Scheme 22



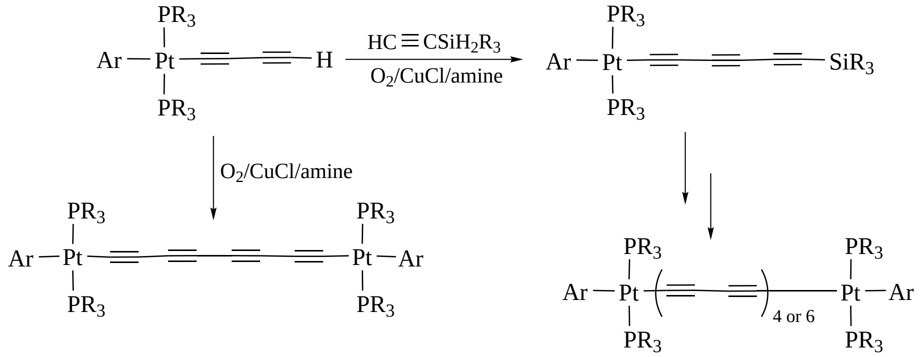
Scheme 21



Scheme 23



Scheme 24



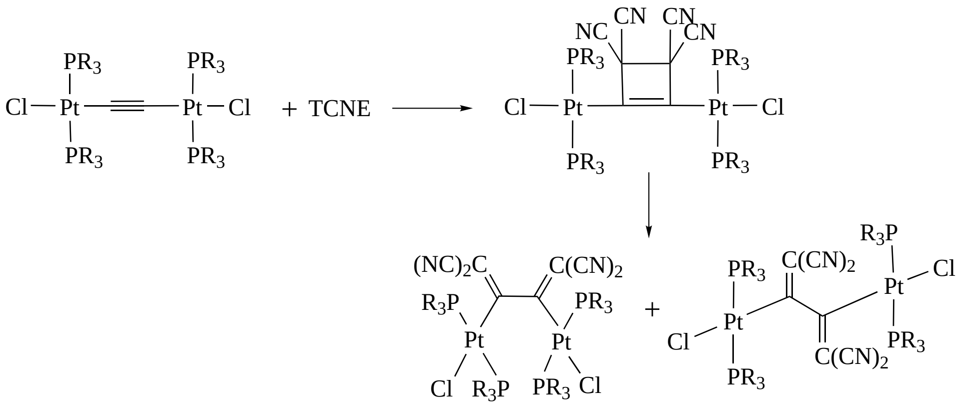
Scheme 25

achieves the extension of the poly-yne units. With use of both reactions, dinuclear complexes with the carbon-rich chain of C_8 or C_{12} are formed (Scheme 25).[37] By coupling of dialkyne, a platinocycle (**8**) is obtained.[38] Similar ideas are also used to build large size molecules (see Section 4.2). The yne-bridged unit undergoes coupling with Tetracyanoethylene (TCNE) to give μ-cyclobutene and *s*-cis/*s*-trans butadiene complexes (Scheme 26).[39]

In the photophysical aspect, many platinum acetylides exhibit a luminescent property. The photo- and electrochemical research for such species combines with the structural chemistry to pave a path toward the exploration of molecular opto-electronic devices, and is described in Section 3.3.

3.2 π-Donor Complexes

One of the most famous compounds of the 1990s has to be the fullerene (*see* ***Carbon: Fullerenes***) C_{60} (*see Buckminsterfullerene*). The first synthesized complexes of C_{60} were the mononuclear and the hexaplatinum complexes via π-coordination. The reaction of $(PPh_3)_2Pt(C_2H_4)$ and C_{60} in toluene produced a dark emerald compound, which was found to be $(PPh_3)_2Pt(\eta^2\text{-}C_{60})$ (see Figure 1). Even more interestingly, in a comparable reaction of $Pt(PEt_3)_4$ and C_{60}, a product of multiple addition $[(PEt_3)_2Pt]_6(\eta^2\text{-}C_{60})$ was recovered (see Figure 2). Both complexes were structurally characterized by X-ray crystallography.[40]



Scheme 26

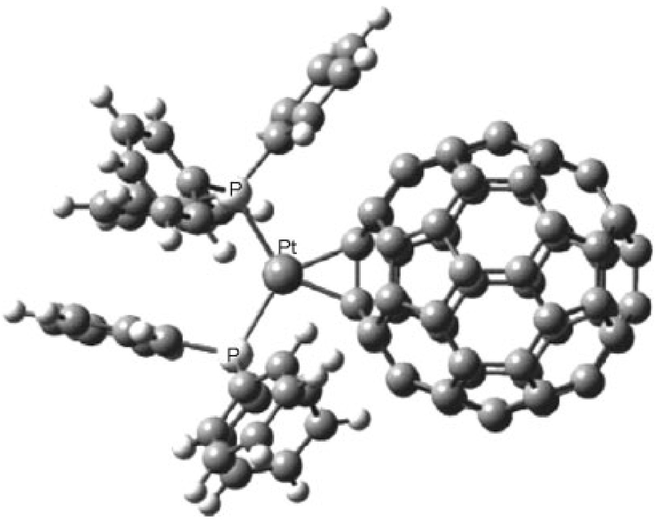


Figure 1 Structure of $[(C_6H_5)_3P]_2Pt(\eta^2\text{-}C_{60})$

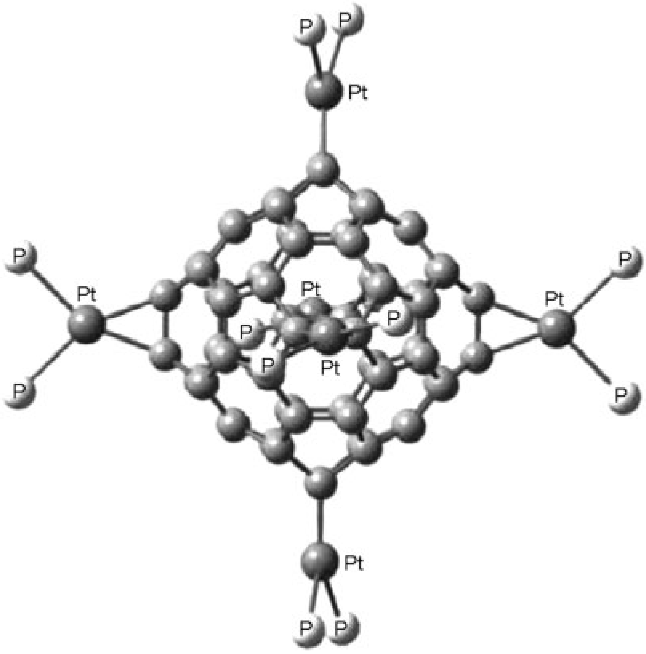

Figure 2 Structure of $[(Et_3P)_2Pt]_6C_{60}$ (The ethyl groups are omitted for clearness)

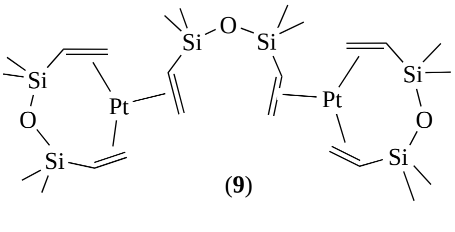
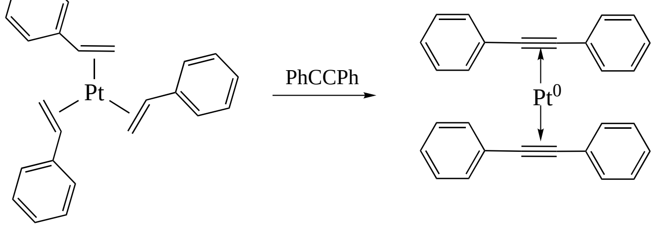
π-Olefin platinum(0) complexes are important starting materials for oxidative addition (*see Oxidative Addition*) or catalysts. Karstedt's catalysts, which are the most active ones for hydrosilylation, have been structurally characterized and found to show the structure of $Pt_2(M^{vinyl}M^{vinyl})_3$ (**9**), wherein M^{vinyl} = divinyltetramethyldisiloxane.[41] A styrene analogue $Pt^0(styrene)_3$ provides a convenient route to get an π-alkyne platinum complex by displacement (Scheme 27).[42] DFT calculations indicate that alkyne in the

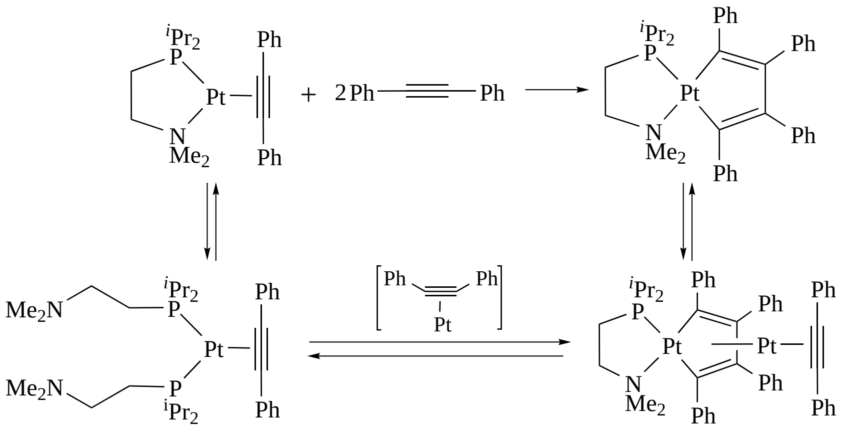


(**9**)

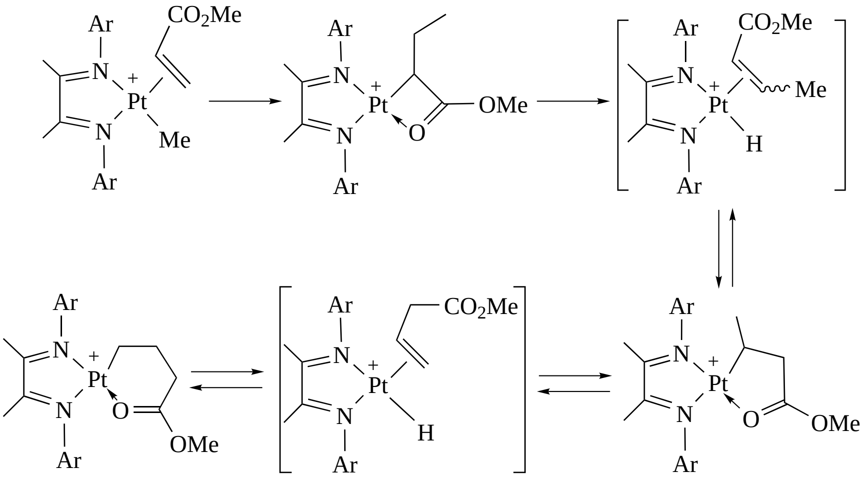


Scheme 27

complexes that have the form of $L_2Pt–C_2H_2$ should be two-electron donor rather than four-electron. The bidentate



Scheme 28



Scheme 29

phosphines can stabilize the coordinated alkene and alkyne better than do the monodentate phosphines.[43] A bidentate aminophosphine ligand is found to promote the alkyne-coupling that may lead to catalytic formation of a benzene derivative (Scheme 28).[44]

Olefin complexes (*see Alkene Complexes*) of platinum(II) are key intermediates in many very important organometallic reactions. However, direct research of well-characterized examples of metal-olefin is relatively rare, because such species are generally unstable. The diimine ligands with bulky substituents at nitrogen can kinetically stabilize the olefin ligands with electron-withdrawing substituents. In a methyl acrylate complex, migratory insertion and β-elimination leading to the formation of cyclometallated isomeric products was monitored by NMR (Scheme 29).[45] This reaction makes a good model for α-olefin polymerization. A similar (N-N)Pt-olefin compound allows the addition-elimination of the Se–Se bond and the measurement for the tunable equilibria, providing valuable reference to catalyzed addition of the main group substrates to unsaturated hydrocarbon (Scheme 30).[46] The Pt(IV)-olefin chemistry for mechanistic (*see* ***Mechanisms of Reaction of Organometallic Complexes***) concerns for alkane activation reactions are included in Section 7.1.

η^2-Alkyne complexes (*see Alkyne Complexes*) of platinum(II) are much more stable than the η^2-olefin complexes. They may be readily transformed to η^1-alkynyl and vinylidene complexes. The coupling of two η^1-alkynyl ligands results in platinacyclopentadiene species.[47] A platinum(II) disilyl(η^2-alkyne) undergoes insertion (*see Insertion*) and reductive elimination (*see Reductive Elimination*) to disilacyclohexene (Scheme 31).[48] Metal-dialkynyls can also play π-donors to form the coordination complexes of various configurations, as shown in (**10–13**) and so on.[49] Such σ,π-bridging modes may have interconversion. Multi- alkynyl complexes can even constitute clusters or higher-order structures.[50]

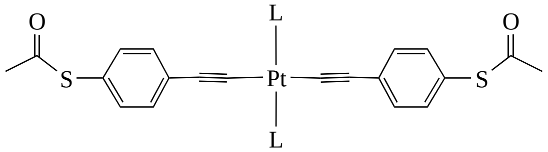
(**13**)

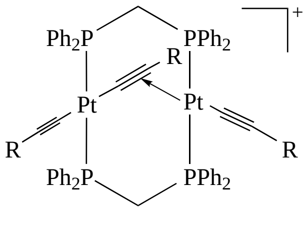
3.3 Organoplatinum with Photophysical Properties

By the end of last century, one characteristic development in chemical research was that chemists were able more efficiently than ever to exploit the synthetic power to assemble molecular devices that exhibited pragmatic properties. Intensive research has been focused on photophysical studies of luminescent materials (*see* ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds***). Alkynyl complexes are one of the most studied systems. For mononuclear dialkynyl complexes in the form of (**14**), the low-energy band ($3.43 \sim 3.51$ eV) corresponding to a $\pi \rightarrow \pi^*$(CCR) transition increases with the ligand σ-donor strength (L = PCy_3 > PBu_3 > PPh_3 > $P(OEt)_3$ > $P(OPh)_3$) (*see* ***Coordination & Organometallic Chemistry: Principles***). These transitions possess charge-transfer character as a result of overlap between π^*(CCR) and metal *p* orbitals.[51] One such compound is successfully fixed between two gold electrodes as a single-molecule electronic junction in a gold-[Pt]-gold setup and shows insulating behavior up to a bias voltage of 5 V.[52]

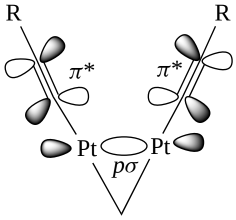


(**14**)

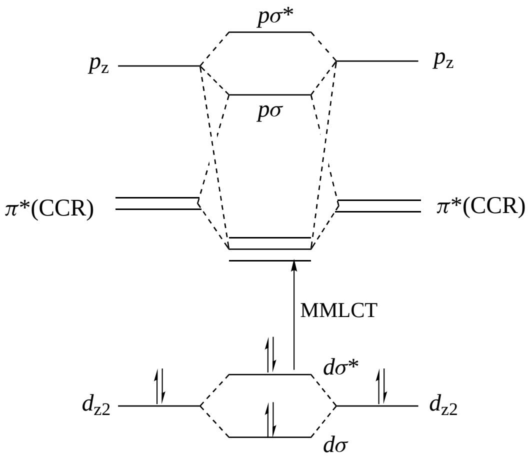
An A-frame dinuclear platinum complex in the form of $[Pt_2(\mu\text{-dppm})_2(\mu\text{-CCR})(CCR)_2]^+$ (**15a**) displays more red-shift lower energy bands than the mononuclear complexes. Such a change is attributed to a metal–metal bond to ligand charge-transfer (MMLCT) [$d\sigma^* \rightarrow p\sigma/\pi^*$(**15b**)] transition ($400 \sim 450$ nm) in the A-frame structure of C_{2v} symmetry, as shown in Scheme 32. The face-to-face complex (**16**) also exhibits intense low-energy bands that involve the MMLCT transition. The coordination of Cu^I or Ag^I with the alkynyl ligands (**17**) would give rise to an increase in the $d\sigma^*$ (Pt) orbital energy, as well as a decrease of the π^* (CCPh) orbital energy, thus leading to further red-shift.[53]



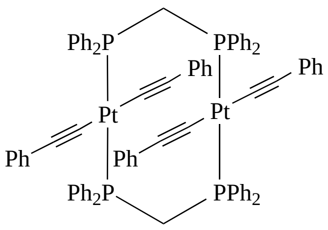
(**15a**)



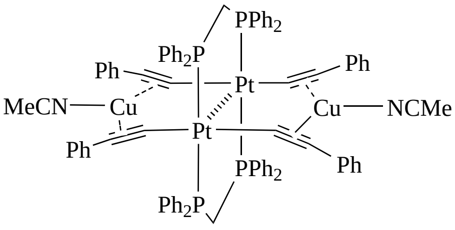
(**15b**)



Scheme 32

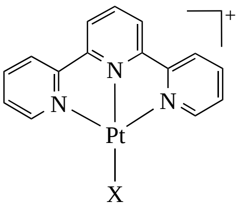


(**16**)

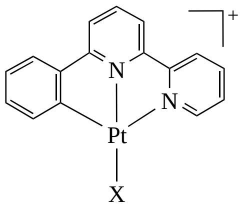


(**17**)

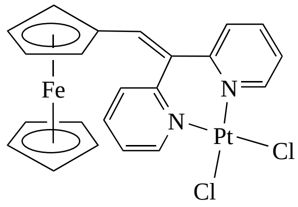
In the same regard, platinum(II) terpyridyl complexes (**18**) earn attention too. For the derivatives with X = Ph, the low-energy bands (460–600 nm) are assigned to formal ^{3}LLCT states that receive substantial contribution from closely lying ^{3}MLCT levels. When X = Me or Cl, luminescence of much red-shift (680–800 nm) is from ^{3}MMLCT owing to metal–metal interactions occurring in head-to-tail dimers or polymers.[54] In a recent study, large solvatochromism of the diynyl complexes (X = C C≡C–C≡CH), presumably due to metal–metal and π-stacked interactions, has been observed.[55] The cyclometallated phenyl bipyridine complexes (**19**) also show tunable excited-state properties, and the dinuclear species can reflect the metal–metal interactions in the [$d\sigma^* \rightarrow \pi^*$] transitions.[56] The electrochemical and spectroscopic properties of the ferrocene-attached (*see Ferrocene*) dipyridyl derivatives (**20**) are found to be strongly influenced upon complexation, indicating the substantial communication of π-conjugation between the ligand and metal.[57] In the bisalkynyl diimine platinum(II) complexes or the related (phen)Pt^{II} derivatives, the Pt $\rightarrow \pi^*$(N-N) MLCT bands dominate the photophysical behavior.[58] The wide tunable luminescent behavior of such complexes has been studied for molecular photochemical devices.[59] The luminescent behavior of organometallic compounds is the theme of the article ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds*** of this volume.



(**18**)



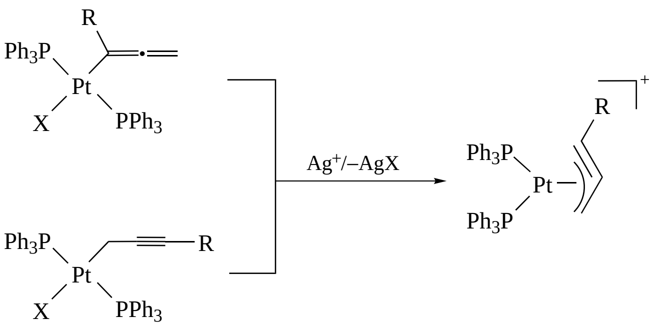
(**19**)



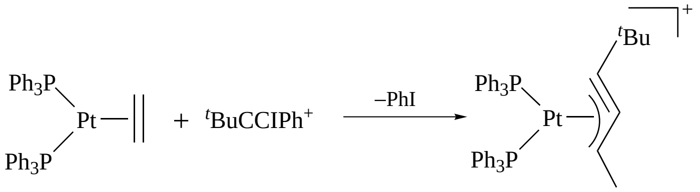
(**20**)

3.4 Complexes with Nonorthodox Bonding

In the polynuclear framework (*see* ***Polynuclear Organometallic Cluster Complexes***), allenyl and propargyl ligands are often bound to the metals with various crossing interactions, which serve to bring the metal atoms into close proximity and stabilize the hydrogen-deficient organic moiety.[60] In the

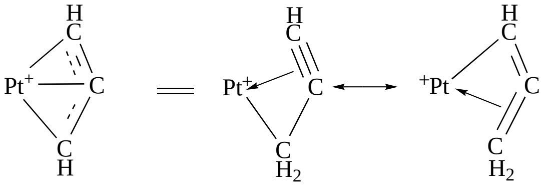


Scheme 33



Scheme 34

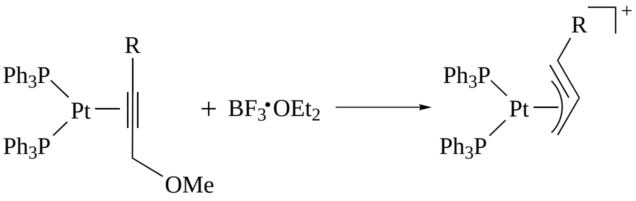
mononuclear complexes, the allenyl and propargyl groups are found to associate to platinum in a resonance structure of η^3-allenyl/propargyl bonding mode (**21**). Halide abstraction either from the η^1-allenyl or from the η^1-propargyl platinum complexes in the form of $Pt(PPh_3)_2(C_3H_2R)(X)$ leads to the formation of cationic η^3-allenyl/propargyl species, as shown in Scheme 33.[61,62] Other synthetic strategies, including insertion of alkynylium (from alkynyl(phenyl)iodonium salts) into Pt-ethylene (Scheme 34)[63] or alkoxy abstraction by Lewis acid from Pt-(propargyl ether) (Scheme 35), provide the same class of products.[64] In the skeleton of PtC_3, the metal is bonded to all three carbon atoms in the same plane. Such a binding form severely distorted the organic moiety to a 145 ∼155° bent shape.



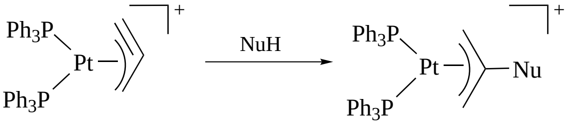
η^3-allenyl/propargyl σ,π-propargyl σ,π-allenyl

(**21**)

The η^3-allenyl/propargyl platinum cations generally exhibit electrophilicity at the central carbon. The unsubstituted η^3-allenyl/propargyl species is particularly reactive and is subject to addition to a wide variety of nucleophiles (*see Nucleophile*). The reactions of the η^3-allenyl/propargyl species with alcohol,



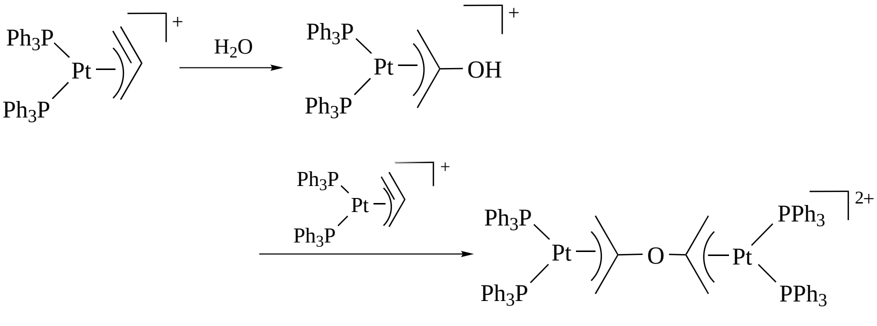
Scheme 35



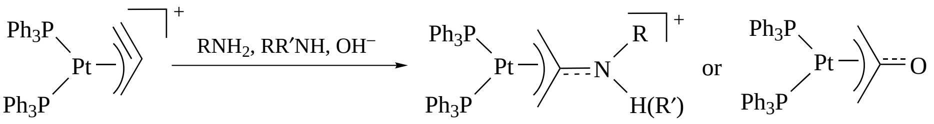
Nu = OR, SR, SeR

Scheme 36

thiol, and selenol result in the formation of central-carbon substituted allyl platinum complexes (Scheme 36). Water that has two active hydrogen atoms undergoes single addition to form a 2-hydroxyallyl and double addition to form a bis(allylplatinum) ether (Scheme 37). Analogous reactions with Group 5 nucleophiles such as primary and secondary amines or with the hydroxide ion yield η^3-aza- or η^3-oxa-trimethylenemethane derivatives, respectively (Scheme 38). The central carbon of the Trimethylenemethane (TMM) derivatives spares its bonding interaction with metal to the

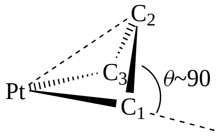


Scheme 37

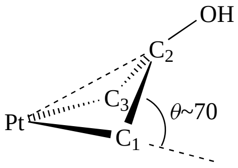


Scheme 38

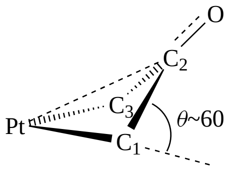
adjacent heteroatom. This is also evidenced by the structural characterization of allyl (**22**), 2-hydroxyallyl (**23**), oxa-TMM (**24**), and platinacyclobutane (**25**). The dihedral angle between the planes of $C_1-C_2-C_3$ and C_1-Pt-C_3 decreases and the bond distance of Pt–C_2 increases with the order (**22–25**).



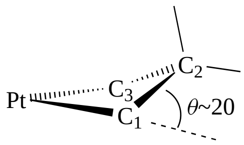
Pt-allyl (**22**)



Pt-2-hydroxyallyl (**23**)



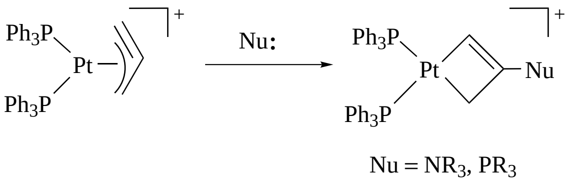
Pt-oxa-TMM (**24**)



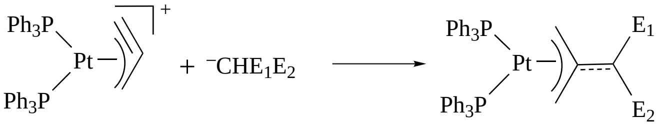
Pt-cyclobutane (**25**)

The reactions with tertiary amines or phosphines that have no active hydrogen atoms result in platinacyclobutene cations, a rare species for late transition metal (Scheme 39). Substituted carbanions are added to the η^3-allenyl/propargyl platinum complex to yield the neutral substituted-η^3-TMM derivatives that undergo further [3 + 2] cycloaddition with good π-acids as TCNE or maleic anhydride to produce highly substituted cyclopentanoids (Schemes 40, 41).

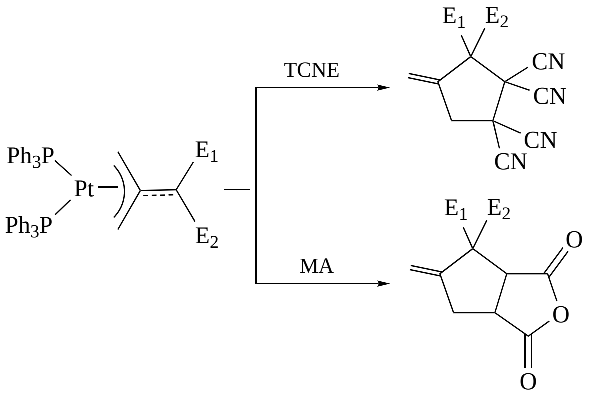
The unsubstituted η^3-allenyl/propargyl platinum complex is such a potent organometallic carbon electrophile that it even reacts with phenol and carboxylic acids, or activates the C–H cleavage in the substituted methanes, alkynes, silanes, enamine, and electron-rich aromatics to form the central-carbon substituted allyl complexes (Scheme 42).[65] Such facile nucleophilic addition (*see Nucleophilic Addition: Rules for Predicting Direction*) could be charge-controlled (*see Charge Controlled Reactions*), and assisted by the presentation of a low lying acceptor orbital on the central atom along the reaction path.[66] A η^3-1-hydroxyallyl complex has been synthesized from an enone complex by treatment with CF_3SO_3H (Scheme 43). The tautomerization of 1-hydroxyallyl proceeds, presumably promoted by triflate anion, to form a keto-coordinating complex.[67]



Scheme 39



Scheme 40



Scheme 41

Dinuclear complexes bridged with dianionic biaryl ligands that exhibit a rare μ-η^3:η^3- bonding mode and can be removed from the complex with stoichiometric oxidants to generate the free biaryls are synthesized via C–H activation and C–C coupling (Scheme 44).[68] Platinabenzenes and its η^3-cyclopentadienyl valence isomer may be prepared from the 2-(cycloprop-2-enyl)vinyl complexes by eliminating the *cis* ligand (Scheme 45).[69] A (cyclopentadienyl)platinabenzene has been obtained in the reaction of [Pt(η^4-cod)Cl_2] (Scheme 46).[70]

Diplatinum complexes with Pt(III)-Pt(III) bonds and quinone-like bridging ligands are prepared from the complex with μ-C_6F_5 group in basic solutions (Scheme 47).[71]

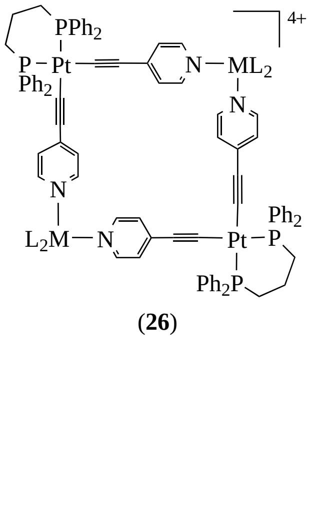
4 CLUSTERS AND MOLECULAR ARCHITECTURES

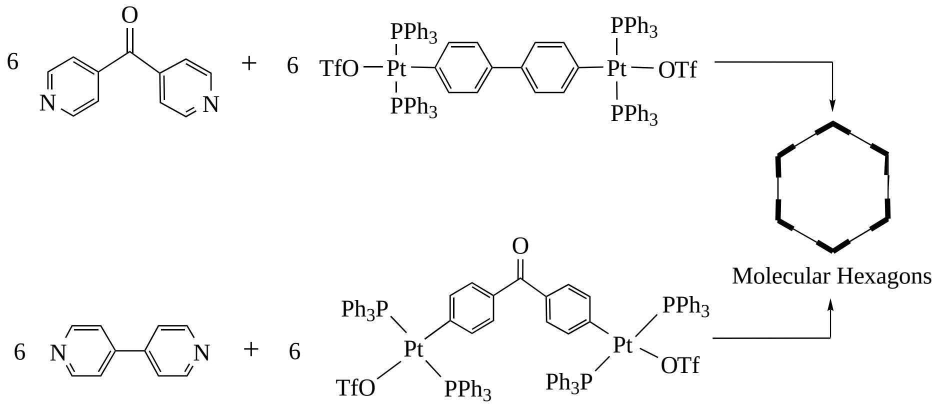
4.1 From Organometallic Clusters to Supermolecules

The previous knowledge in the structural chemistry of organoplatinum plays a crucial role to develop new compounds with a large framework. Conventional bridging ligands such as H, CO, phosphides, and bisphosphines are still used to construct new homo- and heteronuclear metal clusters. With the new synthetic concept, anionic $[Pt_{9\sim15}(CO)_{18\sim30}]^{2-}$ encapsulated in a hexagonal channel could be assembled by ship-in-bottle catalysis of water-gas shift reactions (*see Water Gas Reaction*; *Shift Reaction*).[72] Among the heteronuclear category, platinum mixed with main group metals, such as Hg, Sn,[73] and Ga,[74] are synthesized. $Pt(GaC_5Me_5)_4$ is tetrahedral, and zero-valence is assigned to the central platinum. Beyond metal–metal interactions, ligand design brings versatile linking capability to the architecture of large frameworks. Using such skills, the clusters may be even used as building blocks.

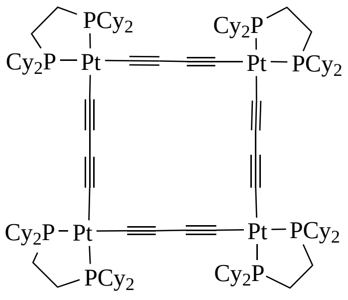
Rational design using coordination as the motif for the construction of supramolecular polygons, polyhedra, and cages has proceeded at a rapid pace.[75,76] Square-planar complexes and linear bifunctional linkages such as alkynyl groups readily serve the building blocks for the molecular squares. Ligand variation affords both the cationic (**26**) and neutral species (**27**),[77] or even chiral assembly (**28**).[78] Such self-assembling processes generally undergo substitution reactions through the designed ligands and coordination.



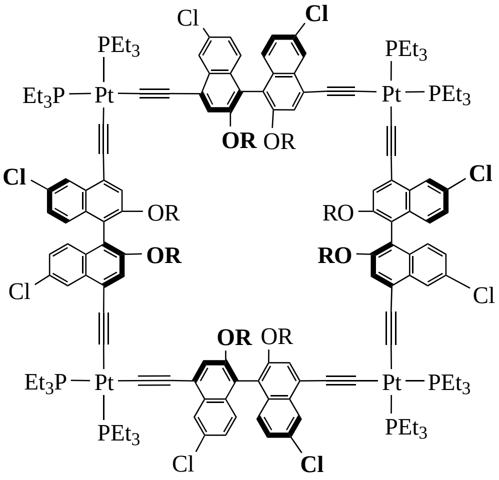
(**26**)



Scheme 48

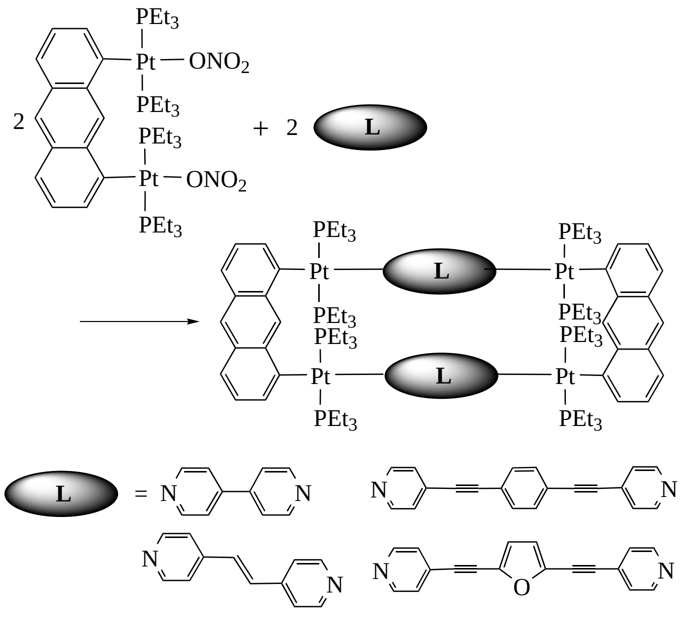


(**27**)

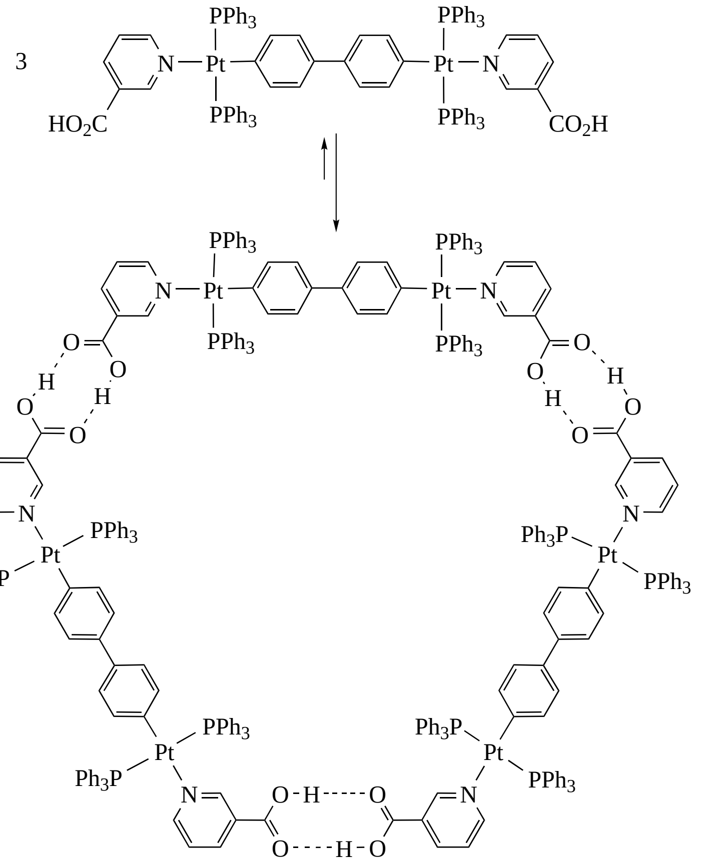


(**28**)

Ketones in 120° sp^2 configuration can give molecular hexagons (Scheme 48). Less symmetric molecular rectangles can be achieved by the reaction of a designed diplatinum clip and linear bridging ligands (Scheme 49). Similar



Scheme 49



Scheme 50

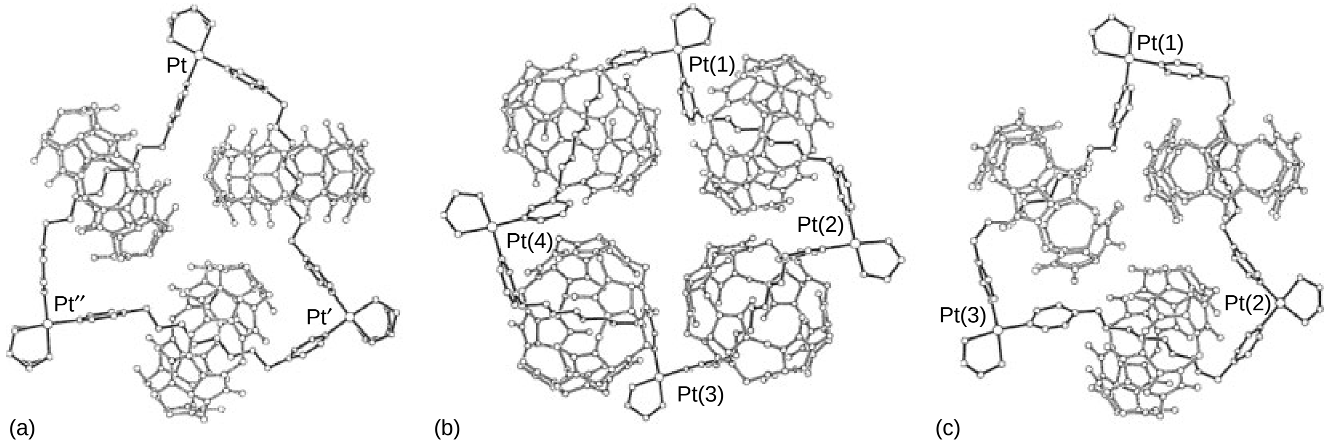


Figure 3 Ball and stick representations for the X-ray crystal structures of molecular necklaces[80]

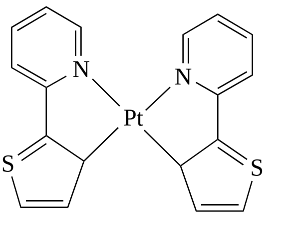
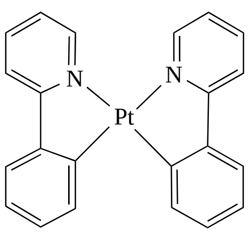
methodology also leads to molecular rings. In addition to metal coordination, hydrogen-bonding also can serve for locking, as shown in Scheme 50.[79] With the idea of rotaxane and the synthetic strategies for the interlocked catenanes, the synthesis for 'molecular necklaces', as shown in Figure 3, was accomplished by using the strings of diaminoalkanes and the beads of cucurbituril.[80] The building block of C_3 symmetry affords the starburst structures and dendrimers.[81] Using platinum clusters as building blocks, a Pt_{18} dendrimer is assembled with alkynyl spacers.[82] Pincer complexes of platinum have been successfully tailored into dendrimers too.[83]

4.2 Polymers Containing Organoplatinum Complexes

Suitable aggregation of molecular organoplatinum may extend to construct oligomeric and polymeric species (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***). A structurally characterized helical chain, as shown in Figure 4, that consists of square-planar cyclometallated complexes (**29a,b**), is connected through a Pt → Ag bond.[84] Conjugated polymers PPE and bifunctional complex [Pt(μ-Cl)Cl(styrene)]$_2$ interact through π-coordination to constitute a three-dimensionally cross-linked network. The photoluminescence of the polymers is efficiently quenched by the Pt(II) coordination.[85] The Pt(0) complexation to PPE shows high charge carrier mobility.[86] Platinum-acetylide oligomers, Ph[CCPt(PBu$_3$)$_2$CCC$_6$H$_4$]$_n$H ($n = 1 \sim 5, 6$), show $^1\pi,\pi^*$ and $^3\pi,\pi^*$ manifolds, indicating the delocalization in both states.[87]



(**29a**)

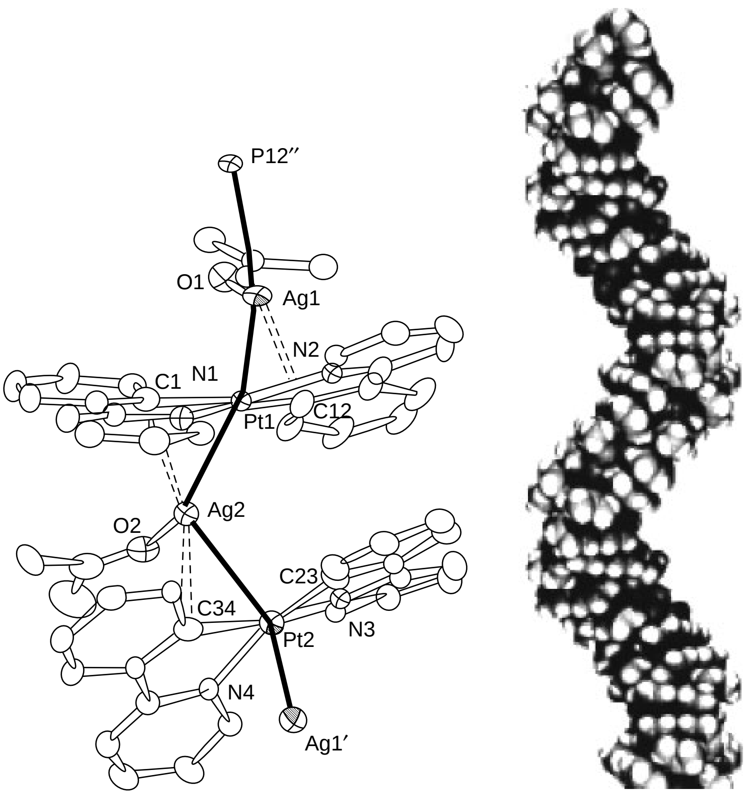


(**29b**)

5 COMPLEXES CONTAINING Pt–Si AND Pt–H BONDS

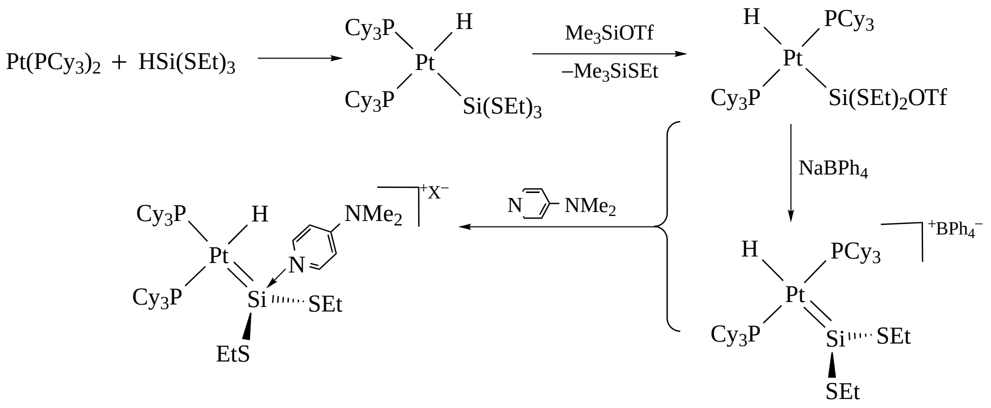
(Phosphinoalkyl)silanes undergo addition to Pt(0) or Pt(II) via Si–C or Si–H cleavage. Such reactions, giving phosphinosilyl metallacycle, are comparable to the cyclometallation (*see Cyclometalation*) in formality.[88,89] Diplatinum μ-silylenes in the form of (**30**) are prepared by the reactions of (R$_3$P)$_2$PtMe$_2$ and (IMP)SiH$_3$ [IMP = 2-^{i}Pr-6-Me(C$_6$H$_3$)].[90] Using steric bulky derivatives such as 2,6-Mes$_2$(C$_6$H$_3$)SiH$_3$, its reaction with Pt^0(PPr$_3$)$_3$ yields (Pr$_3$P)$_2$Pt(H)[SiH$_2$(2,6-Mes$_2$(C$_6$H$_3$))] instead of the dinuclear silylene.[91] Platinum η^2-disilenes in the form of (**31**) has been produced by the reactions of (R$_3$P)$_2$PtCl$_2$ and lithiodisilane, [(^{t}BuMe$_2$Si)$_2$SiLi]$_2$.[92]

Platinum-silylenes are important to numerous transformations involving organosilicon compounds. Base-stabilized Fisher-type cationic silylene complex of platinum(II) may be prepared by anion abstraction from a silyl group, as shown in Scheme 51. The counter anion is crucial

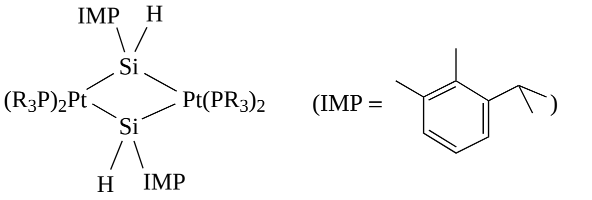


(a) (b)

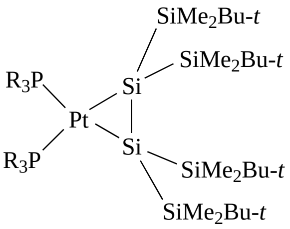
Figure 4 Structure of [{Pt(Phpy)$_2$}$_2${Ag(acetone)}$_2$]$_n$$^{2n+}$[84]



Scheme 51



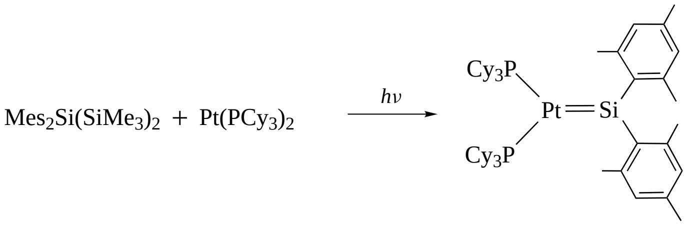
(**30**)



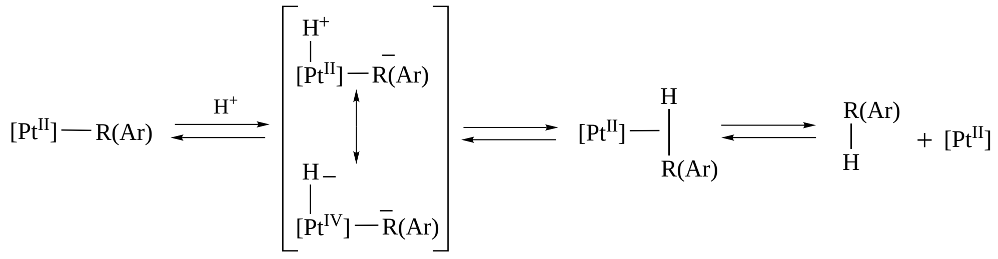
(**31**)

to the intramolecular H-migration from platinum to silicon. In the presence of BPh_4^-, the migration is rapid and irreversible. However, with a triflate counteranion, the migration is slow and reversible.[93] Neutral platinum silylene is generated via photolysis of a mixture of bulky silane $Mes_2Si(SiMe_3)_2$ and $Pt(PCy_3)_2$ (Scheme 52).[94] A series of dinuclear complexes in the general form of (μ-P^P)$(CO)_3(RO_3Si)$Fe–PtL_n has been investigated. In a reaction of $[(dppm)Fe(CO)_3(MeO_3Si)]^-$ with $[(dppm)PtCl_2]$, the product (μ-dppm)$_2(CO)_3$FePtCl[Si(OMe$_3$)] indicates an unusual siloxyl migration from iron to platinum.[95]

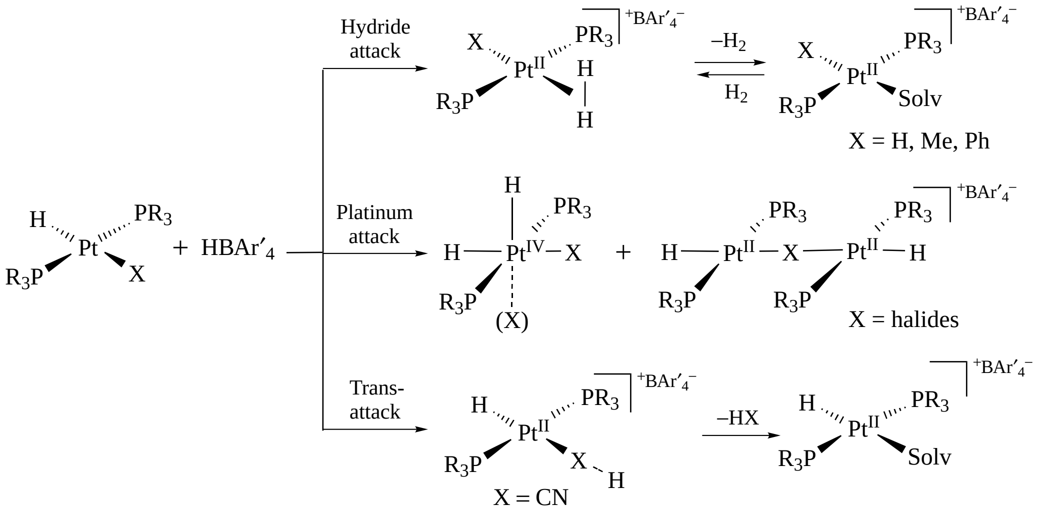
Recent progress in chemistry involving Pt–H bonds is mainly in the Pt(IV) species, which will be described in next Section. Protonation of Pt^{II}-(R or Ar) may achieve a Pt^{IV}-(H)(R or Ar) species that can be interconverted with an alkane (or arene) complex, as shown in Scheme 53, which accounts for why these species are crucial in Pt^{II}/Pt^{IV}-involved C–H activation reactions.[96] A prior study disclosed that protonation of hydridoplatinum(II) of the type *trans*-$(PCy_3)_2$Pt(H)X [X = SiH_3, H, CH_3, Ph, Cl, Br, I, CN, CF_3SO_3] and [*trans*-$(PCy_3)_2$Pt(H)L](BAr'_4) [L = CO, 4-picoline] can take place at three possible sites, that is, H, Pt, or the trans-ligand. The electrophilic attack appears to depend on the Pt-σ adduct strength and the ancillary ligands, as illustrated in Scheme 54.[97] Shilov processes for alkane activation prefer the hard ligands that can stabilize Pt(IV), such as chloride. Thus the success of the Shilov system may be, in part, ascribed to appropriate ligands to access the kinetically more acidic Pt^{IV}-(H)(alkyl) intermediate. Meanwhile, the pathway involving alkane σ-adduct is also possible. As evidence, protonation of a pincer complex (P^C^P)PtH gives a dihydrogen complex (Scheme 55).[98] In contrast, protonation of $Tp'Pt^{IV}(Me)H_2$ in dichloromethane, leading to the formation of a dimeric complex in the form of $[\kappa^2$-((Hpz*)BHpz$^*_2$)Pt(μ-H)$]_2[BAr'_4]_2$, provides a recent example of bridging platinum(II)-hydride. The 3-center-2-electron bond of Pt–H–Pt is analyzed by DFT calculations,



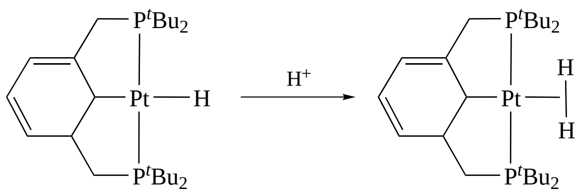
Scheme 52



Scheme 53



Scheme 54



$H^+ = [H(OEt_2)_2](BAr'_4)$, HOTf, $HBF_4\ OEt_2^{\bullet}$

Scheme 55

and is compared with the prior analogs.[99] In a system of Pt^0/Pt^{II}, interconversion between $Pt[P(m\text{-}C_6H_4SO_3Na)_3]_3$ and $(H)Pt[P(m\text{-}C_6H_4SO_3Na)_3]_3^+$ may be simply controlled through variation of the pH of an aqueous solution.[100]

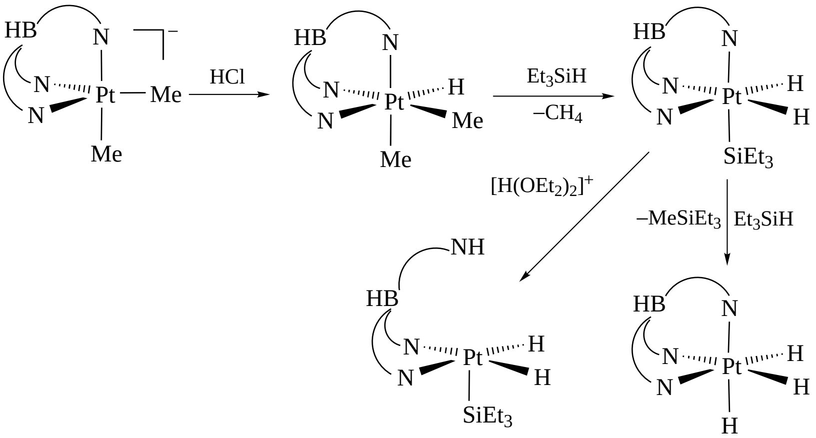
6 ORGANOPLATINUM(IV) COMPLEXES

Platinum(II) species are often known as good electrophiles. However, proper ancillary ligands of nitrogen donors, typically such as phenanthroline (phen) and bipyridine (bipy) derivatives, diimines, and so on, can make the Pt(II) center substantially electron-rich, so that the metal can feasibly undergo further oxidation to the hard electrophiles of Pt^{IV}. On another hand, square-planar 16-electron $platinum^{II}$ complexes make excellent coordination-unsaturated precursors for addition reactions. The +4 oxidation state can be much more stabilized in Pt than in Pd and Ni of the same group. $Platinum^{IV}$ hydrides are of interests as potential intermediates in C–H activation reactions (see Section 7.1) and hydrosilylation (*see Hydrosilation*) reactions as well. These complexes have been known either as stable compounds or considered as short-lived reaction intermediates. The synthetic routes for the formation of such compounds encompass (1) by protonation of organoplatinum(II),[101] (2) by transmetallation (*see Transmetalation*) reactions of organoplatinum with metal hydrides such as Me_3SnH, (3) by the reactions of organoplatinum with water, and (4) by activation of alkane or arene.[102]

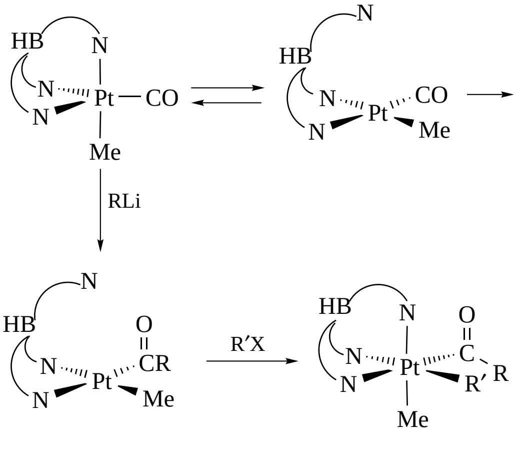
Besides bidentate ligands, tripyrazolylborates (Tp) (*see Tris(pyrazolyl)borates*) derivatives, which are of anionic tridentate in facial configuration, also afford octahedral

Pt(IV) models. Tp′PtMe$_2$H, resulting from the reaction of K[Tp′PtMe$_2$] with anhydrous HCl, is thermally stable.[103] The reaction of Tp′PtR$_2$H and Et$_3$SiH first yields Tp′Pt(H)Me(SiEt$_3$), which transforms to stable Tp′PtH$_3$ in methanol.[104] Treating the six-coordinate Tp′Pt(H)Me(SiEt$_3$) with [H(OEt$_2$)$_2$](BAr′$_4$) leads to the dissociation of one pyrazolyl group to give a stable five-coordinate dihydrido(silyl) complex (Scheme 56).[105] The X-ray crystallography evidences a square-pyramidal geometry. Air-stable TpPtMeH$_2$ is formed by the reaction of TpPt(CO)Me with water (Scheme 57).[106] The reactions of TpPt(CO)Me with organolithium produce acyl or formyl complexes.

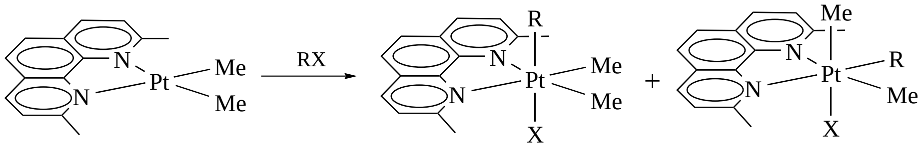
The trialkyl complexes (*see Alkyl Complexes*) of (N-N)Pt^{IV} are typically prepared by oxidative addition (*see Oxidative Addition*), as shown in Scheme 58.[107] The complex (N-N)Pt^{II}Me$_2$ with an imino-cyclohexane ligand, as shown in Scheme 11, undertakes protonation from different acids to give rise to *N*,*N*,*C*-tridentate and *N*,*N*,*C*,*N*-tetradentate chiral aminoalkyl species, respectively (Scheme 59). The chiral selectivity at the aminoalkyl carbon is opposite in



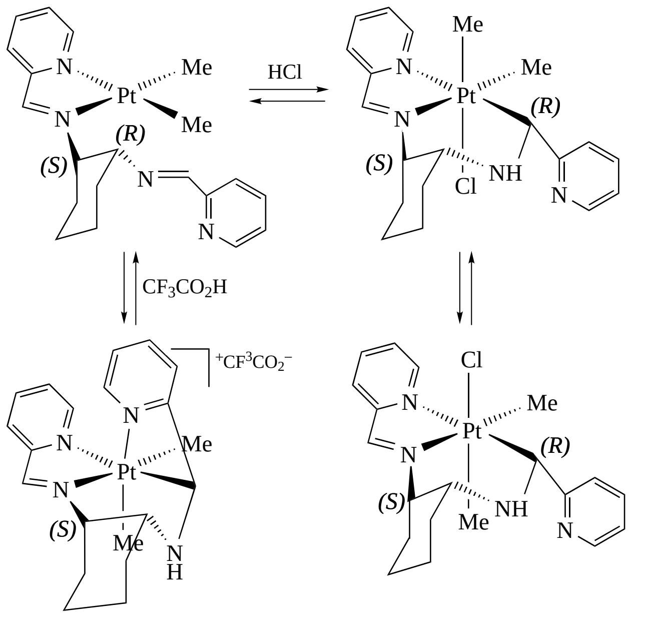
Scheme 56



Scheme 57



Scheme 58



Scheme 59

these two kinds of products, indicating the stereo-control resulting from the ancillary ligand in Pt(IV) may be crucial.[108] In the complexes of (bipy)PtRMe$_2$(Cl), a Pt–Sn bond in platinum^{IV} can be established via insertion of SnCl$_2$ into a Pt–Cl bond.[109] Platinum(IV) complexes with other organic ligands are relatively less studied. TpPtMe$_2$(η^1-C$_3$H$_3$) is prepared by oxidative addition of propargyl bromide to [TpPt^{II}Me$_2$]$^-$ anion. The allenyl-propargyl tautomerization in Pt^{IV} is observed.[110] A complex of Pt^{IV} containing alkyl, alkenyl, and alkynyl ligands attaching to the same metal is obtained by the reaction of a Pt–Sn–Se species with alkyne (Scheme 60).[111] An unusual bis(carbene) platinum is synthesized by the consecutive reaction of bis(arylisocyanide) platinum^{II} with primary amine, followed by cyclometallation (Scheme 61).[112] In a designed tetrakis(azaindolyl)benzene (ttab) diplatinum complex (*see Dinuclear*), the platinum^{II} centers are within van der Waal's distances with the central benzene ring of the ligand. Transformation into a dianionic cyclohexadienyl diplatinum^{IV} complex is observed (Scheme 62).[113]

7 CHEMICAL TRANSFORMATIONS OF ORGANOPLATINUM COMPLEXES

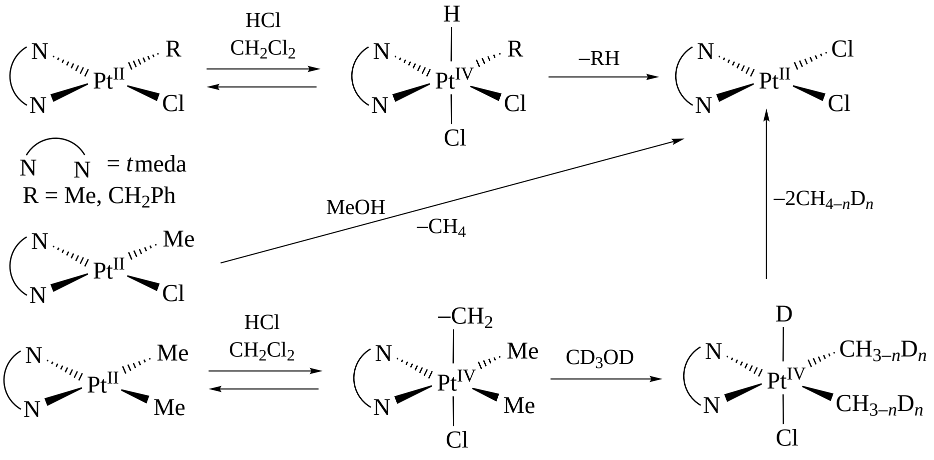
7.1 C–H and C–C Activation

Shilov's catalytic process using a mixture of Pt(II) and Pt(IV) salts for the conversion of methane into methanol and methyl chloride in aqueous solution makes a chemical paradigm for alkane functionalization. One of the new approaches finds oxidative functionalization of methane is catalyzed by a (bipyrimidine)platinum(II) complex in concentrated sulfuric acid at 100 °C.[114] In the reactions of selective functionalization of amino acid, using $K_2PtCl_4/CuCl_2$ catalysts, the formation of amino lactones appears to undergo the C–H activation through Pt(IV) species.[115] Recent extensive research in such a subject concludes the plausible mechanism may comprise the intermediates such as Pt^{II}-alkyl, Pt^{IV}-alkyl, Pt^{IV}-alkyl(hydrido)(oxidative addition adduct) (*see Oxidative Addition*), and σ-alkane adduct, and so on. Of particular interest is that the transformations among such species are expected to enlighten the reaction mechanism for the electrophilic C–H activation.

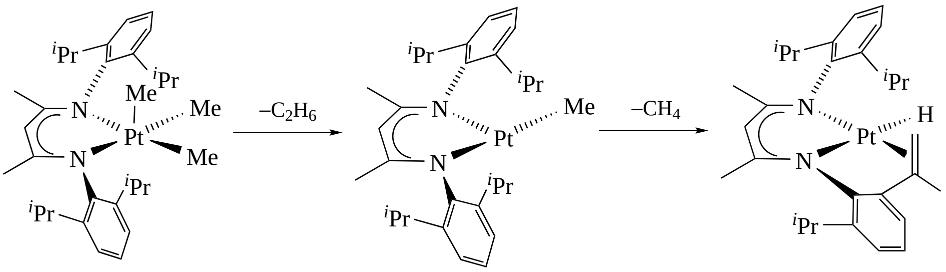
The alkane activation reactions have been observed in several Pt^{II} systems. With a labile coordinating solvent that is not subject to activation itself, such as pentafluoropyridine, $[(tmeda)Pt(Me)(NC_5F_5)]^+$ under 30 atm $^{13}CH_4$ is converted to $[(tmeda)Pt(^{13}CH_3)(NC_5F_5)]^+$ and CH_4, monitored by ^{13}C NMR.[116] Similar methyl exchange in a complex of the type $[(diimine)Pt(Me)(L)]^+$ (L = H_2O, CF_3CH_2OH, MeCN, etc.) is also observed.[117] In both cases, the use of CD_4 resulted in multiple deuterium incorporation into the methane produced, implying the formation of Pt-methane σ-complex intermediate.

By means of studying the protonolysis of various alkylplatinum^{II} complexes (Scheme 63), the microscopic reverse of C–H activation, the different kinetic processes with respect to the variation of the complex and solvent indicate that both the ionic and neutral hydrido(alkyl) platinum^{IV} species are involved, and the alkane σ-complexes account for the results of deuterium scrambling. The deprotonation may undergo these two kinds of intermediates too. The roles of solvent and ancillary ligand are both crucial. Theoretical calculations indicate that the destabilization of ionic species in nonpolar solvent translates to a higher barrier for C–H activation.[118] The kinetic site of protonation is likely at the metal rather than the methyl group, and the reverse deprotonation occurs from Pt^{IV} hydrido(alkyl) according to a comparable study with $(diimine)Pt(Me)_2$ in acetonitrile.[119]

By kinetic investigation in the reactions of reductive elimination (*see Reductive Elimination*) in $[(bpma)Pt(H)(Me)_2]^+$ under high pressure, the measurements of low activation volume for the loss of methane that involves



Scheme 63

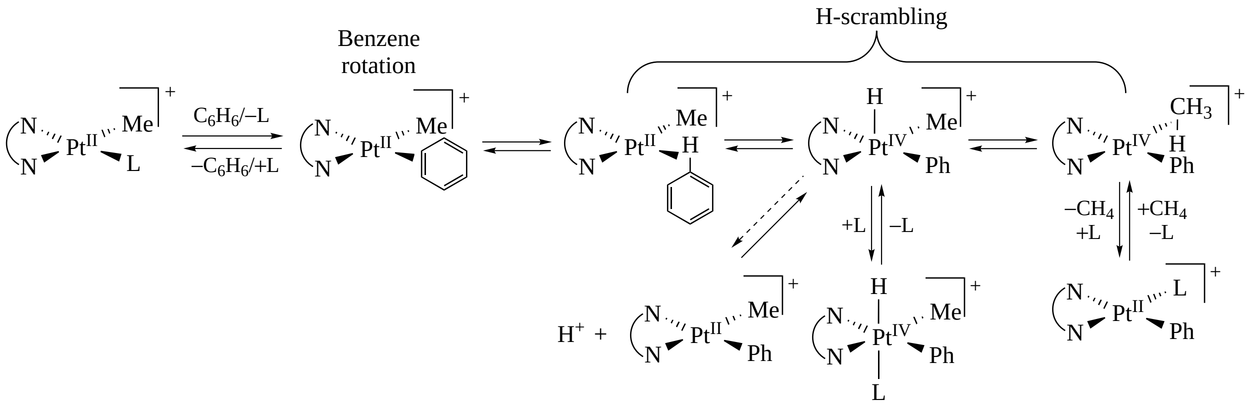


Scheme 64

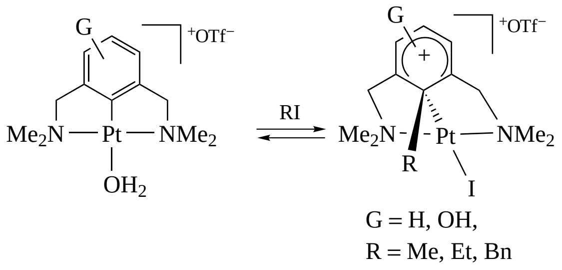
the methyl cis to amine, together with the stereochemistry of deuterium incorporation into the methyl trans to amine, provide the basis for invoking a five-coordinate intermediate via pyridyl dissociation and the Pt-methane σ-complex intermediate.[120] A computational study finds that a preceding ligand loss from the six-coordinate Pt^{IV} complex may facilitate the reductive elimination of alkane.[121] Successful synthesis of a stable five-coordinate Pt^{IV}-trialkyl complex and its conversion into hydrido(olefin) complex via alkane activation indeed echoes the aforementioned mechanism (Scheme 64).[122]

Arene activation reactions are also observed. The better Pt-arene interaction than Pt–CH_4 might be expected to provide additional mechanistic information. The solvent-coordinated cationic complexes $[(N\text{-}N)Pt(Me)(solv)]^+$ (N-N = $[(2,6\text{-}Me_2C_6H_3)N{=}CMe]_2$, solv = H_2O, CF_3CH_2OH) react with benzene to generate $[((N\text{-}N)Pt(Ph)(solv)]^+$. Kinetic and isotope-labeling experiments establish a mechanism that comprises benzene coordination, reversible Ph–H activation, reversible formation of methane-complex, and the dissociation of methane (Scheme 65).[123] For the reactions of benzene with $(N\text{-}N)PtMe_2$, the rate-determining step is C–H bond activation. The kinetic isotope effect as well as the deuterium scrambling patterns indicate that the more sterically crowded ligand such as $[(2,6\text{-}Me_2C_6H_3)N{=}CMe]_2$ switches the rate-determining step to benzene coordination. The electron-rich ligand presumably can ease the displacement of a ligand by benzene, and thus accelerates the C–H activation.[21] Analogous reactions between arene (toluene or xylene) and $[(N\text{-}N)PtMe(OH_2)]^+$ (N-N = $[(2,6\text{-}Me_2C_6H_3)N{=}CMe]_2$) were carried out in CF_3CH_2OH with use of acetonitrile as the trapping agent. $[(N^f\text{-}N^f)PtAr_2]^+$ (N^f-N^f = $[(3,5\text{-}(CF_3)_2C_6H_3)N{=}CMe]_2$) were treated with HBF_4 still using an acetonitrile trap. In both cases, different amounts of the isomeric products $[(N\text{-}N)Pt(Ar)(NCMe)]^+$ were formed. Such a study reveals the dynamic equilibrium between the isomeric $[(N\text{-}N)PtAr(CH_4)]^+$ intermediates and slow exchange between H_2O and CF_3CH_2OH. The coordination of the arene is assumed to be a rate-determining step. Isomeric selectivity is attributed to the five-coordinate transition state structure of $[(N\text{-}N)PtAr(CH_4)(TFE)^+]$ of which the stabilities may be influenced by either steric or electronic factors according to the toluene activation order meta > para > ortho.[124] For the model studies, neutral complex $(dtbpm)Pt^{II}H$(neopentyl) reacts with electron-deficient aryl derivatives to result in reductive elimination (*see Reductive Elimination*) of neopentane as well as the formation of stable $(dtbpm)Pt^0(\eta^2\text{-arene})$ complexes that convert to (dtbpm)PtH(aryl) reversibly.[125]

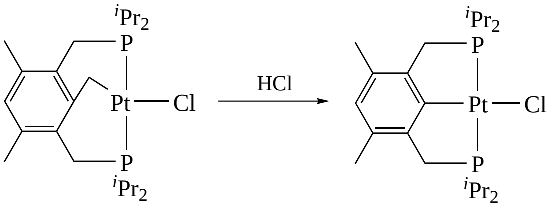
The selective carbon–carbon bond activation under mild conditions is of an essential concern in both organic and



Scheme 65



Scheme 66



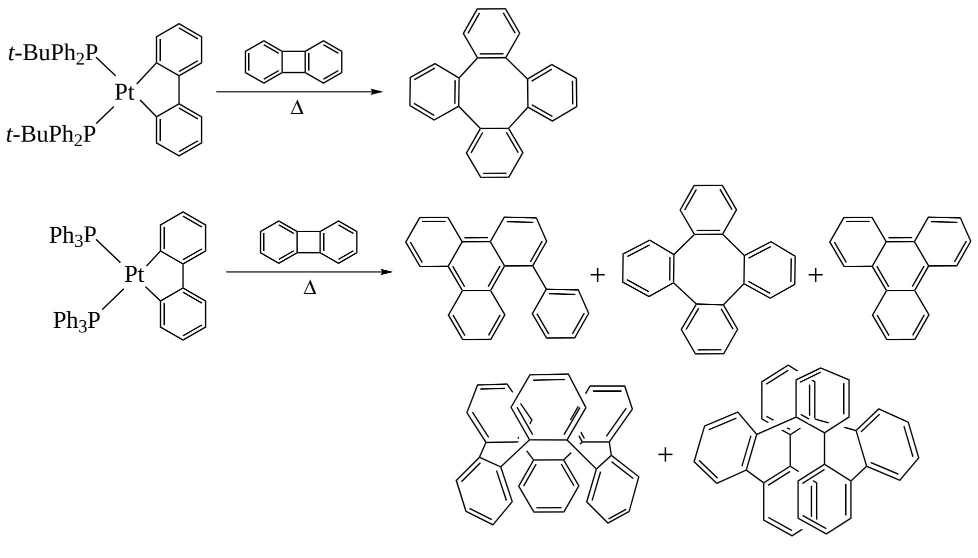
Scheme 67

organometallic chemistry. Platinum involved C–C bond activation such as the reactions of the cationic pincer complex with alkyl halides gives air-stable arenium complexes containing a new C–C bond (Scheme 66). These reactions are analogous to the organic electrophilic aromatic substitution, of which the scope may be broadened with use of the electron-releasing groups on the aromatic ring as activators.[126] A benzylic platinum complex treated with excess HCl results in the loss of MeCl, presumably via an unusual methylene transfer (Scheme 67).[127] Ring opening by relief of strain is a useful route for C–C bond cleavage. The reaction of biphenylene with a series of Pt bisphosphine precursors leads to the formation of phenylene oligomers (Scheme 68).[128]

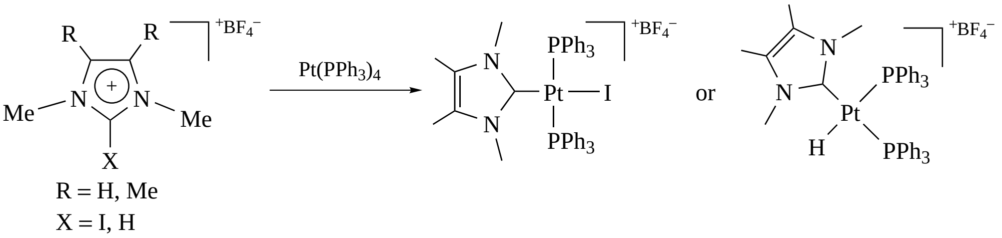
7.2 Fundamental Reactions

In the last decade, two aspects for the study of the oxidative-addition reactions (*see Oxidative Addition*) in organoplatinum chemistry have given rise to the most progress. With regard to oxidation-state change, the reactions of organoplatinum(II) to organoplatinum(IV), particularly with nitrogen-donor ligands, earn the most attention, as described in the previous sessions.[129] Concerning bond activation, the reactions involving main group elements have caused substantial progress. Oxidative addition of imidazolium cation to Pt(0) yields *cis*-aminocarbene complexes (Scheme 69).[130] In addition to conventional C–halide, C–H, and C–C cleavage, the reaction of $Pt(PEt_3)_3$ and $PhSeP(O)(OPh)_2$ at room temperature leads to oxidative addition of P–Se bond to the metal (Scheme 70).[131] The reactions of hydrophosphinylation are established with platinum(0) and phosphinate (Scheme 71). Such reactions are employed for the synthesis of enantiomerically pure *P*-chiral alkenylphosphinates via metal-catalyzed hydrophosphinylation of alkynes.[132] Carbothiolation of alkynes by thioester using Platinum(0) is similarly achieved.[133] The hydridoplatinum-thiolate complex prepared by oxidative addition of ArSH to Pt(0) is found to induce alkyne insertion to form a *cis*-Z stereoisomer of alkenylplatinum-thiolate product (Scheme 72).[134] The substitution reactions may be pragmatic for changing bonds. Si–C bond activation of $ArMe_2SiOH$ was promoted by $[PtBr(PEt_3)_3]BF_4$ and Ag_2O, resulting in aryl transfer from silicon to platinum (Scheme 73).[135]

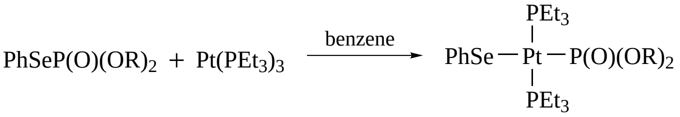
Reductive elimination is one of the most important fundamental bond-forming processes. Kinetic study of competitive



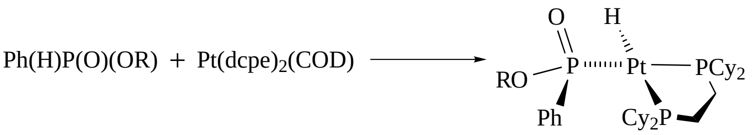
Scheme 68



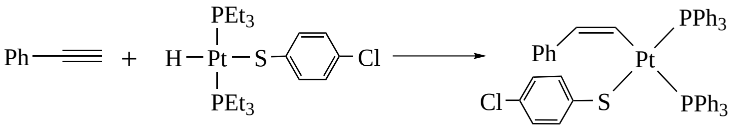
Scheme 69



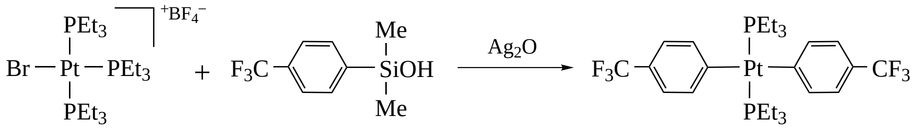
Scheme 70



Scheme 71

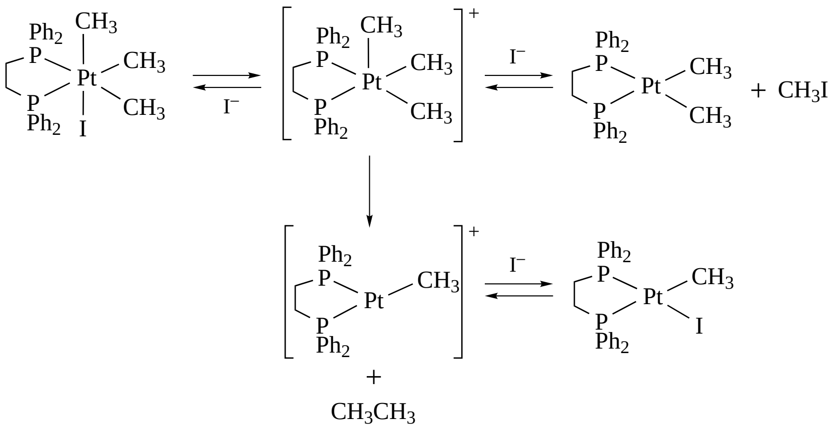


Scheme 72



Scheme 73

formation of ethane and CH_3I from (dppe)Pt(Me)$_3$I indicates that the C–C and C–I couplings undergo two pathways but involve a common cationic five-coordinate intermediate (Scheme 74). The mechanism is likely led by iodide dissociation. It appears that the C–C coupling is thermodynamically favored, but the C–I coupling is the kinetically favored pathway.[136] Analogous reaction of (dppe)Pt(Me)$_3$(OAc) yields CH_3OAc via C–O coupling of the same mechanism.[137] Such reactions represent promising product-release pathways in alkane functionalization involving Pt(IV). In a system lacking a labile ligand such as (P-P)Pt(Me)$_4$, thermolysis that leads to (P-P)Pt(Me)$_2$ and ethane requires more vigorous environments. Kinetic and crossover experiments along with the variation of the bidentate phosphines suggest the five-coordinate intermediate mainly caused by predissociation of one end of the phosphine chelate is essential to reductive elimination.[138] In an electrochemical study for (diimine)PtMe$_2$, homolysis (*see Homolytic Cleavage*) of the Pt–C bond in a short-lived radical cation [(N-N)Pt^{III}(Me)$_2$]$^{\cdot+}$ resulting from one-electron oxidation of the starting Pt^{II} complex in acetonitrile leads to intermolecular methyl transfer, giving rise to the Pt^{II} and Pt^{IV} products of disproportionation.[20] Reductive elimination

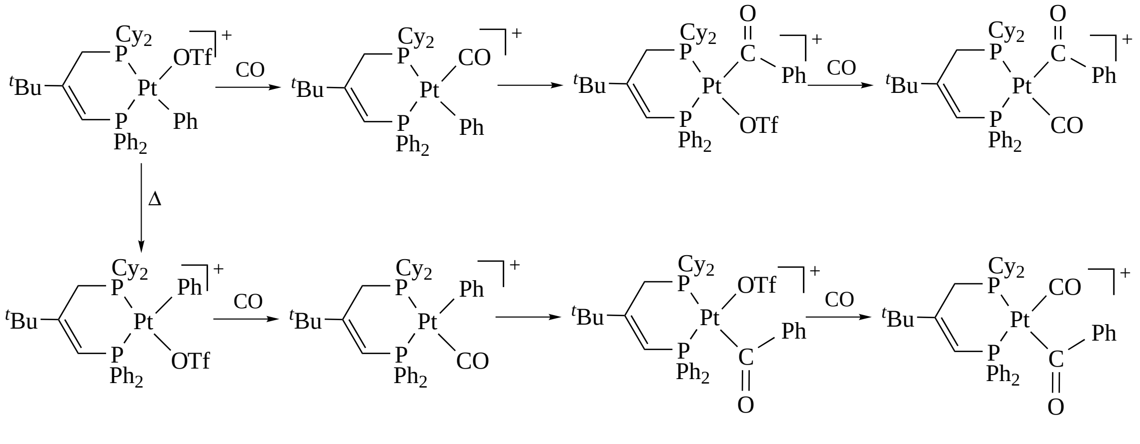


Scheme 74

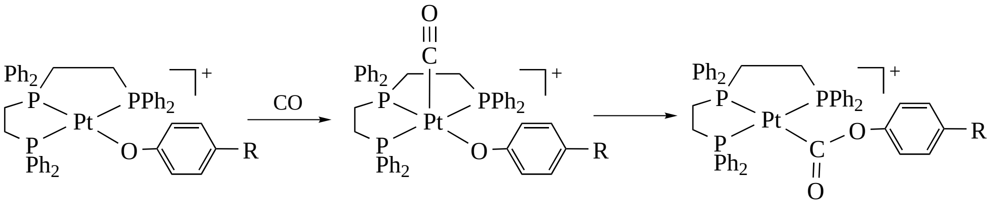
of methane in $[Tp'Pt(Me)_2(H)](BAr'_4)$ is induced by protonation at a pyrazole nitrogen atom. Addition of trapping ligand L to the kinetic products of methane loss gives $[(Tp'H)Pt(Me)L](BAr'_4)$.[139] Therefore, the C–H and C–C activations in different environments need not undertake a common mechanism.

Formation of silanes via reductive elimination in four-coordinate square-planar complex *cis*-$PtMe(SiPh_3)(PMePh_2)_2$ was also examined. A mechanism led by dissociation of $PMePh_2$ followed by CH_3-$SiPh_3$ coupling is evidenced by the kinetic study.[140] In contrast, alkylsilane formation from *cis*-$PtR(SiPh_3)(PMePh_2)_2$, wherein R = Et, or Pr, Bu bearing the β-hydrogens, is found predominantly from *cis*-$PtPh(SiRPh_2)(PMePh_2)_2$, an isomer resulting from the exchange of Pt–R and Si–Ph. Apparently, β-hydrogen elimination (*see β-Hydride Elimination*) of the R group participates in the competition.[141] In *cis*-$Pt^{II}(C{\equiv}CAr)(SiAr'_3)(PMePh_2)_2$, reductive coupling between the silyl and alkynyl ligands without ligand predissociation yields $Pt^0(ArC{\equiv}CSiAr'_3)(PMePh_2)_2$.[142] Again, different mechanisms are undertaken in different environments.

It is generally accepted that carbonylation of metal-alkyl, leading to metal-acyl, proceeds via alkyl migrates from metal to the coordinated carbonyl. However, it is difficult to discern the path of alkyl migration (*see Alkyl Migration*) from CO insertion. This problem may be solved by using an unsymmetric ligand $Ph_2PCH{=}C(t\text{-}Bu)CH_2PCy_2$ (P-P′). Treating (P-P′)$Pt(OTf)_2$ with $BiPh_3$ affords (P-P′)$PtPh(OTf)_2$ in which phenyl is trans to PCy_2. Upon warming to 40 °C, the complex isomerizes to the more stable form in which phenyl is trans to PPh_2. Each of these two species undergoes phenyl migration respectively to form the acyl isomers as shown in Scheme 75, when they are brought into contact with CO.[143] The kinetic study for the reaction of $[Pt(triphos)(OC_6H_4\text{-}p\text{-}R)]^+$ with CO suggests that carbonylation proceeds via a pathway of migratory insertion rather than external nucleophilic attack at the coordinated CO by free or dissociated aryloxide (Scheme 76).[144] The interaction of the lone pair at the aryloxide oxygen with the carbonyl π^* orbital (**32**) is

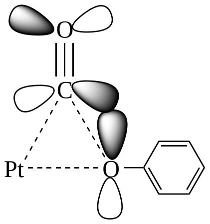


Scheme 75



Scheme 76

attributed in the formation of the C–O bond prior to the complete cleavage of the Pt–O bond.

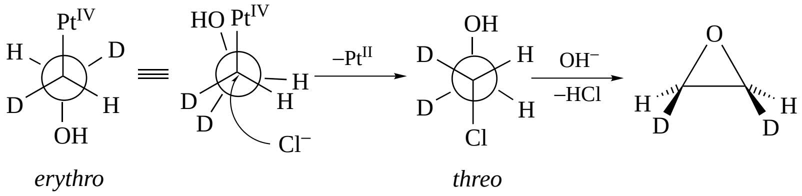


(**32**)

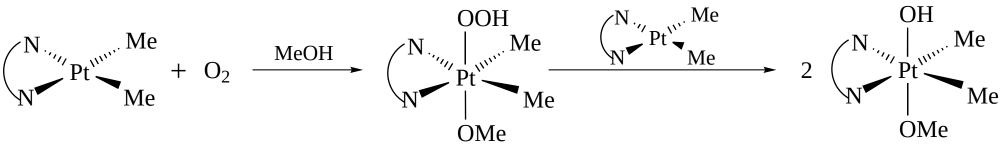
7.3 Ligand Transformations

Nucleophilic addition (*see Nucleophilic Addition: Rules for Predicting Direction*) of the ligands represents a major methodology for organometallic functional transformation. In order to discern how alkane functionalization takes place in aqueous Pt^{IV} systems, a water-soluble platinum^{IV} alkyl, $[PtCl_5(CH_2R)]^{2-}$ (R = H, CH_2OH), is allowed to react with chloride and water. Both kinetics and inversion of stereochemistry support an S_N2 mechanism. Treatment of the *erythreo* isomer of platinum d_2-hydroxyethyl with chloride affords primarily *threo*-ClCHDCHDOH, which is further converted to cis isomer of 2,3-d_2-ethylene oxide, as shown in Scheme 77.[145] The oxidation of (tmeda)$Pt^{II}(CH_3)_2$ to (tmeda)Pt^{IV}(OH)(OCH3)$(CH_3)_2$ by dioxygen in methanol is found to proceed via a two-step mechanism. In the initial step, (tmeda)$Pt^{II}(CH_3)_2$ reacts with dioxygen to yield an intermediate in the form of (tmeda)Pt^{IV}(OOH)(OCH3)$(CH_3)_2$, which successively reacts with a second equivalent of (tmeda)$Pt^{II}(CH_3)_2$ to afford (tmeda)Pt^{IV}(OH)(OCH3)$(CH_3)_2$ (Scheme 78).[146] In the system of Tp′PtH$(Me)_2$, insertion of dioxygen into a Pt–H bond to form Tp′Pt(OOH)Me_2 in benzene has been observed. The hydroperoxo complex has been crystallographically characterized.[147] Insertion of sulfur dioxide into a Pt–C bond of (dcpe)$Pt^{II}(CH_3)_2$ affords (dcpe)$Pt^{II}(SO_2CH_3)(CH_3)$ in quantitative yields under mild conditions. The inserted species is found inert to reductive elimination (*see Reductive Elimination*).[148]

The platinum^{II} complexes with water-soluble bidentate phosphine ligands catalyze the hydration of 3- or 4-pentyn-1-ol, leading to the formation of dihydrofuran derivatives. In the reaction of 2-pentyn-1-ol and (dppbts)$PtCl_2$ (dppbts = [(*m*-$NaSO_3C_6H_4)_2PCH_2CH_2)_2$]), a η^1-allenyl intermediate is



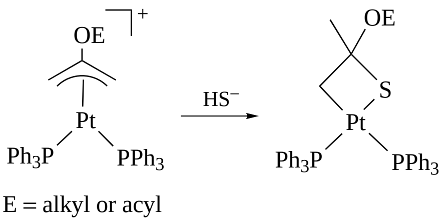
Scheme 77



Scheme 78

characterized. Accordingly, a mechanism involving a η^3-allenyl/propargyl intermediate that undergoes intramolecular nucleophilic attack at the central carbon by the hydroxyl group similar to the reaction of Scheme 37 to achieve the heterocyclic ring closure is proposed. Further nucleophilic substitution releases the dihydrofuran product.[149] The Pt-catalyzed nucleophilic substitution reactions of 2-chloro-2-propenyl ethyl carbonate invoke a three-step mechanism that comprises (1) the formation of η^3-2-chloroallyl intermediate, (2) the formation of platinacyclobutane via nucleophilic addition at the central carbon, and (3) the formation of new η^3-allyl by the elimination of chloride.[150] The regioselective attack of hydrogen sulfide at the central carbon of η^3-2-alkoxyallyl or η^3-2-acyloxyallyl platinum complexes results in a platinathiacyclobutane (Scheme 79).[151] Such reactions are apparently distinguishable from the conventional Pd-catalyzed allyl substitution of which the nucleophilic attack likely takes place at the end carbons. The central-carbon substituted allyl complexes may also be synthesized by insertion of allene into a Pt–R bond.

Several reactions involving organic nitriles introduce nitrogen-containing ligands to platinum. For instance, nucleophilic addition of carbanions to the cationic nitrile complexes of formula $[(bipy)PtMe(NCR)]^+$ yield η^1-imine enol and η^1-enamine complexes (**33**) and (**34**).[152] Addition of nitrones to coordinated organonitriles in Pt^{IV} complex results in [2 + 3] cycloaddition, which leads to the synthesis of oxadiazolines (Scheme 80).[153] Double addition of Si–H bonds in $(PMe_3)_2Pt(SiHPh_2)_2$ to the nitriles produces 3-aza-2,4-disilaplatinacyclobutanes (**35**).[154]



Scheme 79

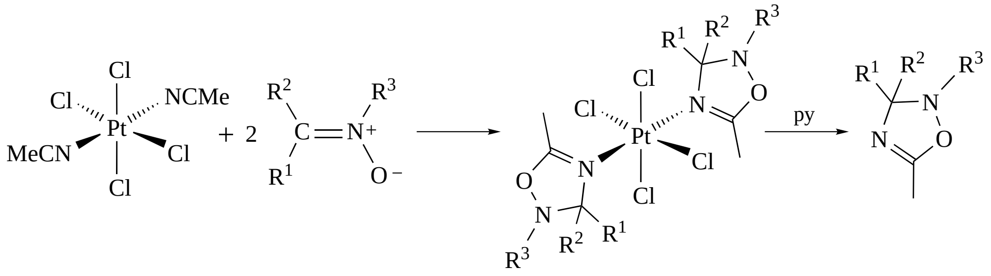
(**35**)

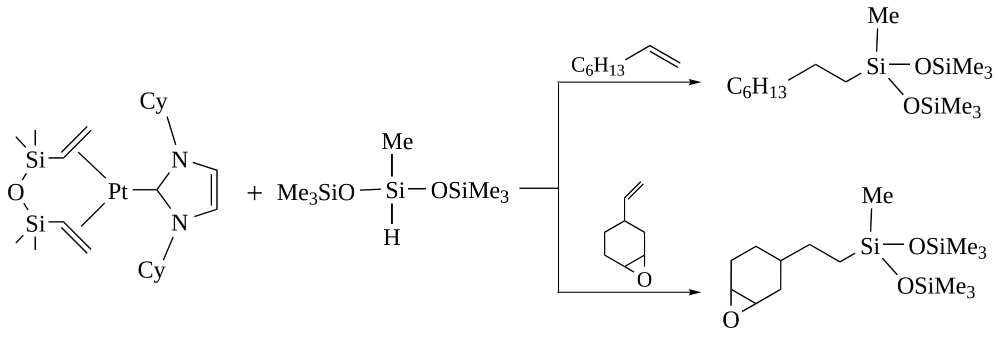
7.4 Organic Synthesis and Catalysis Involving Organoplatinum Complexes

Although the platinum-catalyzed reactions are not as practical as palladium used for the same purpose, several types of unique discoveries still are noteworthy. Besides electrophilic C–H activation, the platinum complexes are efficient catalysts for hydrosilation (*see* ***Hydrosilation Catalysis***) that is important to silicon polymer industry. Platinum carbene catalysts are prepared from Karstedt catalyst (**9**) and imidazolium salts. The trials of model hydrosilylation reactions show very high yields of regioselective products (<1% impurity) with remarkable TON (*see Turnover*) (<30 ppm catalyst load) (Scheme 81).[155]

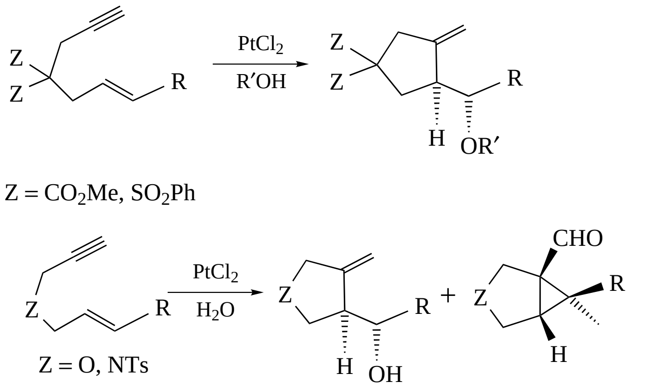
Platinum(II)-catalyzed carbocyclization of α,ω-enynes has been intensively researched lately. For instance, 2-disubstituted 1-en-6-ynes react with methanol in the presence of $PtCl_2$ as catalyst to form carbocycles with exocyclic alkenes. The analogous reactions of 3-allyl propargyl ether or 3-allyl propargyl tosylamine in water using the same catalysts will generate cyclopropyl aldehydes besides the product of cycloisomerization (Scheme 82).[156] The coordination of the



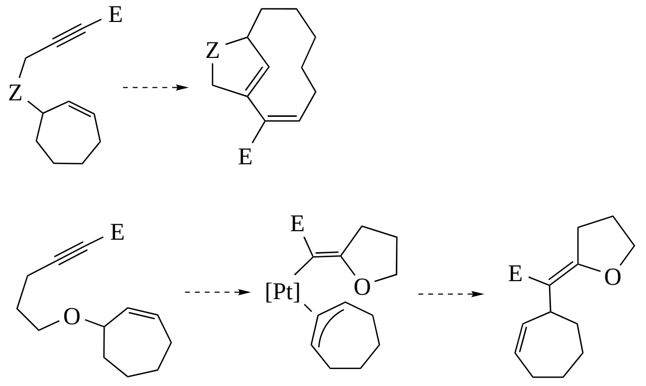
Scheme 80



Scheme 81



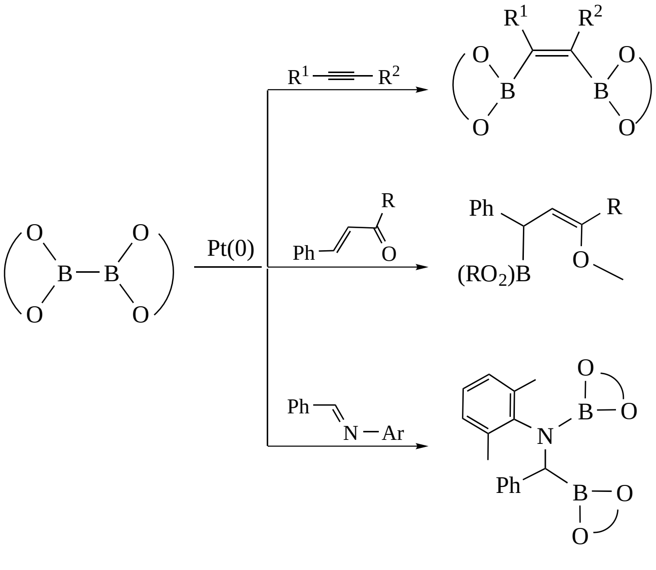
Scheme 82



Scheme 83

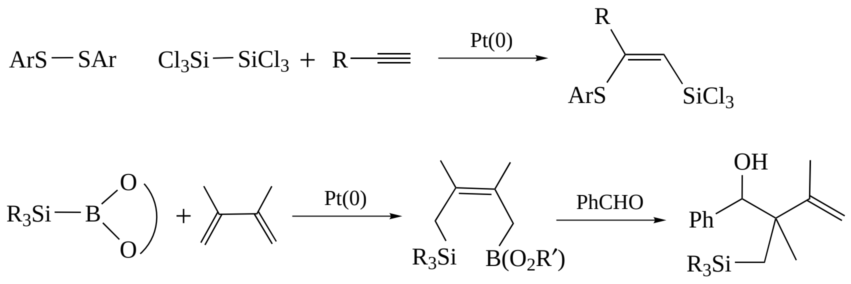
Pt(II) to the alkyne of the substrate likely triggers all these events. The cycloisomerization might undergo a metallacyclic intermediate that proceeds to eliminate β-H. The formation of cyclopropanes is presumably succeeded via alkenyl platinum carbene followed by platina(IV)cyclobutane intermediates. The extension using formal metathesis of the enynes includes two transformations, the formation of 1,3-diene moieties and the stereoselective tetrasubstituted alkene derivatives via O → C allyl shift, both leading to diverse structural motifs and serving as the key step in the total synthesis of bioactive targets (Scheme 83).[157]

For activating the substrates containing main group elements, platinum catalysts are also efficient. Diboration of alkynes catalyzed by $Pt^0(PPh_3)_4$ provides access to isomerically pure cis 1,2-bisboryl alkenes.[158] Diboration to α,β-unsaturated ketones has been accomplished with $Pt^0(C_2H_4)(PPh_3)_2$ as catalyst.[159] Analogous addition to aldimines using the commercially available catalyst $Pt^{II}(COD)Cl_2$ gives rise to α-aminoboronate esters (Scheme 84).[160] Regio- and stereoselective thiosilylation reactions of alkynes using disulfides and disilanes are catalyzed by Pt(0).[161] Platinum-catalyzed silaborative coupling of 1,3-dienes to aldehydes results in regio- and stereoselective allylation with dienes (Scheme 85).[162]



Scheme 84

Platinum-catalyzed double nucleophilic substitution of 2-chloroallyl acetate, yielding 2,3-substituted allyl derivatives, invokes a central-carbon substituted η^3-allyl intermediate that



Scheme 85

is subject to the preceding nucleophilic substitution at 2-carbon.[163] Such reactions expand the scope of allyl chemistry. Zeise's (*see Zeise's Salt*) dimer $[PtCl_2(C_2H_4)]_2$ was recently applied for ring opening of 1,2-cyclopropanated sugar with O-nucleophiles, demonstrating the effort and possibility of the usage of platinum in biosynthesis.[164]

1 HISTORY AND DISCOVERY

The discovery of this element was one of the crowning achievements during the illustrious career of Mme Marie Curie. In order to appreciate the enormity of her task, it should be recognized that the amount of polonium in pitchblende at equilibrium is of the order of 0.1 mg per tonne. During the course of her investigations with thorium and uranium ores, Mme Curie sought the cause of the unusually high levels of radioactivity, which could not be attributed to the uranium alone. Her separation of this element was based largely on the observation that a highly radioactive precipitate was formed from acid solution with H_2S. The chemical procedures she utilized forced the conclusion that the source of the greater than expected radioactivity was attributable to an element that coprecipitated with Bi_2S_3. Vacuum sublimation of the precipitate brought about a separation of the highly radioactive component. The sublimed material was probably metallic polonium. The methods used by Mme Curie yielded only traces of the new element, and the progress of the separation was followed by measuring the radioactivity. Polonium has the distinction of being the first element whose discovery was made solely on account of its radioactivity.

Most of our knowledge about the chemistry of this element was developed during the period following World War II, primarily from the nuclear energy research establishments of the USA and UK. Hence, references appearing prior to this time are historically complete but scientifically dated. Of recent reviews,[1–8] that by Bagnall[1] and the one in the Gmelin series[5] are the most up-to-date and thorough.

It was not until neutron-rich sources became available that weighable quantities of polonium became available. It can be prepared in milligram quantities by the irradiation of bismuth with neutrons. The reaction which takes place is the following:

$$^{209}_{83}\mathrm{Bi}(n,\gamma)^{210}_{83}\mathrm{Bi}(\beta, 5.0d)^{210}_{84}\mathrm{Po} \qquad (1)$$

Details on the separation procedures can be found in Gmelin.[5]

1.1 Isotopes of Polonium

Naturally occurring isotopes of polonium are formed during the radioactive decay of ^{238}U (^{218}Po, ^{214}Po,^{210}Po), ^{232}Th (^{216}Po, ^{212}Po), and ^{235}U (^{215}Po and ^{211}Po). In addition to these seven naturally occurring isotopes, at least 20 additional isotopes of this element have been prepared by the particle bombardment of various bismuth and lead isotopes. However, the isotope ^{210}Po has played the major role in adding to our knowledge about the chemistry of this element.

2 INORGANIC CHEMISTRY OF THE ELEMENT

2.1 Metallic Polonium

Polonium is a member of the oxygen group of elements and has the electronic configuration [Xe]$4f^{14}5d^{10}6s^26p^4$. In this group, there occurs the transition from the typical nonmetals (oxygen and sulphur) to the metalloids (selenium and tellurium) and the metal (polonium).

Solutions containing the metal, most commonly in nitric acid, will deposit the metal on a platinum electrode by electrodeposition. Polonium metal is deposited spontaneously from such solutions on to metals such as silver or nickel. The metal can be sublimed off such support metals at low pressures. Thermal decomposition of polonium sulfide also yields the metal. In much the same way as tellurium, the metal can be obtained from its solutions by the action of reducing agents such as hydrazine, tin(II) ion, titanium(III) ion, and dithionite. Such metal precipitates appear as gray-black powders. Thin foils, silvery in color, have been prepared by vacuum sublimation of the metal.

The metal is soft and has properties similar to those of bismuth. It melts at 254 °C and boils at 962 °C. Two allotropic crystalline forms are recognized, the low-temperature α form and the high-temperature β-form. The α form crystallizes in the 0^1_h space group and the β-form in the $D^5{}_{3d}$ space group.

The metal has been found to diffuse easily into support metals and considerable research has been reported in this area. X-ray and optical spectra have been measured and numerous reports appear in the literature.

A Japanese patent[9] describes the treatment of metal surfaces with amorphous layers of second metals having a thickness of 0.2–2.5 µm. The metal component includes one, or more, of the following: V, Nb, Ta, N, P, As, Sb, Bi, Cr, Mo, W, S, Se, Te, and Po. The introduction of such a surface coating is claimed to improve wear and burning resistance of the metal. Also, the coating serves to increase the retention of oil films by the metal surface thus improving lubrication properties.

The deposition of polonium on metal wires gives rise to a useful α-source.[10] Tips of metal wires having a length 10 mm and a diameter of 0.2 mm were utilized. They were made of Al, Ni, Pd, Pt or Au. Each was immersed in 100 µl of a solution containing ^{210}Po (300 Bq ml^{-1}) for 15 h at 27°. Alpha particle emission was measured using a liquid scintillation system. There was an observed diminution in the α-pulse spectra for all of the wires except Al. This was attributed to the mutual diffusion between the wire metal and ^{210}Po. The ^{210}Po deposited on the Al wire had a tendency to be eluted with the liquid scintillator. This was attributed to physical absorption on the porous metal oxide layer on the A1 wire and ^{210}Po. The ^{210}Po deposited by the Al wire had a tendency to be eluted with the liquid scintillator. It was possible to prepare a ^{210}Po -A1 wire as a useful α-source by heating at 120° for 30 minutes.

The thermochromatography of trace amounts of a number of elements including Po, Am and Cf in their elemental states was studied.[11] The deposition temperatures suggest the existence of different types of intersection between the adsorbate atoms and the Ti surface. The technique is presented as having practical analytical applications.

The crystal structures of α- and β-Po metal were redetermined.[12] An isotopic mixture of ^{208}Po and ^{209}Po was used. The structure was determined in a helium atmosphere from x-ray powder diffraction patterns. Previous reports were considered unreliable because of the growth of Pb at a rate of 0.5 percent per day and self-heating effects. Because of the longer half lives of ^{208}Po, 2.8 years and ^{209}Po, 103 years, the growth rate of Pb and the self-heating are greatly reduced. α-Po possesses a simple cubic space group Pm3m with a equal to 3.359 ± 0.001 Å and d 9.142. β-Po possesses a rhombohedral space group R3m with a 3.868 ± 0.001 Å α 98°14.4′ and d 9.392.

Weighable amounts of ^{210}Po were produced by the irradiation of ^{209}Bi with slow neutrons.[13] An aqueous solution of 2×10^{-3} M Po in 0.8 M HC1 was electrolyzed and Po metal was deposited on precipitated Ag, Ni and Cu. Metallic Po was subsequently electrolytically deposited on Pt. Po metal sublimed at 400° at 1 µ and condensed in the form of a silvery mirror. Po metal dissolves readily in concentrated nitric acid to form a yellow solution. With dilute HNO_3, the metal forms an unidentified white solid. With 2N HCl, a pink solution is formed. In concentrated HNO_3, the Po dissolves as Po(IV) (yellow) which, can be reduced by SO_2, As_2O_3 or hydrazine to form a pink solution, presumably Po(II). The latter, subjected to oxidation by H_2O_2 or Cl_2 reverts to the yellow color. In air, at room temperature, the metal converts to the oxide. The oxide sublimes at 885° at atmospheric pressure, but undergoes thermal decomposition at 900° or at 500° at 1 µ to reform the metal. The oxide dissolves in dilute HCl to form a yellow solution, and in HBr to form an orange-red solution. Evaporation yields $PoCl_4$ and $PoBr_4$, respectively. In HI, the oxide forms a volatile, insoluble black solid. At room temperature the oxide has a face-centered cubic structure, a = 5.687 ± 0.005 Å. It undergoes a phase transformation at 80° to a red, tetragonal form, a = 5.626 ± 0.005 Å. The dioxide has the space group Oh5-Fm3m. The Po-O distance is 2.44 Å and Po(IV) radius is 1.04 Å when the 0 radius is taken as 1.40 Å.

Surfaces coated with Po can be freed of certain impurities such as Pb and Bi.[14] This is accomplished by immersion of the surface in an aqueous solution containing ammonium hydroxide and ammonium persulfate at room temperature for a period of time not exceeding 15 minutes.

2.2 Compounds with Hydrogen

By analogy with the other members of the chalcogen family, the compound H_2Po should be expected to exist. Such a compound has never been isolated in weighable quantities and only tracer-scale evidence has been furnished for its existence. Because of the increasing metallic nature of the elements as one proceeds to the heavier members of a family, such a compound would predictably be extremely unstable. Hydrogen telluride, for example, is itself unstable with respect to its component elements.

Indirect evidence for the existence of H_2Po has been found in measurements of ionization brought about by α radiation from ^{210}Po in an H_2 atmosphere. The very high increases in observed ionization which were observed (no solid window was present between the polonium source and the ionization chamber) were attributed to formation of H_2Po.

More conventional chemical approaches have been used in attempts to synthesize H_2Po. It has been reported to form by the addition of magnesium metal powder to aqueous solutions containing dissolved polonium or by the action of hydrogen generated in situ in such solutions. Claims have been made for the condensation of H_2Po at liquid air temperatures when it is generated by the action of nascent hydrogen on aqueous solutions containing polonium. It appears to be considerably less stable than BiH_3 and is thermally unstable with respect to the elements, decomposing at 34.5 °C. Other claims have been made for the existence of polonium hydride, but it has never been isolated in analytically identifiable quantities.

During the detection of ionization over the range of α-rays from polonium in a hydrogen atmosphere, abnormally rapid increases were observed when no solid window was present between the Po and the ionization chamber.[15] This was not explainable by the volatility of Po nor to the transfer of Po together with the recoil atoms of Ra G. This was explained by the assumption that a hydride, H_2Po is formed, which diffuses into the ionization chamber. Such a compound is rapidly destroyed by a small concentration of air or through the action of α-rays. The formation of such a hydride would explain the very high absorption power of Pt and Pd for Po.

2.3 Oxides of Polonium

The evidence for the existence of PoO and Po_2O_3 is insubstantial. When $PoSO_3$ or $PoSeO_3$, whose own existence

is questionable, decompose, the product formed has been claimed to be PoO, but definitive experimental data are lacking. The synthesis of Po_2O_3 has never been claimed, but it has been speculated that it possesses a cubic structure like that of Bi_2O_3.

Only PoO_2 has been well characterized. It has been prepared by the reaction between the metal and oxygen. It has been successfully prepared using various oxygen pressures and temperatures ranging from 200–700 °C. It has been described as yellow-orange to brick red in color. The color changes from yellow-orange to brick red with increasing temperature and is described as brown-red at 780 °C. PoO_2 sublimes in an oxygen atmosphere, but thermally decomposes when heated at low pressures. The thermodynamic properties of PoO_2 have been measured.

PoO_2 at low temperature, possesses a face-centered cubic symmetry similar to fluorite, but converts into a high-temperature tetragonal form at 80 °C. The two allotropic forms coexist, even at room temperature. This is due to the heat evolved by α particle collisions with the crystal lattice.

Trioxides of sulfur, selenium, and tellurium are well recognized, but polonium trioxide has yet to be prepared in weighable quantities.

Barium oxide undergoes reaction with PoO_2 in an oxygen atmosphere at 900–950° to form $Ba_4Po_3O_{10}$ and $BaPoO_3$.[16] At PoO_2:BaO molar ratios of 0.71–0.77 and 1.04–1.25, the respective compounds are formed. At 1000°, these compounds evolve PoO_2 and Ba_2PoO_4 is formed. The PoO_2 vapor pressure was measured. Vapors of PoO_2 do not undergo reaction with CdO or ZnO at temperatures below 1050°.

Trioxides of lanthanum and gadolinium absorb PoO_2 in an oxygen atmosphere at 850–900°.[17] At a PoO_2:M_2O_3 (M=La,Gd) molar ratio equal to or less than 1.0 the formation of $La_2O_2PoO_3$ and $Gd_2Po_2O_7$ occurs. The vapor pressure of PoO_2 over $La_2O_2PoO_3$ and $Gd_2Po_2O_7$ at 820–1010° and 820–1030°, respectively, were measured. Also, the heats of formation of the two reactions were measured. $La_2O_2PoO_3$ undergoes thermal decomposition in vacuum at 440°.

2.4 Hydroxides of Polonium

The addition of alkali to an aqueous solution of Po^{II} in hydrochloric acid produces a precipitate, described as dark brown in color. This may be the hydroxide or hydrated oxide of Po^{II}. The substance has never been analyzed and very rapidly converts to Po^{IV}.

Our knowledge about the properties of polonium compounds requires that the chemistry be carried out on freshly prepared solutions since radioactive decay leads to the formation of lead isotopes upon standing. Thus, the addition of hydroxide to solutions containing Po^{IV} yields pale yellow wooly precipitates. It is well known that the acidity of hydroxides decreases as the atomic weight increases within a group. This is especially true in the case of Group 16 elements. The solubility of weighable amounts of the hydroxide of Po^{IV} has been measured as a function of the hydroxide concentration. The solubility is linear, with a slope close to two and can be described by the equation:

$$PoO(OH)_2 + 2OH^- \longrightarrow PoO_3^{2-} + 2H_2O \qquad (2)$$

A number of other experiments carried out at tracer level concentrations are consistent with the formation of the hydroxide of Po^{IV} and the polonite ion. Deposits of polonium on gold electrodes are soluble in boiling water and this has been attributed to formation of $Po(OH)_4$. Tracer level ^{210}Po can be precipitated from its aqueous solutions in the presence of $Bi(OH)_3$ or $Fe(OH)_3$ carriers with alkali and is presumably carried as the hydroxide. Tracer level ^{210}Po dissolves in aqueous alkali and the solubility increases with increasing concentration of hydroxide ion. Also, a neutral species, postulated to be $Po(OH)_4$ was identified by paper chromatography.

A method is described for the determination of α-radioactivity in groundwaters.[18] The α-emitters, Po, Ra, Th, and U are precipitated as the hydroxides with NH_3 using Ba (II) and Fe (II) as carriers. The overall yield for all emitters is greater than 80%. Greater sensitivity is achieved with a large sample volume.

A method very similar to that just described is utilized for the analytical determination of ^{210}Pb and ^{210}Po.[19] The two isotopes, in water samples, are concentrated by coprecipitation with iron (III) hydroxide at pH 9–10 using ammonia as the precipitant. The precipitate is redissolved using H_2O_2 and HCl. The isotopes, in samples from soils, sediment algae, or shellfish are leached out at 250° with HNO_3/HF, $HClO_4$, and HCl. An aliquot of the leaching solution is used for ^{210}Po determination, which is carried out at 85–90° for hours by suspending a silver disk in a hydrochloric acid solution at pH 1.5 and containing hydroxylamine hydrochloride and sodium citrate. No preliminary separation is required and the ^{210}Po recoveries are essentially quantitative.

A linear free energy relationship is used to predict the Gibbs free energies of formation of crystalline phases of PoO_2 and $Po(OH)_4$.[20] It is necessary to know the thermodynamic properties of the aqueous tetravalent cation, Po(IV). Details on the form of the equation used are given. The relation is used to predict the Gibbs free energies of formation of the crystalline phases as well as thermodynamically unstable phases. Use of the equation requires that the energy of formation of Po(IV) is known.

An improved method for the analytical determination of Po has been described.[21] The method involves the precipitation of $Fe(OH)_3$ on polyacrylic fibers. This matrix serves as a column upon which ^{210}Po is deposited or coprecipitated with the iron. The research presents details of the technique including ^{210}Po data for Po in coastal waters. The method is described as simple, adaptable, and reliable.

A Japanese patent[22] deals with the analytical determination of Po in the semiconductor industry. Po, in phosphoric

acid solution, is first concentrated and then precipitated, presumably as the hydroxide. The precipitate is utilized as an analytical sample.

A Japanese patent[23] deals with additive coatings on battery cathodes. These coatings include PoO_2. The batteries use cathodes composed of a heat treated lithium compound and MnO_2 together with an additive, MO_2, where M is selected among a number of metals including Po. The mixture is heat treated at 270−380° to give a battery claimed to possess high capacity.

A Russian report[24] deals with the release of ^{210}Po from a Li-Pb eutectic. The eutectic was heated at 450° in a noble gas stream in various concentrations of water vapor. The release of ^{210}Po was measured. The release of ^{210}Po varied with the temperature and the state of the eutectic surface. Polonium in the gaseous phase varied from 5 to 80% of the overall concentration. Interpretation of the data invokes the formation of chemical compounds between polonium and lead as well as the formation of hydroxides of polonium.

2.5 Sulfides of Polonium

Because ^{210}Po is the daughter of ^{210}Bi, and because it has been produced by the neutron irradiation of ^{210}Bi, an established procedure for its separation has involved its precipitation from acid solution with H_2S. Measurements of the radioactivity indicated that the precipitation was essentially quantitative. Suggestions that the precipitate was Po_2S_3 did not survive the scrutiny of experiment.

Evidence for the existence of PoS is much stronger. Aqueous solutions in HCl containing Po^{II} and Po^{IV} yield a precipitate of PoS. During the course of this reaction, Po^{IV} is reduced to Po^{II} with the concurrent oxidation of sulfide to free sulfur. The same sulfide can be prepared by the reaction between polonium hydroxide and ammonium sulfide. The compound has not been successfully prepared by the direct reaction between the elements.

The biologically mediated emission of Po from a culture solution insulated with a sea sediment extract was observed.[25] The emitted Po compound was considered to be lipophilic because it collected in organic solvents. Microorganisms are responsible for the emission of volatile Po compounds because no volatile compounds of Po were formed in a sterile medium. There exists an argument for the existence of a biotic source for atmospheric Po in the environment, which possibly originates from abiotic sources. The emission behavior of both Po and S in the culture experiments was compared. The chemical form of the emitted Po is not known, but it was emitted with dimethyl sulfide. A volatile Po compound was formed when methylcobalamin was used in the experiments.

2.6 Chlorine Compounds of Polonium

The tetrachloride is the best known and best characterized of the binary polonium halides. It has been prepared in a number of ways. The direct action of chlorine at 200 °C on the metal, the reaction between PoO_2 and CCl_4 vapors at 200 °C, and the evaporation to dryness of solutions containing Po^{IV} in aqueous HC1 under a CCl_4 atmosphere have all been reported to yield the tetrachloride. It has been described as a bright yellow solid which when heated in a sealed tube undergoes a series of color changes. It becomes a straw-colored liquid at about 300 °C and turns scarlet at 350 °C. It can be sublimed at low pressure and at temperatures below 210 °C. Under an atmosphere of chlorine it turns purple-brown at 400 °C and then blue-green at 500 °C. Under an NH_3 atmosphere at 100 °C it converts to ammonium hexachloropolonate, $(NH_4)_2PoCl_6$.

Like $TeCl_4$, it hydrolyzes readily in the presence of moisture. It is moderately soluble in a number of alcohols and ketones. Also, in the manner of $TeCl_4$, it forms bright yellow solutions in aqueous HCl, which suggests the formation of the hexachloropolonates. The formation of $PoCl_6{}^{2-}$ in 12.2 M HCl is highly probable, but not definitive.

The action of some reducing agents, specifically SO_2 hydrazine, or arsenite, reduces solutions of Po^{IV} in HCl to pink solutions containing Po^{II}. Not all reducing agents effect this reduction.

The thermal decomposition of $PoCl_4$ at low pressures and at temperatures in the range of 200−250 °C, as well as the reduction of the tetrachloride by hydrogen at 200 °C and the direct reaction between metallic polonium and stoichiometric quantities of Cl_2, have all been reported to yield $PoCl_2$. It has been described as red, orange red, and ruby red in color. It melts above 350 °C and can be sublimed at reduced pressure at 200 °C under a nitrogen atmosphere. Evidence suggests that the addition of a mole of Br_2 forms $PoCl_2Br_2$. $PoCl_2$ is less stable than the tetrachloride and is very readily oxidized to Po^{IV}. Freshly prepared solutions in HCl are pink in color, but they are extremely unstable with respect to oxidation.

Some evidence based on electrochemical investigations has been presented for the existence of Po^{III}, but it is tenuous, at best.

The extensive use of solvent extraction methods and ion-exchange chromatography in the separation of radioactive elements has furnished good evidence for the existence of $[PoH_2OCl_5]^-$ and $[PoCl_6]^{2-}$. The coprecipitation of ^{210}Po with ammonium salts of $PbCl_6{}^{2-}$, $SnCl_6{}^{2-}$, $TeCl_6{}^{2-}$, and $PtCl_6{}^{2-}$ suggests the existence of isomorphism and the formation of $(NH_4)_2PoCl_6$. In fact, with mg quantities of ^{210}Po, a number of M_2PoCl_6 salts have been prepared where M is Cs^+, $NH_4{}^+$, K^+, Rb^+, and $NMe_4{}^+$. The reaction between $PoCl_4$ and NOCl yields a yellow solid, not unequivocally characterized, which may contain $PoCl_6{}^{2-}$ with NO^+ as the counter-ion.

It has been suggested that the white solid formed when $PoCl_4$ undergoes hydrolysis may be the oxychloride, $PoOCl_2$.

The tetrachloride of polonium is prepared by dissolving the metal in hydrochloric acid and evaporating to dryness.[26] $PoCl_4$, is a hydroscopic yellow solid which melts at 300° and is soluble in ethanol and acetone. The tetrachloride can be converted to dichloride, $PoCl_2$, by reduction with sulfur

dioxide or hydrazine. $PoCl_2$ can also be prepared by the thermal decomposition of the tetrachloride in vacuo. Metallic polonium can be deposited electrolytically on a gold foil from a solution containing 65 Mc. of polonium in nitric acid. The electrode potential of the Po/Po (IV) couple is E°, 0.76 volts.

The absorption spectrum of Po in HCl solutions reveals the presence of at least two complexes,[27] A and B. Complex A absorbs with a maximum at 344 mμ. Complex B absorbs with a maximum at 418 mμ. The 418 mμ absorption can be used for the colorimetric determination of polonium. Although the 344 mμ absorption is stronger in weakly acidic solutions, it is difficult to utilize because of chlorine formation brought about by radiation from the polonium. The absorbance of the complex at 344 mμ was estimated by the use of a method involving the log absorbancy curves for the complex and for the chloride ion.

Weighable quantities of ^{210}Po were produced by the irradiation of ^{209}Bi with slow neutrons.[28] The free element was produced by electrochemical deposition on platinum. The Po metal dissolves readily in dilute nitric acid and yields an unknown white solid. The metal oxidizes slowly in air at room temperature, but rapidly at 250−300°. The oxide dissolves in HC1 or HBr to give, respectively, yellow and orange-red solutions. Evaporation of these solutions gives $PoCl_4$ and $PoBr_4$.

An unidentified compound, not polonium hydroxide and presumed to be $PoOCl_2$, was obtained by the evaporation of a dilute hydrochloride acid containing polonium.[29] The residue is soluble in polar organic solvents such as ethanol, ethylene glycol, dioxane, acetone, and methyl ethyl ketone. It is insoluble in benzene or chloroform.

Polonium metal was formed by the reduction of $PoCl_4$, $PoOCl_2$ as well as from the nitrate or the acetate. The solvents involved were hydrochloric acid and polar organics such as acetone, ethanol, and methyl ethyl ether. Mercury served as the reducing agent and a polonium-mercury amalgam is formed.

2.7 Bromine Compounds of Polonium

The tetrabromide of polonium has been prepared in several ways, which parallel those described for the tetrachloride. These include the direct reaction between the elements at 200 °C, dissolution of the metal in aqueous hydrobromic acid solution followed by evaporation, and by the reaction between gaseous HBr and PoO_2. Its existence has been confirmed by chemical analysis.

It has been characterized as a bright red solid, which melts in an atmosphere of bromine at about 325 °C. Exposure to the atmosphere converts it to PoO_2 and, predictably, it hydrolyzes when dissolved in water. Because of the intense α-radiation emitted by polonium, determination of its crystal structure has been difficult due to the resulting disorder.

Like the tetrachloride, it dissolves in aqueous HBr to produce an orange or red solution ($PoBr_6^{2-}$?) and it is soluble in alcohols and ketones, but not in nonpolar organic solvents.

The addition of CsBr to concentrated solutions of $PoBr_4$ in HBr causes the precipitation of Cs_2PoBr_6. This material has been studied crystallographically and shown to possess a structure like that of Cs_2TeBr_6. Crystalline $(NH_4)_2PoBr_6$ has also been isolated.

The preparation of polonium tetrabromide has been achieved in several ways.[23] These include the following:

1. The dissolution of Po or PoO_2 in HBr and evaporating to dryness
2. The heating of polonium in a stream of bromine vapor
3. The heating of PoO_2 in dry HBr

A solution of $PoBr_4$ in $2NH_4Br$, when treated with CsBr, yields a precipitate of Cs_2PoBr_6. The latter is dark red in color and decomposes at 300°. Polonium tetrabromide is soluble in aqueous HBr, ethanol, and acetone. It is highly hygroscopic and on hydrolysis yields a white solid whose composition has not been determined.[30]

Polonium dibromide is purple-brown in color and sublimes at 110° at reduced pressure with some decomposition. It is prepared by the reduction of $PoBr_4$ with H_2S or by heating $PoBr_4$ to 200° in vacuo. The dibromide is soluble in ketones as well as in dilute, aqueous HBr in which it forms a purple solution. In the latter solution, the dibromide is oxidized rapidly to Po(IV).

$PoCl_2$ undergoes reaction with bromine vapor to give a pink solid, probably $PoCl_2Br_2$. At 100°, $PoBr_4$ undergoes reaction with ammonia gas to yield $(NH_4)_2PoBr_6$. This compound explodes at 200° in a sealed tube.

$(NH_4)_2PoBr_6$ crystallizes face-centered cubic, $a = 10.82$ Å, four moles per unit cell, the density is $3.78\ g\ ml^{-1}$. $PoBr_4$ is also face-centered cubic with $a = 5.60$ Å. One Po atom is randomly distributed over a four-fold position.[31]

The Po-Br bonding in $(NH_4)_2PoBr_6$ is described as largely covalent, which is attributed to the Po-Br bond distance of 2.60 Å and a Po(IV) radius of 0.65 Å.

Cs_2PoBr_6 also crystallizes as a face-centered cubic crystal with $a = 10.99$ Å, having four molecules per unit cell and a density of $4.75\ g\ ml^{-1}$. The Po-Br distance is 2.6 Å giving a Po(IV) radius of 0.69 Å. The bonding is described as covalent.

2.8 Iodine Compounds of Polonium

The iodine chemistry of polonium differs from that of the other halogens in that evidence exists for the formation of PoI_6 in a PoI_4-I_2 system at iodine pressures of 30−70 Torr. PoI_4 has been prepared by the direct reaction between the elements, by the reaction between the dioxide and HI, and by the addition of HI to an aqueous solution of $PoCl_4$ in HCl. PoI_4 hydrolyzes in water and it is only slightly soluble in ketones and alcohols. It is soluble in HI with strong evidence for the formation of PoI_6^{2-}, which gives a red-brown solution at room temperature.

There exists no support for the synthesis of the diiodide as a crystalline solid. Its existence has been claimed in studies of

the dissociation of PoI_4 in iodine vapor at temperatures in the 200–315 °C range.

When Po^{IV} ion in nitric acid is treated with HIO_3, white crystals of the iodate separate. The crystals decompose at 350–400 °C, but a satisfactory analysis has not been obtained for this material.

The vapor pressures of lead and polonium iodides have been investigated.[32] The metals were heated in an atmosphere of iodine in a closed system. The pressure of the products was determined by a statistical method. At less than 80 atomic percent iodine, PoI_4 forms in the condensed phase. At 473°K PoI_4 dissociates into PoI_2. Above 80 atomic percent iodine, the condensed phase exhibits the presence of PoI_6. The enthalpy of evaporation of PoI_6 is 116 kj $mole^{-1}$. These experiments suggest that the separation of polonium from lead can be accomplished by their volatization in iodine vapors at elevated temperatures.

The vapor pressures of iodides of polonium were measured in a closed system.[32] Metallic polonium was heated in iodine vapor and the pressures were measured. At iodine concentrations below 80 atomic percent and with increasing temperatures, polonium tetraiodide is formed in the condensed phase. The tetraiodide dissociates into PoI_2 beginning at a temperature of 473 °K. The evaporation enthalpy of PoI_2 is 94.4 kj $mole^{-1}$. At 80 atomic percent the condensed phase exhibits the presence of PoI_6.

The separation of polonium from lead is an important procedure in radiochemistry. It was proposed,[33] based upon studies of the vapor pressure of the iodides of lead and polonium, that polonium diiodide should serve for the pyrochemical separation of ^{210}Po from ^{206}Pb.

2.9 Fluorine Compounds of Polonium

The chemistry in this area is greatly limited. During the period of the Manhattan Project considerable study was devoted to the synthesis of volatile heavy metal fluorides. PoF_6 has been prepared by the reaction between ^{208}Po electroplated on platinum and elemental fluorine. Analytical data were never obtained for the hexafluoride, which is reported to be stable in the vapor phase but disproportionates to the tetrafluoride on cooling.

PoF_4 has not been definitively characterized. Both $^{210}PoCl_4$ and $^{210}PoO(OH)_2$ yield a white solid when they undergo reaction with aqueous HF. This may be PoF_4. The solubility of Po^{IV} in aqueous HF increases with increasing HF concentration and this behavior has been interpreted in terms of the formation of the $PoF_6{}^{2-}$ ion.

No report exists for the preparation of PoF_2.

Theoretical studies on the atomic number dependence of the relative effects on chemical bonding, including polonium, have been carried out,[34,35] for example PoF_6 was investigated. An analysis of bond overlap population using both nonrelativistic and relativistic DV-Xα molecular orbital calculations was performed. The results are compared with those obtained using bond energy calculations.

2.10 Polonium Compounds Containing Nitrogen

No direct evidence has been reported for the existence of a simple binary nitride. The formation of explosive Po_4N_4 has been postulated in studies of the thermal decomposition of $(NH_4)_2PoBr_6$.

Treatment of $PoCl_4$ with aqueous nitrite yields a white, crystalline solid which has been postulated to be a basic nitrite, but no definitive evidence has been presented.

The formation of a white solid formulated as $Po(NO_3)_4{\cdot}N_2O_4$ has been reported by the reaction between $PoCl_4$ or PoO_2 with liquid N_2O_4. At reduced pressure the N_2O_4 can be removed and the tetranite decomposes to $PoO_2{\cdot}3HNO_2$. A similar solvated salt, $PoO_2{\cdot}0.5HNO_3$, has been reported to form when a solution of $PoO(OH)_2$ in nitric acid is evaporated at reduced pressure. Solid $PoCl_4$, when added to aqueous nitrate, forms a basic nitrate, but the normal nitrate has not been isolated or identified from such a reaction.

Although salts containing the anion $[Po(NO_3)_x]^{x-4}$ have never been isolated, solvent extraction studies with ^{210}Po indicate that anionic nitrate complexes are formed in nitric acid solutions which contain the metal cation.

2.11 Oxo Anion Salts of Polonium

Evidence for the existence of sulfites is based primarily on analogies with the chemistry of tellurium. However, no sulfites of polonium have been isolated or characterized. Thus, the reaction of the metal with SO_3 or fuming H_2SO_4 forms a dark red products may be $PoSO_3$. The reaction of PoO_2 with gaseous SO_2 forms a white material which may be the sulfite.

Evidence for the existence of $Po(SO_4)_2$ is stronger. The reaction between $PoCl_4$ or the hydroxide of polonium with sulfuric acid (0.5–5.0 N) yields a white solid identified as the hydrated solid. The solubility of this material increases with increasing acid concentration, which suggests the formation of anionic sulfate complexes. The white solid loses its water of hydration thermally and leaves a purple solid identified as the anhydrous sulfate.

The salts $2PoO_2{\cdot}XO_3$ (X=S, Se) have been reported to form when the tetrachloride or hydroxide of polonium is treated with more dilute acid (0.02–0.25 N). The basic sulfate is yellow in color, while the selenate is white.

The existence of a carbonate is questionable. An aqueous solution saturated with CO_2, when allowed to react with $PoO(OH)_2$, forms a white solid which may be a basic carbonate. The solubility of the solid with increasing carbonate concentration suggests the formation of carbonatopolonate anions.

Although a normal acetate has not been isolated and characterized, the increase in the solubility of PoO_2 with

increasing acetate concentration is taken as evidence for the formation of complex acetatopolonate anions.

The formation of an orange-yellow precipitate when Po^{IV} is added to a 1 M chromate solution is taken as evidence of the formation of $Po(CrO_4)_2$. This precipitate hydrolyzes to form a dark-brown solid whose composition approximates the stoichiometry $2PoO_2{\cdot}CrO_3$.

Both the tetrachloride and the basic oxide of Po^{IV} yield a white, gelatinous precipitate when added to phosphoric acid. Based on elemental analysis, its composition has been given as $2PoO_2{\cdot}H_3PO_4$. The formation of a normal phosphate has not been demonstrated.

No perchlorates of polonium have been isolated.

2.12 Anions Containing Polonium

By analogy with tellurium, which forms tellurides, the existence of polonides should be expected. Soluble tellurides, such as sodium telluride, are extremely sensitive to oxidation. Especially in solution, they revert rapidly to elemental tellurium. Because of its greater metallic character, polonides should oxidize even more rapidly than tellurides. Nevertheless, evidence has been presented for the existence of a number of polonides.

Among the alkali metals, only Na_2Po has been prepared. It has been prepared only at the tracer level by cocrystallization with sodium telluride. Na_2Po appears to be isomorphous with Na_2Te. The preparation was carried by reduction of an alkaline solution containing Po and Te with $Na_2S_2O_4$.

The following polonides have been prepared by the direct reaction between the elements: BaPo (cubic, NaCl structure), ZnPo (cubic, zincblende structure), CdPo (gray, zincblende structure), HgPo (black, NaCl structure), GaPo (orange, liquid at room temperature owing to α-particle stoppage), InPo (blue, low melting owing to α-particle stoppage).

A very limited body of literature exists on the chemistry of polonates. In aqueous potassium hydroxide, the formation of $PoO_3{}^{2-}$ has been postulated based on solubility studies. The fusion of weighable amounts of Po with KOH or KNO_3 is reported to yield potassium polonate. Both Sr_2PoO_4 and $Ba_4Po_3O_{10}$ have been reported to form by the reaction between SrO and BaO with PoO_2 vapor at temperatures of about 900 °C.

The treatment of radioactive waste was studied using the following methods:[36] chemical extraction, cement based stabilization, vitrification, and soil washing. Although the major constituents of interest were radium, lead, and uranium, polonium, because of its radioactivity, was also studied. Among the reagents used for the extraction of radioactive components were hydrochloric, nitric, and acetic acids, EDTA, and potassium chloride solutions. EDTA was found to be the most effective reagent for the extraction of radioactive species. The greatest decrease in radioactivity was noted by sequential extractions using combinations of mineral acids with EDTA or potassium chloride with EDTA.

The average ionic charge of polonium species in chloride solutions was measured using an anion-exchange method.[37] The method is based on measurements of the distribution ratio of polonium at a constant internal chloride ion concentration of the anion-exchanger phase. At 1.0M hydrochloric acid or sodium chloride solutions at pH of 1.0, tracer concentration of Po(IV) exist in the amionic forms $[PoCl_4(OH)]^{-1}$ and $[PoCl_4(OH)_2].^{-2}$

1 INTRODUCTION

The total number of publications that describes organometallic chemistry of polonium makes up one of the smallest segments of chemical literature. The element is very rare; its natural concentration in pitchblende ores is only about 0.1 mg per ton. Twenty-one isotopes are known, all of which are radioactive. Of these, ^{210}Po is most commonly used for chemical purposes because it can be synthesized in milligram amounts from $^{209}_{83}$Bi by an (n,γ) reaction. The $^{210}_{83}$Bi undergoes β-decay (5.0 days) to produce $^{210}_{84}$Po. This isotope has a half-life of about 138 days. Although the isotopes ^{208}Po and ^{209}Po have longer half-lives, 3 years and 100 years respectively, they are not available in practical chemical quantities. Another major difficulty encountered in the synthesis of organometallic compounds of polonium is the fact that the intensity of the α-emission of this isotope brings about a rapid decomposition of organic compounds. Even if polonium were available in macro quantities and its isotopes were stable, another problem would complicate the study of its organic chemistry. This is the fact that carbon–metalloid bonds become thermodynamically less stable as the metalloid becomes heavier. It is well known that organoselenium compounds have a great tendency to deposit elemental selenium upon standing. The deposition of elemental, black tellurium takes place much more readily in the case of organotellurium compounds. It is reasonable to expect that the carbon to polonium bond would be extremely weak.

Because the element is so rare, highly radioactive, and extremely expensive, classical chemical methods cannot be utilized in the study of its organometallic chemistry. Hence, one does not find any published information on the synthesis, physical properties, or spectroscopic characteristics of organopolonium compounds. It would be reasonable to make the assumption that the organic chemistry of polonium should parallel that of tellurium, the element just above it in group 16. Therefore, the identification of organopolonium compounds has relied almost exclusively on chromatographic behavior. Tellurium compounds having analogous chemical structures have been used as reference compounds. Often, ^{127}Te-labeled compounds have been utilized.

A considerable body of published information dealing with the formation of organometallic polonium compounds has evolved from studies of the β-decay products of ^{210}Bi organometallics.

Gmelin[1] presents the most recent and most comprehensive review of this subject. Of the 26 references cited in Gmelin, 18 are authored by Nefedov and his coworkers.[2] The organic chemistry of polonium is also discussed in texts authored by Bagnall.[3,4]

2 ORGANIC DERIVATIVES OF DIVALENT POLONIUM

2.1 Dialkyl and Diaryl Polonides

Among the organometallic derivatives of the chalcogen group, those having the structures R_2M and Ar_2M (M = O, S, Se, Te) are the best known. Dimethyl polonide has not been isolated and characterized. It has been thought to be produced in a number of different reports. The radioactive decay of ^{210}Pb tetramethyl as well as the reaction between sodium telluride–containing polonium and dimethyl sulfate have both been reported to yield some dimethylpolonium. When aqueous solutions containing polonium and acetic acid are electrolyzed, high losses of polonium occur during its deposition at a gold electrode. This has been explained in terms of the formation of methyl radicals, $CH_3\cdot$, which undergo reaction with the deposited polonium to produce a presumably volatile $(CH_3)_2Po$. The methyl radicals are postulated to arise from the decomposition of acetic acid by α-emission from the polonium. In spite of the use of cold vapor traps, no direct evidence for the formation of dimethylpolonium was obtained.

Ethyl radicals, $C_2H_5\cdot$, have been reported to assist in the gas-phase transport of the isotopes ^{212}Po and ^{216}Po. One interpretation of this phenomenon suggests the formation of diethyl polonide. However, an alternate explanation involves the dissociation of $(C_2H_5)_2Po$ into volatile H_2Po and ethylene.

Radiolead contains ^{210}Pb, ^{210}Bi, and ^{210}Po. Treatment of the naturally occurring isotope mixture with phenylmagnesium bromide removes most of the ^{210}Pb and ^{210}Po with concurrent formation of the phenyl–bismuth compounds. Because of the relatively short half-life of ^{210}Bi($t_{1/2} = 5.0$ days, β-emission), there occurs the formation and accumulation of organopolonium compounds, ^{210}Po ($t_{1/2} = 138$ days, α-emission). Chromatographic techniques have been utilized for the identification of the organopolonium compounds formed around the β-decay products of organo-^{210}Bi compounds.

Among the organopolonium compounds arising from the β-decay of $^{210}BiAr_3$ are the diaryl polonides, $^{210}PoAr_2$; Ar = Ph, o-MeC_6H_4, m-MeC_6H_4, p-$MeC_6H_4$$p$-$ClC_6H_4$, p-BrC_6H_4, p-$MeOC_6H_4$, p-$NH_2C_6H_4$, α-$C_{10}H_7$. The yield of (m-$MeC_6H_4)_2Po$ is notably higher, and this has been attributed to a greater electron density in the aromatic ring arising from a hyperconjugative effect.

It has been postulated that in the β-decay of R_3BiCl_2, the R_3Po^+ ion is formed initially. The cation then dissociates into R_2Po and R^+.

The yield of Ph_2Po from $^{210}BiPh_3$ is more than three times that formed by the β-decay of $^{210}BiPh_5$.

$PoCl_4$ can be prepared and separated because of the greater stabilities of the inorganic compounds toward α-emission. Mixtures of $PoCl_4$ and $TeCl_4$ have been allowed to undergo reaction with the Grignard reagent. Following treatment with RMgBr in Et_2O/C_6H_6, hydrolysis, reextraction into an organic solvent, drying, and removal of organic solvent, a number of $^{210}PoR_2$ compounds have been reported. Among the diaryl polonides prepared in this way are the p-tolyl, p-methoxyphenyl, and the α-naphthyl derivatives.

2.2 Triarylpolonium Halides

These compounds have the formula Ar_3PoX (X = F, Cl, Br, I). Compounds of this type have also been identified among the β-decay products of Ar_3BiX_2, formed by the reaction between the aryl Grignard reagent and halogenated radiolead. In general, the yield of Ar_3PoX from $Ar_3{}^{210}BiX_2$ increases in the sequence Br > Cl > F.

Triarylpolonium halides that have identified include those for X = F, Ar = 2-Me-, 3-Me-, and 4-MeC_6H_4, and the p-xylyl derivative. For X = Cl, in addition to the tolyl and xylyl derivatives, Ar = p-Cl-, p-Br-, p-MeO-, p-EtO-, and p-$H_2NSO_2C_6H_4$, and α-naphthyl. Similar compounds have been reported in which X is bromide.

When $^{210}PoCl_4$ in the presence of carrier $TeCl_4$ is treated with ArMgBr in the conventional manner, but the product is treated with KI, a number of triarylpolonium iodides have been reported. It has been claimed by Nefedov and coworkers[1] that black precipitates of Ar_3(Po,Te)I can be recrystallized from $EtOH/Et_2O$ or $EtOH/H_2O$.

2.3 Diarylpolonium Dihalides

These compounds, whose general formula is Ar_2PoX_2, have been detected among the β-decay products of $Ar_3{}^{210}BiX_2$. For X = F, compounds which Ar is 2,5-dimethylphenyl, p-tolyl, p-anisyl, p-methoxyphenyl, and α-naphthyl have been claimed to be indentified by chromatographic analysis. Another method of preparation has also been reported. This involves the treatment of Ar_2Po with Ar_3BiF_2 and subsequent chromatographic purification. Similar compounds have been reported in which X is chloride or bromide.

One method of preparation of Ar_2PoCl_2 is described in which Ar_2Po is chlorinated by SO_2Cl_2 in carbon tetrachloride. The diaryl dihalide is precipitated out of the chloroform solution by the addition of petroleum ether. In this manner, the preparation of Ar_2PoCl_2 has been reported in which Ar is p-anisyl, mesityl, and α-naphthyl. The bis(α-naphthyl)polonium dichloride can be recrystallized from p-xylene.

Diaryl polonides are converted to the dibromides when they undergo reaction with Ar_2TeBr_2. Essentially, this is an oxidation reaction in which Po is oxidized from Po^{II} to Po^{IV} and tellurium is reduced from Te^{IV} to Te^{II}. Also, diaryl polonides add elemental bromine to form the dibromides. Thus, treatment of $(C_9H_{11})_2Po$ or (α-$C_{10}H_7)_2Po$ in benzene with bromine yields the dibromides. They can be precipitated by the addition of petroleum ether and recrystallized from benzene/petroleum ether. In a manner parallel to that just described, p-tolyl and α-naphthylpolonium diiodides, Ar_2PoI_2, have been obtained by the addition of I_2 to the respective diaryl polonides.

2.4 Diarylpolonium Oxide

The conversion of $(C_9H_{11})_2Po$, dimesityl polonium, to the oxide, $(C_9H_{11})_2PoO$, by oxidation with air has been claimed. The corresponding telluride is not oxidized under these conditions.

2.5 Other Evidence for Organopolonium Compounds

Concentrations of ^{210}Po were measured in the North Atlantic troposphere.[5] Concentrations of ^{210}Po were measured in rain water, surface seawater, and the marine microlayer. An excess of ^{210}Po activity was measured in the aerosol relative to what was expected on the basis of ^{210}Pb and aerosol residence times. In surface seawaters, deficiencies of ^{210}Po were observed. The mechanism of ^{210}Po enrichment in the atmospheric aerosol was attributed to possible enrichments from the organic components of the marine microlayer or air−sea exchange of organic polonium species. However, no organic compounds of polonium were actually isolated or characterized.

The volatilities of 13 polonium compounds that are soluble in organic solvents was investigated.[6] All of the compounds were found to volatilize below 200 °C at atmospheric pressure. Polonium was found to form soluble organic compounds with the following chelating agents: 2, 3-butanediol; 4, 4, 4-trifluoro-1-(2-thiene); 8-quinoline; diethyldithiocarbamate; thiocarbanilide; 1, 5-diphenylcarbohydrazide; 1-phenyl-3-thiosemicarbazide; thiosemicarbazide; and thiourea.

1 INTRODUCTION

The concept of a polyhedron[1] is a useful way of describing diverse chemical structures. In this context, a polyhedron may be regarded as a set consisting of (zero-dimensional) points, that is, its *vertices*; (one-dimensional) lines connecting some of the vertices, that is, its *edges*; and (two-dimensional) surfaces formed by the edges, that is, its *faces*. The *degree* of a vertex is defined as the number of edges meeting at that vertex.

Polyhedra can appear in chemical structures as *coordination polyhedra*, in which the vertices represent ligands surrounding a central atom that is often, but not always, a metal, and *cluster* polyhedra, in which the vertices represent multivalent atoms and the edges represent bonding distances. In this connection, the five regular or Platonic polyhedra (Figure 1) are key building blocks for many molecular structures. They are characterized by the following properties: (1) all faces are equivalent regular polygons; (2) the vertices are all equivalent; (3) the edges are all equivalent. The special symmetries of regular polyhedra are described by the standard Euclidean point groups, that is, T_d, O_h, I_h, and their subgroups. Also of chemical significance are *deltahedra*, in which all faces are triangles. The most spherical deltahedra (Figure 2) are those in which the degrees are most similar. They are found in the structures of the borane anions $B_nH_n{}^{2-}$ ($6 \leq n \leq 12$). Note that the six- and twelve-vertex most spherical deltahedra (Figure 2) are also regular polyhedra, that is, the octahedron and icosahedron (Figure 1), respectively.

2 POLYHEDRAL TOPOLOGY

The topology of a polyhedron can be described by a graph, called the 1-skeleton of the polyhedron.[2] The vertices and edges of the 1-skeleton correspond to the vertices and edges, respectively, of the underlying polyhedron. Of fundamental importance are relationships between possible numbers and types of vertices (v), edges (e), and faces (f) of polyhedra. In this connection, the following elementary relationships are particularly significant:[3]

1. *Euler's relationship:*

$$v - e + f = 2 \tag{1}$$

   This arises from the properties of ordinary three-dimensional space.

2. *Relationship between the edges and faces:*

$$\sum_{i=3}^{v-1} i f_i = 2e \tag{2}$$

   In equation (2), f_i is the number of faces with i edges (i.e. f_3 is the number of triangular faces, f_4 is the number of quadrilateral faces, etc.). This relationship arises from the fact that each edge of the polyhedron is shared by exactly two faces. Since no face can have fewer edges than the three of a triangle, the following inequality must hold in all cases:

$$3f \leq 2e \tag{3}$$

3. *Relationship between the edges and vertices:*

$$\sum_{i=3}^{v-1} i v_i = 2e \tag{4}$$

   In equation (4), v_i is the number of vertices of *degree i* (i.e. having i edges meeting at the vertex). This relationship arises from the fact that each edge of the polyhedron connects exactly two vertices. Since no vertex of a polyhedron can have a degree less than three, the following inequality must hold in all cases:

$$3v \leq 2e \tag{5}$$

4. *Totality of faces:*

$$\sum_{i=3}^{v-1} f_i = f \tag{6}$$

5. *Totality of vertices:*

$$\sum_{i=3}^{v-1} v_i = v \tag{7}$$

Equation (6) relates the f_i's to f and equation (7) relates the v_i's to v.

In generating actual polyhedra, the operations of capping and dualization are often important. *Capping* a polyhedron P_1 consists of adding a new vertex above the center of one of its

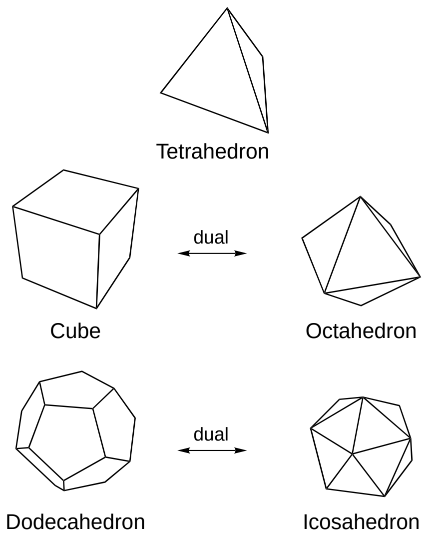

Figure 1 The five regular polyhedra showing the cube/octahedron and dodecahedron/icosahedron dual pairs

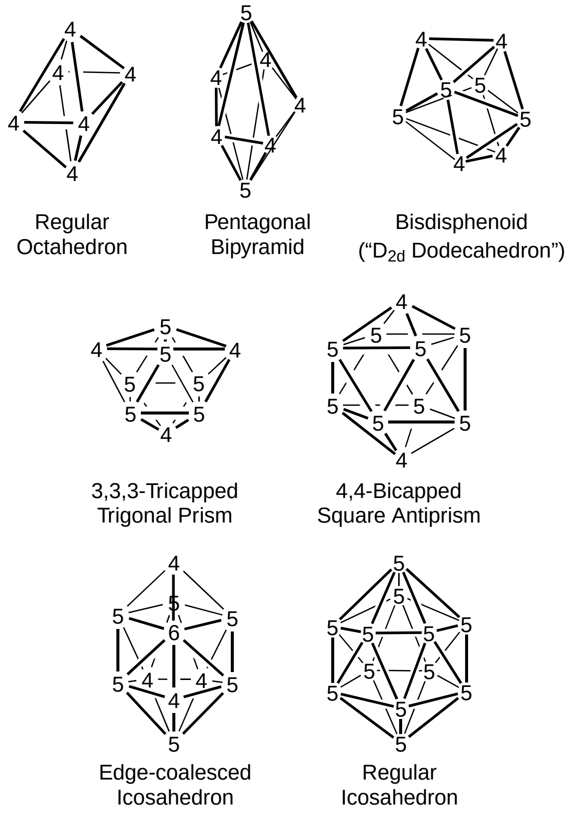

Figure 2 The most spherical deltahedra, found, for example, in the structures of the boranes $B_nH_n^{2-}$ ($6 \le n \le 12$). The numbers on the vertices indicate the vertex degrees

faces F_1 followed by adding edges to connect the new vertex with each vertex of F_1. This capping process gives a new polyhedron P_2 having one more vertex than P_1. If a triangular face is capped, the following relationships will be satisfied where the subscripts 1 and 2 refer to P_1 and P_2, respectively: $v_2 = v_1 + 1$; $e_2 = e_1 + 3$; $f_2 = f_1 + 2$. Such a capping of a triangular face is found in the capping of a tetrahedron to form a trigonal bipyramid (Figure 3a). In general, if a face with f_k edges is capped, the following relationships will be satisfied: $v_2 = v_1 + 1$; $e_2 = e_1 + f_k$; $f_2 = f_1 + f_k - 1$. An example of such a capping process converts a pentagonal pyramid into a pentagonal bipyramid (Figure 3b).

A given polyhedron P can be converted into its dual P* by locating the centers of the faces of P* at the vertices of P and the vertices of P* above the centers of the faces of P. Two vertices in the dual P* are connected by an edge when the corresponding faces in P share an edge.

The process of dualization has the following properties:

1. The numbers of vertices and edges in a pair of dual polyhedra P and P^* satisfy the relationships $v^* = f$, $e^* = e$, $f^* = v$.
2. Dual polyhedra have the same symmetry elements and thus belong to the same symmetry point group.
3. Dualization of the dual of a polyhedron leads to the original polyhedron.
4. The degrees of the vertices of a polyhedron correspond to the number of edges in the corresponding face polygons in its dual.

The regular polyhedra (Figure 1) provide examples of dual pairs of polyhedra. Thus the octahedron ($v = 6$, $e = 12$, $f = 8$) is the dual of the cube ($v = 8$, $e = 12$, $f = 6$). The tetrahedron ($v = 4$, $e = 6$, $f = 4$) is its own dual.

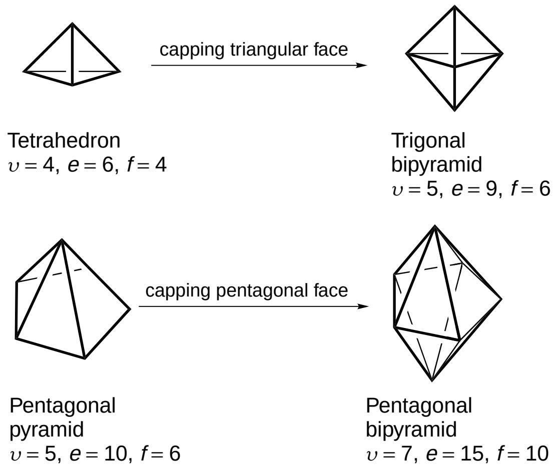

Figure 3 Examples of polyhedral capping: (a) capping a tetrahedron to form a trigonal bipyramid; (b) capping a pentagonal pyramid to form a pentagonal bipyramid

3 SCHLEGEL DIAGRAMS

Polyhedra are frequently depicted as two-dimensional 'perspective' drawings as aids to help visualize the actual three-dimensional structures. For more complicated polyhedra, these two-dimensional perspective drawings begin to have limitations since both their drawing requires skill and reconstruction of their original three-dimensional picture requires more imagination. These difficulties can be minimized by the use of Schlegel diagrams[4] rather than conventional perspective drawings to depict three-dimensional polyhedra in two dimensions. Schlegel diagrams are well known to mathematicians studying polyhedra and higher dimension polytopes but are relatively unfamiliar to chemists.

In order to obtain a Schlegel diagram of a polyhedron P, select any face of P as the *base face*, F_0. The plane containing the base face F_0 separates three-dimensional space into two half-spaces, one of which contains the entire volume of P. Select a point x_0 in the other half-space. Draw a straight line from x_0 to each of the vertices of P. Each such line will intersect the plane of F_0 at a point representing the corresponding vertex. Connect a pair of vertex projections onto the plane of F_0 with straight lines if and only if the corresponding vertices of P have an edge between them. This process leads to a projection of the three-dimensional plane of the face F_0; this projection is called the *Schlegel diagram* of the polyhedron P.

Any given polyhedron can have as many different Schlegel diagrams as it has different faces. The procedure for drawing the Schlegel diagram of the square pyramid using the square face as the base face F_0 is illustrated in Figure 4.

The following features of Schlegel diagrams are of interest:

1. The location of the point x_0 can always be chosen so that the edges in the Schlegel diagram can be drawn as *nonintersecting* straight lines. This is one of the big advantages of Schlegel diagrams over conventional perspective drawings.
2. Schlegel diagrams depict the topological but not the metric features of polyhedra. Thus, the vertex neighborhood relationships depicted by edges are preserved. However, edge lengths and angles are distorted. Since many important chemical relationships are topological rather than metric, this distortion is not necessarily serious.
3. Schlegel diagrams may not preserve all symmetry elements of the original polyhedron because of the metric distortion. The preservation of symmetry elements in Schlegel diagrams is maximized if a unique face of the polyhedron is selected as the base face.

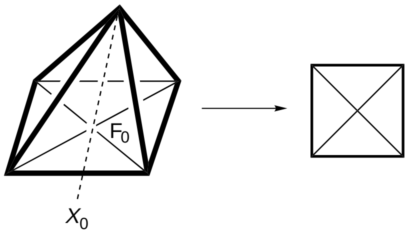

Figure 4 The Schlegel diagram of the square pyramid

The regular octahedron gives the Schlegel diagram in Figure 5. The big triangle corresponds to the base face and contains all of the other faces in the Schlegel diagram. The small triangle in the center is the projection of the face opposite to the base face. The other triangles correspond to the remaining six faces of the octahedron. This Schlegel diagram of an octahedron shows how Schlegel diagrams fail to preserve metric and symmetry properties since in a regular octahedron all of the eight triangular faces are congruent and all of the 12 edges have the same length.

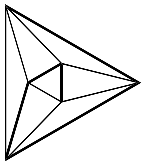

Figure 5 The Schlegel diagram of the regular octahedron

Table 1 Some properties of all polyhedra with six or fewer vertices

					Vertices			Faces

4 ENUMERATION AND CLASSIFICATION OF POLYHEDRA

The problem of classification and enumeration of polyhedra is a complicated one. Thus there appear to be no formulas, direct or recursive, for which the number of combinatorially (topologically) distinct polyhedra having a given number of vertices, edges, faces, or any combination of these elements can be calculated.[5,6] Duijvestijn and Federico have enumerated by computer the polyhedra having up to 22 edges according to their numbers of vertices, edges, and faces and their symmetry groups and present a summary of their methods, results, and literature references to previous work.[7] Their work shows that there are 1, 2, 7, 34, 257, 2606, and 32 300 topologically distinct polyhedra having 4, 5, 6, 7, 8, 9, and 10 faces or vertices, respectively. Tabulations are available for all 301 ($= 1 + 2 + 7 + 34 + 257$) topologically distinct polyhedra having eight or fewer faces[8] or eight or fewer vertices.[9] These two tabulations are essentially equivalent by the dualization relationship discussed above. Some of the properties of the polyhedra having six or fewer vertices are listed in Table 1.

Glossary

Cluster: molecular compound containing three or more metal atoms which are joined to one another via direct and substantial metal–metal bonding
Hydrocarbyl: ligand bonded through carbon and containing hydrogen
Nuclearity: the number of metal atoms constituting the framework of a metal cluster

1 INTRODUCTION

This article concerns the transition metal clusters (*see Cluster*) of three or more metal atoms which contain a hydrocarbyl (*see Hydrocarbyl*) ligand as a part of the metal–carbon cluster core.[1] Because the chemistry of trimetallic clusters is the most well developed, these examples will be stressed. While many of the features of cluster chemistry are common with those of organometallic complexes containing a single metal atom, there are notable differences in structures and reactivities owing to the tendencies of ligands to bridge between two or more metal atoms and for ligands bound to only a single metal atom to undergo facile intramolecular migrations between metal atoms. A bridging ligand (*see Bridging Ligand*) is denoted in a chemical formula by the Greek letter μ and, if more than two metal atoms are bridged, a subscript indicates the number of metals bridged by a ligand; thus the formula $(\mu\text{-H})Os_3(\mu_3\text{-CPh})(CO)_{10}$ indicates a hydride bridging two osmium atoms and a CPh fragment bridging three metal atoms. Also *see* ***Carbonyl Complexes of the Transition Metals***; ***Hydride Complexes of the Transition Metals***; ***Dinuclear Organometallic Cluster Complexes***; ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***.

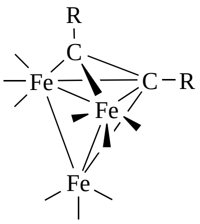
1.1 Structure and Bonding

Organometallic complexes containing a single metal center usually obey the so-called 18-electron rule (*see Effective Atomic Number Rule*), whereas the bonding in bulk metals is best described according to band theory (*see Band Theory*).[2,3] Understandably, bonding descriptions of cluster compounds may be expected to become increasingly complex as the size of the cluster increases.

Small clusters almost invariably follow the 18-electron rule, that is, for each metal atom the sum of its valence electrons (the electrons donated by the ligands and the electrons provided via metal–metal bonds) equals 18; these clusters are said to be ‘saturated’. Common exceptions, having less than 18 electrons per metal atom, are found in clusters of the early transition metals (which contain mainly halide, oxygen, or nitrogen donor ligands) and clusters containing Pd, Pt, or, less commonly, Rh or Ir. It has been common to define saturation for a particular cluster geometry in terms of the number of electrons donated by the ligands combined with the metal valence electrons, required to give each metal atom 18 electrons in a particular cluster geometry. Since metal–metal bonds represent a shared electron pair, a closed triangular array of metals (three metal–metal bonds) requires 48 electrons to be saturated. Clusters that do not obey the 18-electron rule, called ‘unsaturated’ (*see Electron Deficient Compound*), are typically much more reactive than those that do. One of the best known examples of an unsaturated cluster is $H_2Os_3(CO)_{10}$, a 46-e cluster that has two electrons fewer than the number required by the 18-electron rule. This cluster reacts very rapidly at room temperature with Lewis bases ($L = PR_3$, CO, halides, and others) to form saturated 48-electron clusters, $H_2Os_3(CO)_{10}L$; for comparison, the saturated cluster $Os_3(CO)_{12}$ requires temperatures above 100 °C to react with most Lewis bases, the high temperature being required to generate an unsaturated intermediate by CO dissociation.

As the cluster nuclearity increases, the structures and electron counting of saturated clusters conform to the polyhedral skeletal electron pair (SEP) theory.[3] For organometallic clusters the carbon fragments of the hydrocarbyl ligands are frequently part of the cluster skeleton. Thus, $Fe_3(PhCCPh)(CO)_9$ (**1**) would be considered to be unsaturated according to the 18-electron rule, as the alkyne ligand is a four-electron donor to a $Fe_3(CO)_9$ cluster, which requires

six electrons to fulfill the 18-electron rule for each metal atom. However, according to the SEP theory the cluster, the framework of which is Fe_3C_2, is saturated and is described as a *closo* structure (*see Closo Cluster*) based upon a trigonal bipyramid.



(**1**)

For still larger clusters, particularly those which consist of several fused polyhedral units, the electron counting and structural predictions are much more complex.[2]

Beyond the question of cluster core geometry, there remains the problem of explaining the arrangement of ligands around the cluster core, for example, the adoption of bridging or terminal ligand coordination.[3] No theory has adequately addressed this problem, which is particularly severe for carbonyl, hydride, and hydrocarbyl ligands. One interesting proposal that has been applied to metal carbonyl clusters concerns nonbonded interactions between ligands on the cluster surface and the match of the cavity size available in the ligand shell to the size of the cluster core.[4,5] Other theories invoke electronic arguments.[6]

1.2 Paramagnetic Clusters

While rare, a number of moderately stable clusters having an odd number of electrons have been prepared, for example, $[Fe_3(CO)_{11}]^{1-}$ and $(Cp^*Ni)_3(\mu_3\text{-CH})(\mu\text{-H})$. Many more which have only transient existences can be prepared by electrochemical redox processes.[7] These paramagnetic complexes are generally more reactive than the saturated analogs. Examples in which direct comparisons can be made between clusters differing only in electron count include ligand substitution (see Section 2.1) and structural isomerization. Isomerization of the clusters $[Cp^*Ir(CpCo)_2(CO)_3]^{-1/0/+1}$ occurs between isomers differing in the number of bridging versus terminal CO ligands. The relative rates of isomerization increased in the order 48 e $\ll$ 49 e $\ll$ 47 e, with the range covering 10^8.[8] Electrochemical or chemical oxidations of 48-e $H_3Ru_3(\mu_3\text{-CX})(CO)_6(L)_3$ generate 47-e clusters $[H_3Ru_3(CX)(CO)_6L_3]^{1+}$, which exist as equilibrium mixtures of isomers differing in the orientation of one of the ligands L.[9] The rate constant for isomerization for the 47-e species is 4 orders of magnitude greater than that for the 48-e species. The 47-e clusters have lifetimes, which are correlated with the oxidation potentials of the precursors, ranging from seconds to many hours at room temperature. Decomposition occurs by disproportionation, via rate-limiting outer-sphere electron transfer, back to the 48-e precursor and very unstable 46-e species (*see* ***Paramagnetic Organometallic Complexes***; ***Electrochemistry: Applications in Inorganic Chemistry***; ***Electron Transfer in Coordination Compounds***; ***Electron Transfer Reactions: Theory***).

2 SYNTHESES

The first syntheses of organometallic clusters relied almost entirely upon serendipity, and even now designed syntheses of clusters of a desired metal composition are rarely achieved from lower nuclearity precursors. The basis for most syntheses involves ligand substitution of a hydrocarbon for a carbonyl ligand of a cluster having the desired metal composition, and then modification of the hydrocarbon unit while maintaining unchanged the metal-cluster core.[10]

2.1 Ligand Substitution on Metal Carbonyls

The first applications of ligand substitution (*see Ligand Substitution*) for the syntheses of organometallic clusters used thermal activation to remove carbonyl ligands from clusters such as $M_3(CO)_{12}$ (M = Fe, Ru, and Os). The high activation energy required for CO loss dictated that only very stable organometallic cluster products could be isolated and less stable intermediates were undetectable. For example, pyrolysis of $Os_3(CO)_{12}$ at 120 °C in the presence of ethylene gives $H_2Os_3(\mu_3\text{-}\eta^2\text{-C=CH}_2)(CO)_9$, but the intermediates $Os_3(CO)_{11}(CH_2\text{=}CH_2)$ and $HOs_3(\mu_2\text{-}\eta_2\text{-CH=CH}_2)(CO)_{10}$, which can be prepared by alternative, low-temperature routes, are not observed. Photolysis is sometimes more successful if the products are thermally sensitive. Some examples of these reactions are shown in equations (1–3).[9,10,56]

$$Os_3(CO)_{12} + C_6H_6 \longrightarrow H_2Os_3(\mu_3\text{-}\eta^2\text{-}C_6H_4)(CO)_9 \qquad (1)$$

$$Os_3(CO)_{12} + PPh_3 \xrightarrow[n=1-3]{} Os_3(CO)_{12-n}(PPh_3)_n \qquad (2)$$

$$Ru_3(CO)_{12} + H_2\text{=CHCH=CH}_2 \longrightarrow (\mu\text{-H})Ru_3(\mu_3\text{-}\eta^3\text{-HCCHCMe})(CO)_9 \qquad (3)$$

Less brutal approaches to displacement of CO ligands have provided the opportunity for designed syntheses. The most successful approaches are (1) the use of trimethylamine *N*-oxide to convert a bound CO ligand to CO_2, (2) the use of one-electron oxidation or reduction to generate more labile (*see Labile*) cluster radical intermediates, and (3) the use of nucleophiles (*see Nucleophile*), such as halide ions, to promote CO dissociation.

Trimethylamine *N*-oxide can be used to chemically remove carbonyls as CO_2; an example is shown in equation (4). While thermal substitution produces a mixture of products

(equation 2), the addition of one equivalent of trimethylamine N-oxide selectively gives the monosubstituted product. Since the mechanism involves nucleophilic attack by the oxide on a carbonyl carbon, the reaction can be extremely rapid but does require the presence of an electrophilic carbonyl ligand. Consequently, the reagent is ineffective for anionic metal carbonyls and for more highly substituted clusters.

$$Os_3(CO)_{12} + ONMe_3 + PPh_3 \longrightarrow Os_3(CO)_{11}(PPh_3) + CO_2 + NMe_3 \quad (4)$$

Odd-electron metal clusters are frequently much more labile than are clusters which satisfy the electron counting rules. Catalytic substitution can be effected by one-electron reduction (or in some cases oxidation).[11,12] The sequence of reactions leading to catalytic substitution is shown in Scheme 1. This scheme for catalytic substitution depends upon the substituted product having a less favorable reduction potential than the starting cluster.

Clusters containing weakly coordinating ligands are valuable starting materials for thermally unstable complexes. Such clusters containing weakly coordinating ligands are sometimes described as being ‘lightly stabilized’. Examples of weakly coordinating ligands include acetonitrile, pyridine, ammonia, ethylene, cyclooctene, and THF. Most of these compounds are prepared via $ONMe_3$-promoted substitution. In some examples, the weakly coordinating ligand bridges two or more metals and can reversibly generate a reactive site while remaining coordinated to another metal atom. Even dichloromethane has been observed as a bridging ligand with both chlorine atoms coordinating to metals. Examples of reactions using lightly stabilized clusters are shown in equations (5) and (6).

$$Os_3(CO)_{11}(NCMe) + H_2C{=}CH_2 \longrightarrow Os_3(CO)_{11}(H_2C{=}CH_2) + NCMe \quad (5)$$

$$(\mu\text{-H})Os_3(\mu_3\text{-SMe})(CO)_9 + H_2C{=}CH_2 \longrightarrow (\mu\text{-H})Os_3(\mu_2\text{-SMe})(CO)_9(H_2C{=}CH_2) \quad (6)$$

Nucleophilic activation by halides or other anionic reactants has been noted.[9,13,56] In this process, associative attack by the nucleophile on the cluster generates a labile intermediate. This attack may occur at a carbonyl ligand, forming an acyl derivative. Stable acyls can be isolated, for example, $[Ru_3(CO)_{11}(CO_2Me)]^-$ from $Ru_3(CO)_{12}$ and methoxide, and are indeed more labile for CO dissociation than the cluster precursor. If the nucleophilic attack is reversible, ligand substitution can be catalyzed by nucleophiles. For example, bis(triphenylphosphine)imminium chloride catalyzes PPh_3 substitution on $Ru_3(CO)_{12}$ at 25 °C. Surface-mediated activation by silica has been used to synthesize some substituted derivatives of $Os_3(CO)_{12}$.[14]

$$Fe_3(\mu_3\text{-PPh})_2(CO)_9 + e^- \longrightarrow [Fe_3(\mu_3\text{-PPh})_2(CO)_9]^-$$

$$[Fe_3(\mu_3\text{-PPh})_2(CO)_9]^- + PR_3 \longrightarrow [Fe_3(\mu_3\text{-PPh})_2(CO)_8(PR_3)]^- + CO$$

$$[Fe_3(\mu_3\text{-PPh})_2(CO)_8(PR_3)]^- + Fe_3(\mu_3\text{-PPh})_2(CO)_9 \longrightarrow Fe_3(\mu_3\text{-PPh})_2(CO)_8(PR_3) + [Fe_3(\mu_3\text{-PPh})_2(CO)_9]^-$$

Scheme 1

2.2 Template Syntheses

Metal clusters can be assembled around main group atoms, such as S or P, which form very strong bonds to metals and which are capable of bridge bonding.[15] An example is given in equation (7).[16]

$$2Ru_3(CO)_9(\mu_3\text{-PhCCH})(\mu_3\text{-S}) \longrightarrow Ru_6(CO)_{16}(\mu_3\text{-PhCCH})_2(\mu_4\text{-S})_2 + 2CO \quad (7)$$

2.3 Condensation of Metal Fragments

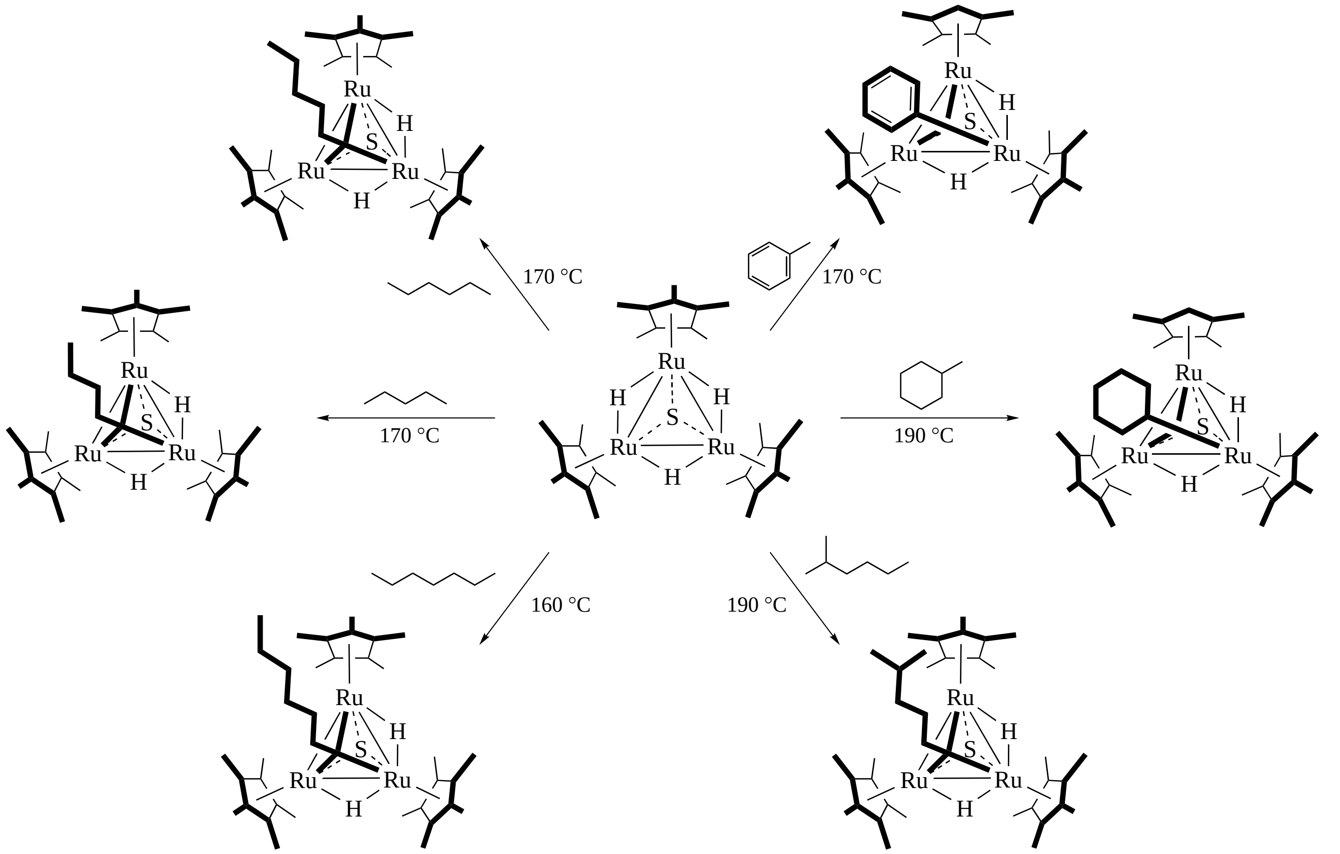
A number of elegant syntheses of mixed-metal clusters have been accomplished through the condensation of unsaturated metal complexes with metal donors.[17] For example, condensation of the unsaturated cluster $H_2Os_3(CO)_{10}$ with the alkylidyne (*see Alkylidyne*) complex $CpW(CO)_2(CR)$ produces $H_2Os_3W(\mu_3\text{-CR})(CO)_{12}$. Metal–metal, metal–carbon, or carbon–carbon multiple bonds may serve as the sites for metal fragment condensation. Other examples are shown in equations (80 and (9).

$$Ru(\text{cyclooctatriene})(\text{cyclooctadiene}) + CpW(CO)_2(CR) \longrightarrow RuW_2(\mu_3\text{-RCCR})(CO)_7Cp_2 + RuW_3(\mu\text{-CR})(CO)_4Cp_3 \quad (8)$$

$$(H)Ru_3(COMe)(CO)_{10} + CpW(CO)_3(CCPh) \longrightarrow CpWRu_3(COMe)(CO)_9(C{=}CHPh) \quad (9)$$

2.4 Oxidative Addition Reactions

Oxidative addition (*see Oxidative Addition*) of H–C, H–Si, H–Sn, Cl–C, and other σ-bonded atom pairs have been used to add group 14 donor ligands to metal clusters. Additions of H–C, H–Si, and H–Sn bonds require an unsaturated metal center. A number of studies of the mechanism are consistent with a mechanism involving addition at a single metal atom through a three-center, synchronous process, the same as commonly occurs for monometallic complexes.[18] Some examples of H–Si addition to unsaturated (equation 10) and lightly stabilized (equation 11) Os_3 clusters are shown. Oxidative additions of unactivated C–H bonds are rarer. Preferential addition of terminal C–H bonds to



Scheme 2 (Reproduced from K. Matsubara, A. Inagaki, M. Tanaka, and H. Suzuki, *J. Am. Chem. Soc.*, 1999, **121**, 7421)

$H_3Ru_3(\mu_3\text{-}S)(Cp^*)_3$ form alkylidyne complexes $H_2Ru_3(\mu_3\text{-}S)(\mu_3\text{-}CR)(Cp^*)_3$ (Scheme 2).[19]

$$H_2Os_3(CO)_{10} + HSiEt_3 \longrightarrow H_3Os_3(CO)_{10}(SiEt_3) \quad (10)$$

$$Os_3(CO)_{11}(NCMe) + HSi(OEt)_3 \longrightarrow HOs_3(CO)_{11}[Si(OEt)_3] + NCMe \quad (11)$$

Additions of polar X–C bonds (e.g., X = Cl, Br, I, or OR) usually occur by nucleophilic attack by an electron-rich cluster at carbon; this reaction is less common for clusters than it is for mononuclear metal complexes. One example is addition of iodobenzene to $Ru_3(CO)_{12}$, forming $Ru_3(\mu\text{-}I)(\mu,\eta^1\text{: }\eta^6\text{-}C_6H_6)(CO)_8$.[20]

3 CHEMICAL REACTIVITY

In large part, the reactivity of a metal cluster is the same as that of the individual metal fragments. The unique features of cluster reaction chemistry involve the bridging of ligands between two or more metal atoms, ligand migration between metal atoms, and metal–metal bond cleavage and formation.

3.1 Ligand Substitution

A reaction common for all molecular metal clusters is replacement of one two-electron donor ligand by another. The mechanism is most commonly dissociative, but associative substitutions (*see Associative Substitution*) also occur.[21] A number of studies have applied quantitative analyses of the associative kinetics in terms of steric and electronic properties of the incoming ligands. Such analyses allow the identification of a 'steric threshold'.[22] Ligand substitution on mixed-metal clusters may be faster than the rates for the corresponding homometallic clusters. However, substitution need not occur at the most labile metal atom, since intramolecular ligand migration preceding or following addition of the incoming ligand can occur to give the thermodynamically more stable product. Frequently, substitution occurs with a high degree of selectivity for one metal atom in a mixed-metal cluster. The substitutional site preference in mixed-metal trigonal bipyramidal clusters has been explained in terms of electronegativity differences.[23] Studies of substitution on $Fe_{3-n}Ru_n(CO)_{12}$ and on $(\mu\text{-}H)Fe_{3-n}Ru_n(\mu\text{-}CNMe_2)(CO)_{10}$ revealed that the relative rates are mixed Fe/Ru clusters > Fe_3 > Ru_3; however, substitution occurs exclusively on Ru. It

is believed that CO dissociation occurs from an Fe atom, but that CO (or PR_3) migration generates the more stable product.

More commonly, it is to be expected that the reactivity of a mixed-metal cluster will be comparable to that of the most labile metal. For example, the rates of CO dissociation from $(\mu\text{-H})Ru_{3-n}Os_n(\mu\text{-COMe})(CO)_{10}$ fall in the series as: Ru_3 (4500) > Ru_2Os (1100) > $RuOs_2$(220) ≫ Os_3 (1). If this is the case, the relative rates for a series can provide information concerning the number of metal atoms which participate in such a transformation (*see also* ***Mechanisms of Reaction of Organometallic Complexes*** and *Ligand Substitution*).

3.2 Addition and Elimination of Molecular Hydrogen

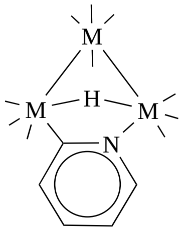
The addition (oxidative addition, *see Oxidative Addition*) and elimination (reductive elimination, *see Reductive Elimination*) of molecular hydrogen is frequently involved in transformations of hydrocarbyl moieties attached to metal clusters. In most cases, oxidative addition of molecular hydrogen requires a vacant coordination site on a single metal atom. The rates for reductive elimination (*see Reductive Elimination*) of hydrogen from $(\mu\text{-H})_3Ru_{3-n}Os_n(\mu_3\text{-COMe})(CO)_9$ decrease in the order: Ru_3 > Ru_2Os > $RuOs_2$ ≫ Os_3; this trend indicates that hydrogen elimination occurs from only one metal atom, even though each hydride bridges two metal atoms in the ground state. Bridge–terminal hydride migration has been proposed to precede reductive elimination. Several examples of H–H addition across a metal–metal bond are known. In some cases it had been proposed that the addition occurred after homolytic or heterolytic metal–metal bond cleavage, rather than ligand dissociation. Recent studies have shown that the mechanism is ligand dissociation, and then reassociation.[24]

A recent innovation has been the use of para-hydrogen to track the fate of the hydrogen atoms in addition reactions (*see* ***Mechanisms of Reaction of Organometallic Complexes*** and ***Hydride Complexes of the Transition Metals***).[25]

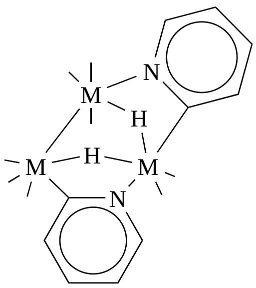
3.3 C–X σ Bond Activation

Oxidative addition (and the reverse process, reductive elimination, *see Reductive Elimination*) of C–H bonds is a very important process for organometallic clusters (*see* ***Mechanisms of Reaction of Organometallic Complexes***). Most commonly, oxidative addition of C–H bonds of coordinated ligands occurs at adjacent metal centers. A large variety of hydrocarbyl (*see Hydrocarbyl*) complexes are derived in this way. For example, pyridines react with $M_3(CO)_{12}$ to give both $HM_3(\mu\text{-NC}_5H_4)(CO)_{10}$ (**2**) and $H_2M_3(\mu\text{-NC}_5H_4)_2(CO)_8$ (**3**).[10] It is presumed that the pyridine initially coordinates to a single metal atom through the nitrogen, and then C–H oxidative addition occurs at an adjacent metal atom. Other C–X σ bonds, which can be cleaved in reactions on clusters include C–P, C–As, C–N, and C–S. An example of C–P cleavage is shown in equation (12). Reversible P–C cleavage has been observed for PPh_3/PPh_2 ligands on a triruthenium cluster.[26]

$$Ru_3(CO)_{11}(PPh_3) \longrightarrow \underset{33\%}{Ru_3(CO)_7(\mu\text{-PPh}_2)_2(\mu_3\text{-}\eta^2\text{-C}_6H_4)} + \underset{50\%}{Ru_4(CO)_{11}(\mu\text{-PPh})(\mu_4\text{-}\eta^4\text{-C}_6H_4)} + \underset{7\%}{Ru_5(CO)_{13}(\mu\text{-PPh})(\mu_5\text{-}\eta^6\text{-C}_6H_4)} \qquad (12)$$



(**2**)



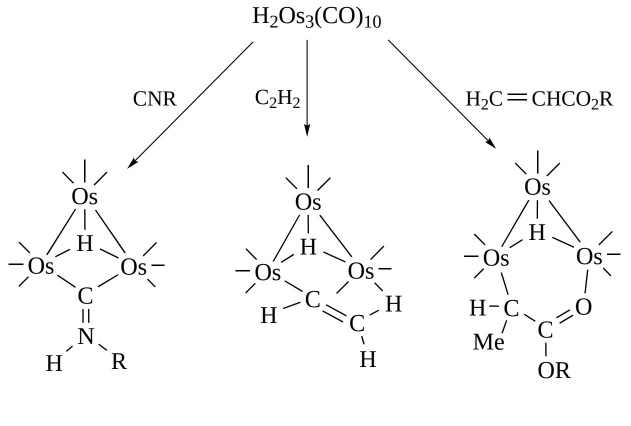
(**3**)

3.4 Protonation

Protonation, another example of oxidative addition, commonly occurs at metal–metal bonds to form a bridging hydride, although the initial site of protonation may be on a coordinated ligand. Even interstitial hydrides can be generated and removed via acid–base reactions. Protonations of neutral clusters usually require strong acids, such as CF_3CO_2H or CF_3SO_3H. Protonations of clusters may be relatively slow and, in some instances, exhibit extremely large kinetic-isotope effects.[27] Hydrogen migration onto coordinated ligands may follow.

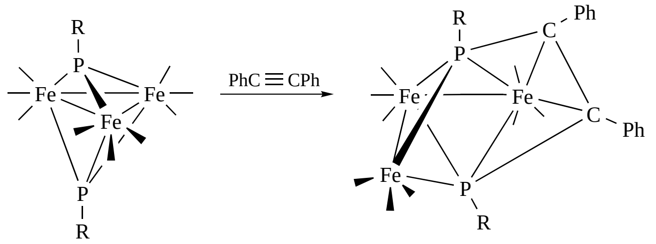
3.5 Insertion Reactions

Insertions (*see Insertion*) of alkene, alkyne, carbonyl, carbene, and other unsaturated ligands into metal–hydride or metal–carbon bonds are well documented.[9] In these reactions, both groups must be coordinated to the metal before insertion can occur. One difference between the reactions of cluster-bound ligands and monometallic analogs is that the ligand produced by insertion frequently forms bridges between two or more metal atoms. For example, acetylene and $H_2Os_3(CO)_{10}$ produce $HOs_3(\mu\text{-}\eta^2\text{-CH=CH}_2)(CO)_{10}$. Other examples are shown in Scheme 3. Insertions into other metal–element bonds are also possible.[9] For example, alkyne insertion into the Fe–P bond of $Fe_3(\mu_3\text{-PR})(CO)_{10}$ gives $Fe_3(\mu_3\text{-}\eta^3\text{-}$



Scheme 3

RPCHCR′)$(CO)_{10}$. A second example is shown in equation (13).

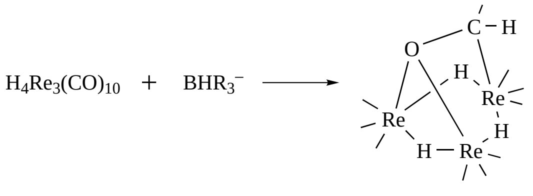


(13)

3.6 Nucleophilic Attack on Cluster-Bound Ligands

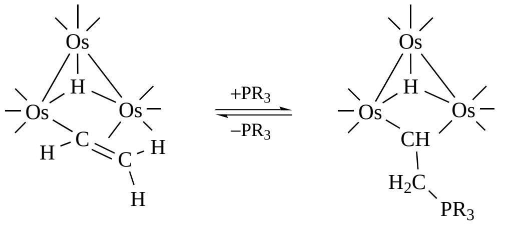
As is the case for monometallic complexes, ligands, such as CO and π-bound hydrocarbons, are activated toward nucleophilic attack. These reactions, which do not require coordination of the nucleophile to the metal, can be extremely rapid.[9,56]

Nucleophilic attack by hydride, alkoxide, or alkyl anions on a carbonyl ligand generates the corresponding acyl ligand. The cluster product is frequently much more labile than the neutral starting cluster, and thus the product may be derived by CO loss, for example, $Ru_3(CO)_{12}$ and methyllithium give $[Ru_3(\mu\text{-O=CMe})(CO)_{10}]^-$. Although hydride attack on coordinated CO usually generates an unstable formyl ligand, in one instance an oxymethylene ligand is formed; treatment of $[H_4Re_3(CO)_{10}]^-$ with $[BH(s\text{-Bu})_3]^-$ yields $[H_3Re_3(\mu_3\text{-}\eta^2\text{-}OCH_2)(CO)_9]^{2-}$ (equation 14).



(14)

Coordinated C–C multiple bonds are also susceptible to nucleophilic attack. Reversible addition of phosphines occurs with $HOs_3(\mu\text{-}\eta^2\text{-CH=CH}_2)(CO)_{10}$, forming $HOs_3(\mu\text{-}\eta^1\text{-CHCH}_2PR_3)(CO)_{10}$ (equation 15). Additions of carbanions or hydride are irreversible. Other examples are shown in equations (16) and (17).



(15)

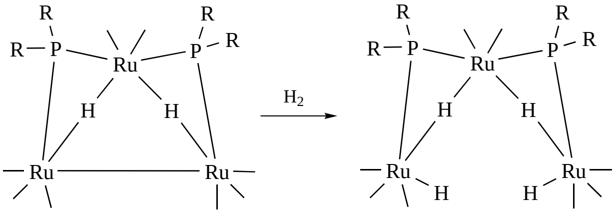
$$HRu_3(\mu_3\text{-}\eta^2\text{-CCPh})(CO)_9 + \text{CN-}t\text{-Bu} \longrightarrow HRu_3(\mu_3\text{-}\eta^2\text{-PhCCCN-}t\text{-Bu})(CO)_9 \quad (16)$$

$$HOs_3(\mu\text{-}\eta^2\text{-CHCH}_2)(CO)_{10} + CN^- \longrightarrow [HOs_3(\mu\text{-}\eta^1\text{-CHCH}_2CN)(CO)_{10}]^- \quad (17)$$

3.7 Fragmentation and Framework Rearrangement

In addition to ligand dissociation, an unsaturated metal cluster can be formed via metal–metal bond cleavage. The reactive intermediate may then undergo complete fragmentation, may achieve saturation by addition of a two-electron donor ligand, or may rearrange to another geometry. Since metal–metal bond strengths are comparable to metal–ligand bond strengths, metal–metal bond cleavage must always be considered as a factor in any reaction.[28]

Metal–metal bond cleavage can accompany oxidative addition reactions. An example of reversible addition of hydrogen accompanied by metal–metal bond cleavage is shown in equation (18). However, it has been shown that the mechanism actually involves CO dissociation prior to hydrogen addition, and then CO reassociation.[24]



(18)

Associative attack by two-electron donors can occur under mild conditions if the addition is accompanied by metal–metal bond cleavage. An example is addition of phosphine ligands at 5 °C to $CoFeW(\mu_3\text{-PMe})(CO)_8Cp$, which forms $CoFeW(\mu_3\text{-PMe})(CO)_8(PR_3)_2$ via cleavage of the Fe–Co and W–Co bonds.

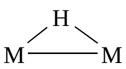
4 FLUXIONALITY

A characteristic feature of most organometallic clusters is stereochemical nonrigidity on the NMR timescale (*see*

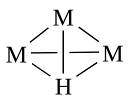
Stereochemical Nonrigidity of Organometallic Complexes)[29] This feature has generated interest with respect to fundamental mechanisms of intramolecular migrations and the possible participation of fluxionality in transformations on clusters. However, fluxionality (*see Fluxional Molecule*) can frustrate the characterization of new compounds.

4.1 Carbonyl Ligands

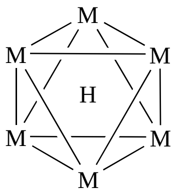
Fluxionality (*see Fluxional Molecule*) of carbonyl ligands occurs both among carbonyls attached to the individual metal atoms of the cluster and as intermetallic ligand exchange. At a single metal center, carbonyls are scrambled via a three-fold rotational process. Carbonyl exchange between metal atoms occurs by migration of carbonyls between terminal and edge-bridging coordination.[4] The argument is still open concerning the mechanism.[29]



(**4**) μ-H



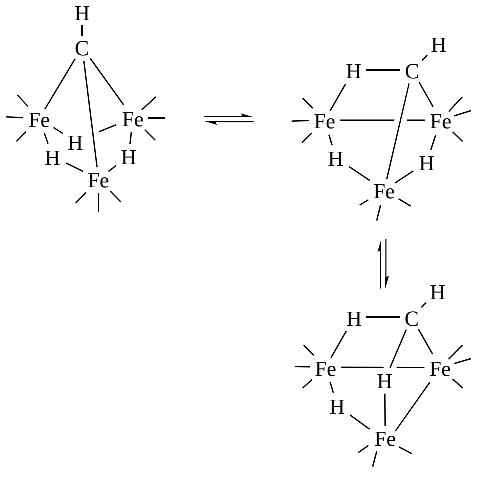
(**5**) μ_3-H



(**6**)

4.2 Hydride Ligands

Hydride ligands are the most versatile of all organometallic ligands. Hydrides can coordinate to a single metal (terminal coordination), bridge two (μ-H, **4**) or three (μ_3-H, **5**) metal atoms, or occupy an interstitial position inside a metal polyhedron (**6**). Hydrides bound to transition metal clusters most commonly bridge two metal atoms. Interconversion

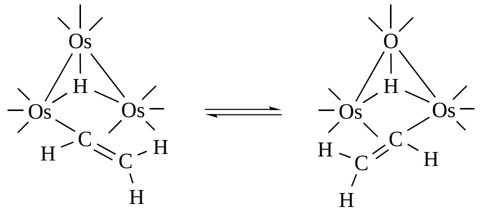


(19)

between bridging and terminal coordination, which has a low activation barrier, provides a facile pathway for hydride fluxionality (*see* ***Hydride Complexes of the Transition Metals***). Hydride fluxionality between metal–metal and metal–carbon bridging sites has also been observed. A classic example is $(\mu\text{-H})_3Fe_3(\mu_3\text{-CH})(CO)_9$ and its tautomers in which exchange between the methylidyne hydrogen and the hydride ligands occurs (equation 19).

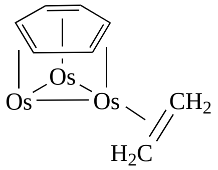
4.3 Hydrocarbyl Ligands

A variety of fluxional (*see Fluxional Molecule*) processes involving hydrocarbyl ligands attached to metal clusters have been identified.[9] Alkylidene (*see Alkylidene*) ligands can undergo fluxional processes via bridge–terminal interconversion in the same manner as carbonyl ligands. Fluxional rotation of μ_3-η^2-alkyne, -aryne, and -1,1-alkenylidene units about a triangular M_3 face is very common. Fluxionality of μ_2-η^2-alkenyl units has been documented in a number of cases. This process involves exchange of σ and π bonds between the two bridged metal atoms (equation 20).[30]



(20)

A process unique to metal clusters is rotation of a face-bonded arene ligand on a triangular metal framework. Fluxionality of carbonyl, ethylene, and benzene ligands of $Os_3(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-}C_6H_6)(CO)_8(\eta^2\text{-}CH_2{=}CH_2)$ (**7**) has been studied by 2D NMR methods.[31] The face-capping benzene ligand undergoes a 1,2 ring-hopping motion such that the arene ring rotates relative to the Os_3 ring. The η^2-alkene rotates about the Os–alkene bond and also undergoes a trigonal twist isomerization involving the carbonyl ligands. This sort of bonding mode is also found for fullerenes (*see* ***Carbon: Fullerenes***).



(**7**)

4.4 Others

Intermetallic fluxionality (*see Fluxional Molecule*) of phosphine ligands has been found for some triplatinum clusters.[32] Isocyanide ligands (*see Isocyanide Ligands*) display very similar fluxional behavior to CO. Fluxionality of

the metal-cluster framework has been noted. For example, multinuclear NMR studies of $[Rh_9E(CO)_{21}]^{2-}$ (E = P or As), $[Rh_{10}E(CO)_{22}]^{3-}$, and $[Rh_{12}Sb(CO)_{27}]^{3-}$ revealed complete fluxionality of both carbonyl and metal polyhedra at high temperatures.[33] Interconversion of open and closed structural isomers $Ru_5Pt(PBu_3)(CO)_{15}(C)$ is rapid on the NMR timescale; the process is said to resemble diffusion of metal adatoms across a metals surface.[34]

5 CHEMISTRY OF CLUSTERS CONTAINING C_n (n = 1–3) FRAGMENTS

While numerous clusters containing exotic hydrocarbyl ligands have been prepared and unique chemical reactivity demonstrated, the most well-established chemistry concerns hydrocarbyl fragments bound to the metal framework through one, two, or three carbon atoms. A sampling of the chemistry of these fragments will illustrate many of the unique aspects of organometallic cluster chemistry.

5.1 C_1 Units on Clusters

Interconversion of alkyl, alkylidene, alkylidyne, and carbide moieties has now been demonstrated in a variety of cluster systems. This work provides perhaps the most complete picture of the fundamental reactivity of the prototypical organometallic cluster.

Interstitial carbon atoms are a unique aspect of organometallic cluster chemistry (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***).[35] Carbon atoms that are completely encapsulated by six or more metal atoms are inert. Even partially exposed carbides, such as $Fe_5C(CO)_{15}$ and $Fe_4C(CO)_{13}$, are relatively unreactive. However, a few examples of reactions of exposed carbides to produce alkylidyne ligands are known.[36] For example, $Fe_4(\mu_4\text{-}C)(CO)_{13}$ reacts with methanol to give $[Fe_4(\mu_4\text{-}CCO_2Me)(CO)_{12}]^-$. Protonation of $[Fe_5(\mu_5\text{-}C)(CO)_{14}]^{2-}$ yields first $[HFe_5(\mu_5\text{-}C)(CO)_{14}]^-$ and then $HFe_4(\mu_4\text{-}\eta^2\text{-}CH)(CO)_{12}$. Electrophilic attack by methyl triflate on $[Fe_4(\mu_4\text{-}C)(CO)_{12}]^{2-}$ yields $[Fe_4(\mu_3\text{-}CMe)(CO)_{12}]^-$, yet the reaction with methyl iodide produces $[Fe_4(\mu_4\text{-}CC(O)Me)(CO)_{12}]^-$, presumably via a radical intermediate. These transformations are shown in Scheme 4.[36]

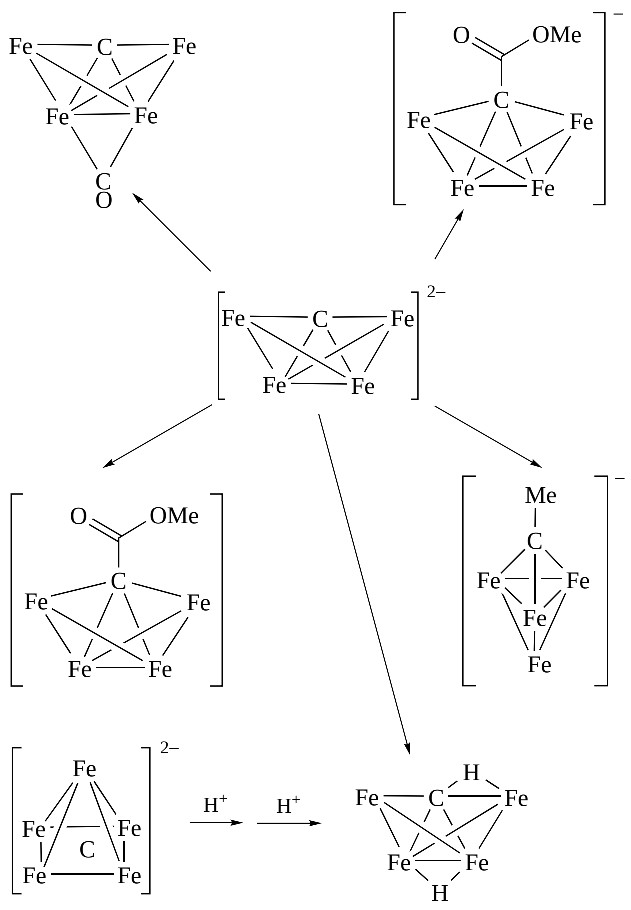
(**11**) μ_4-η^2-CX



Scheme 4

Alkylidyne (*see Alkylidyne*) ligands are found as terminal CR, μ-CR (**8**), μ_3-CR (**9**), or μ_4-ligands (**10** and **11**). Of these, (**10**) and (**11**) are the least well represented, and their chemistry is for the most part unexplored. In this geometry, the CX ligand is found between the wings of butterfly metal framework, as in the clusters $HFe_4(CH)(CO)_{12}$, $HFe_4(COMe)(CO)_{12}$, or $[Fe_4(CCO_2Me)(CO)_{12}]^-$. As shown, the μ_4-CX ligand may be η^1 (**10**) or η^2 coordinated (**11**); the factors that determine the coordination mode are not thoroughly understood. This butterfly geometry may mimic the binding of an alkylidyne ligand at a step site on a metal surface, thus making studies of the chemistry of μ_4-CX ligand of general interest. However, isoelectronic (*see Isoelectronic*) species, such as $[Fe_4(\mu_3\text{-}CX)(CO)_{12}]^-$ (X = Me, OMe), adopt another structure which contains a μ_3-CX ligand capping a face of a metal tetrahedron. The factors that influence the adoption of each structure are presently unknown, and the differences in reactivities between the CX ligand in the two coordination modes are also unexplored. One systematic approach to the synthesis of $M_4(CX)$ clusters involves the addition of metal fragments to alkylidynetrimetal clusters. Examples of this approach are shown in equations (21)

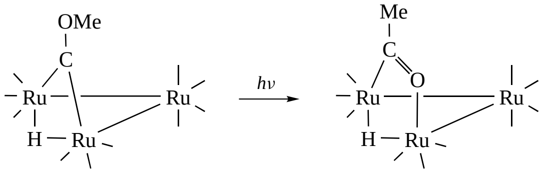
and (22).

$$HRu_3(\mu\text{-}CX)(CO)_{10} + Ru(CO)_5 \longrightarrow HRu_4(\mu_4\text{-}\eta^2\text{-}CX)(CO)_{12} \quad (21)$$

$$X = OMe, NMe_2$$

$$Co_2Mo(\mu_3\text{-}CCO_2R)(CO)_3Cp_3 + Fe_2(CO)_9 \longrightarrow Co_2MoFe(CCO_2R)(CO)_5Cp_3 \quad (22)$$

There are a few examples of coordination of an alkylidyne as a bridging ligand between two metals.[9,36] Most of these concern alkylidynes with π-donor substituents, such as OMe or NMe_2. The reactivity is similar to that of the μ_3-CX ligand. One unusual reaction is the rearrangement of $HRu_3(\mu\text{-}\eta^1\text{-}COMe)(CO)_{10}$ to $HRu_3(\mu\text{-}\eta^2\text{-}O{=}CMe)(CO)_{10}$ under photolytic conditions (equation 23).



(23)

The chemistry of the μ_3-CX ligand has been much more thoroughly explored. One of the first organometallic clusters to be synthesized was $Co_3(\mu_3\text{-}CMe)(CO)_9$. Subsequently, the chemistry of the $Co_3(\mu_3\text{-}CX)(CO)_9$ derivatives was studied by Seyferth and coworkers. The bonding in clusters such as $Co_3(\mu_3\text{-}CX)(CO)_9$ is most properly described as an sp or sp^2 hybridized carbon bonded to the Co_3 framework. π interactions between available p orbitals of the methylidyne substituent and the Co_3C cluster orbitals have been identified. Cluster donation to the empty substituent orbital results in unusual stabilities for carbocations, such as $[Co_3(CCH_2)(CO)_9]^+$.[37] On the other hand, π donors such as NMe_2 stabilize radical cation clusters, for example, $[H_3Ru_3(CNMe_2)(CO)_6(PPh_3)_3]^+$.[38]

Lewis acids (*see Lewis Acids & Bases*) react with $Co_3(\mu_3\text{-}CX)(CO)_9$ (X = halogen or alkoxide) to form the moderately stable ketenylidene complex $[Co_3(CCO)(CO)_9]^+$.[37] Although the structure still has not been established unambiguously, the crystal structures of a number of related clusters show that the coordination of the ketenylidene is flexible (see Section 5.2).

Lewis bases (Y, *see Lewis Acids & Bases*) react with $Co_3(\mu_3\text{-}CX)(CO)_9$ (X = halide) to give either $Co_3(\mu_3\text{-}CY)(CO)_9$ or $Co_3(\mu_3\text{-}CC(O)Y)(CO)_9$. The latter may be formed by solvolysis to the ketenylidene cation. The former products are most likely formed via radical reactions. On the other hand, neutral Lewis bases L can replace the chloride from $H_3Os_3(\mu_3\text{-}CCl)(CO)_9$ to form $H_2Os_3(\mu_3\text{-}CL)(CO)_9$, where L is a nitrogen, phosphorus or sulfur donor.[9]

Protonation of a carbonyl ligand can give rise to a hydroxymethylidyne ligand, COH. Examples include $HM_3(\mu\text{-}COH)(CO)_{10}$ (M = Fe, Ru, and Os), $Co_3(\mu_3\text{-}COH)(CO)_9$, and $HFe_4(\mu_4\text{-}\eta^2\text{-}COH)(CO)_{12}$. Hydrogen migrations from oxygen to the metal–metal bond and the reverse reaction have been noted. Hydroxymethylidynes are likely intermediates in the coupling reactions shown in equations (24) and (25). Protonation or alkylation of isocyanides produce the analogous aminomethylidyne ligands, as shown in equations (26) and (27).

$$[(\mu\text{-}H)Co_3(\mu_3\text{-}CH)_2Cp_3]^+ + CO \longrightarrow [Co_3(\mu_3\text{-}\eta^2\text{-}HCCOH)Cp_3]^+ \quad (24)$$

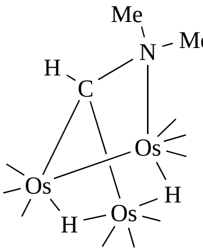
$$Os_3(CO)_{11}(NCMe) + H_2O + HCCH \longrightarrow HOs_3(\mu_3\text{-}\eta^2\text{-}HCCHCOH)(CO)_9 \quad (25)$$

$$[HM_3(CO)_{10}(CNR)]^- + E^+ \longrightarrow HM_3(CO)_{10}(\mu\text{-}CNRE) \quad (26)$$

$$M = Fe, Ru; E = H, Me$$

$$H(\mu\text{-}H)Os_3(CO)_{10}(CNR) \longrightarrow (\mu\text{-}H)Os_3(\mu\text{-}CNHR)(CO)_{10} \quad (27)$$

Alkylidenes have been prepared by reduction of alkylidynes, by C–H oxidative addition from alkyls, and by treatment of unsaturated metal clusters with diazoalkanes. In most instances, the alkylidene adopts a $\mu_2\text{-}\eta^1$ coordination mode. However, alkylidenes with heteroatom substituents may also be found in terminal coordination modes.[39] The latter are typically prepared by the Fischer-type carbene route (*see Fischer-type Carbene Complexes*) (sequential addition of nucleophilic and electrophilic alkylating agents to carbonyl or isocyanide ligands), by condensation of metal fragments with mono- or dimetallic carbene complexes, or by C–H activation of alkylamines.[39] These heteroatom substituted carbenes may also bind in a $\mu_3\text{-}\eta^2$ mode, as in (**12**).



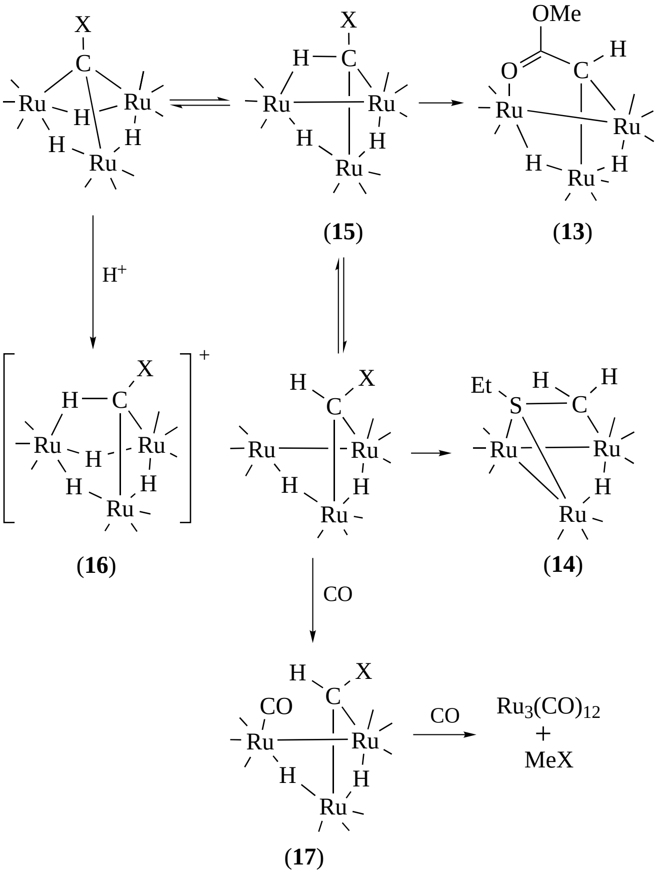
(**12**)

Few alkyls bound to clusters have been prepared. Alkyls containing β-hydrogens are usually unstable with respect to β-elimination (*see β-Elimination*). Alkyls can be stabilized by bridging via a C–H or other bond.[9,32] Examples include $HOs_3(\mu_2\text{-}\eta^2\text{-}H\text{–}CHMe)(CO)_{10}$, $HOs_3(\mu_2\text{-}\eta^2\text{-}H\text{–}CH_2)(CO)_{10}$, $HOs_3(\mu\text{-}\eta^2\text{-}CH_2CO_2Et)(CO)_{10}$, and $HRu_3(\mu_3\text{-}\eta^2\text{-}CH_2SEt)(CO)_9$. These complexes are formed from alkylidenes or alkylidynes by reductive elimination of a C–H bond or by alkene insertion into a metal–hydride bond.

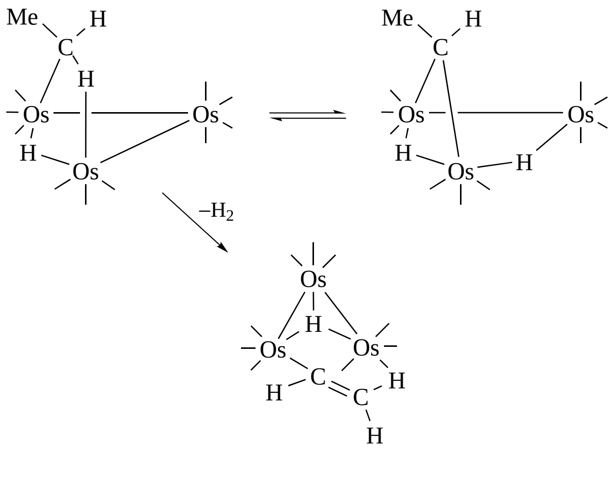
The interconversion of alkylidyne, alkylidene, and alkyl species is amply demonstrated in the chemistry of reductive

elimination (*see Reductive Elimination*) from $H_3M_3(\mu_3\text{-}CR)(CO)_9$ (M = Fe, Ru, and Os). The proposed mechanism for this reductive elimination is shown in Scheme 5. Reactions of $H_3Ru_3(\mu_3\text{-}CX)(CO)_9$ with CO produce MeX and $Ru_3(CO)_{12}/Ru(CO)_5$ when X = Ph, CO_2Me, Cl, or H. Alkylidene and alkyl intermediates can be isolated in several cases. Pyrolysis of $H_3Ru_3(\mu_3\text{-}CCO_2Me)(CO)_9$ in the absence of CO forms $H_2Ru_3(\mu_3\text{-}CHCO_2Me)(CO)_9$ (**13**). This product is formed by reductive elimination of a single C–H bond followed by coordination of the acyl to the unsaturated metal site thus created. Pyrolysis of $H_3Ru_3(\mu_3\text{-}CSEt)(CO)_9$ yields $HRu_3(\mu_3\text{-}\eta^2\text{-}CH_2SEt)(CO)_9$ (**14**); in this case the sulfur atom stabilizes the two vacant sites formed by reductive elimination. Under CO, complete elimination of MeX ultimately yields $Ru_3(CO)_{12}$, which is in equilibrium with $Ru(CO)_5$ under the reaction conditions. Although several pre-equilibria may be postulated to account for the kinetics, the most attractive mechanism, shown in Scheme 5, involves reversible migration of a hydrogen atom from a position bridging a Ru–Ru vector to a position bridging a Ru–C vector, generating intermediate (**15**), reversible cleavage of the agostic (*see Agostic Bonding*) Ru–H–C bond, and rate-determining addition of CO to form a saturated alkylidene cluster; subsequent reductive eliminations are faster than the first. Later studies draw a more complicated picture; pyrolysis of $H_3Ru_3(\mu_3\text{-}CSEt)(CO)_9$ to yield $HRu_3(\mu_3\text{-}\eta^2\text{-}CH_2SEt)(CO)_9$ involves CO dissociation before the rate-determining step and methyl acetate elimination from $H_3Ru_3(\mu_3\text{-}CCO_2Me)(CO)_9$ is unaffected by added CO.[40]

The 'agostic' C–H–M bond (*see Agostic Bonding*) is well established in metal-cluster chemistry. Fehlner and coworkers have shown that $H_3Fe_3(\mu_3\text{-}CH)(CO)_9$ exists in solution in equilibrium with $H_2Fe_3(\mu_3\text{-}\eta^2\text{-}HCH)(CO)_9$ and $HFe_3(\mu_3\text{-}\eta^3\text{-}H_2CH)(CO)_9$ (equation 19). Although the equilibrium constant is not so favorable for the agostic Ru analogs, dissolution of $H_3Ru_3(\mu_3\text{-}CX)(CO)_9$, where X = Et or $CHPhCH_2Ph$, in fluorosulfonic or trifluoromethanesulfonic acid forms $[H_3Ru_3(\mu_3\text{-}\eta^2\text{-}HCX)(CO)_9]^+$ (**16**) by protonation of the Ru–C bond. Protonation of the metal–carbon bond occurs because the HOMO is metal–carbon bonding in character. The NMR spectra provide evidence for fluxional (*see Fluxional Molecule*) migration of the agostic hydrogen to each of the three M–C edges. No exchange occurs between the agostic hydrogen and the hydride ligands on the NMR timescale. Agostic alkylidene-alkyl equilibria are also well known. In solution, $H_2Os_3(\mu\text{-}CH_2)(CO)_9L$ is in equilibrium with $HOs_3(\mu\text{-}\eta^2\text{-}HCH_2)(CO)_9L$, a slightly less stable tautomer.[41] The same tautomeric equilibrium exists for $H_2Os_3(\mu\text{-}CHMe)(CO)_{10}/HOs_3(\mu\text{-}\eta^2\text{-}HCHMe)(CO)_{10}$ ($K_{eq} = 0.14$); in this system, β-elimination (*see β-Elimination*) from the ethyl group is thermodynamically favored, but α-elimination is ca. 100 times faster at 19 °C (Scheme 6).



Scheme 5



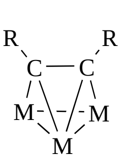
Scheme 6

The chemistry of these C_1 fragments displays all of the unique features of organometallic cluster chemistry. (1) Ligands commonly bridge two or more metal atoms in coordination modes not seen for monometallic complexes. (2) Hydrogen migrations between metal and hydrocarbyl

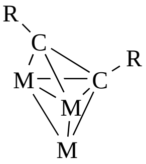
ligands are facile. (3) Intramolecular, intermetallic ligand migrations are important.

5.2 C_2 Units on Clusters

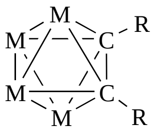
Some of the most prolific reactants in organometallic chemistry are alkynes.[42] At some time or the other every new cluster is reacted with an alkyne. Not surprisingly, alkyne complexes dominate the C_2-containing clusters. Alkynes most commonly bridge the triangular face of the cluster, either as μ_3-η^2-$\|$ (**18**) or as μ_3-η^2-$\perp$ (**19**) ligands. In tetrametallic and larger clusters, alkynes can also bind in a μ_4-η^2 mode (*see Alkyne Complexes*) (**20**).



(**18**) μ_3-η^2- $\|$

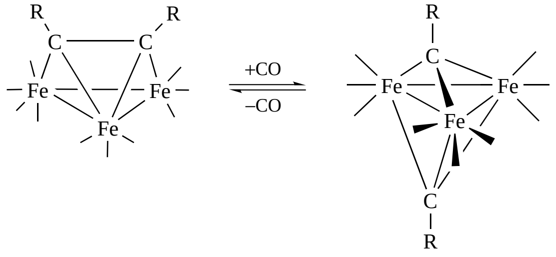


(**19**) μ_3-η^2- $\perp$



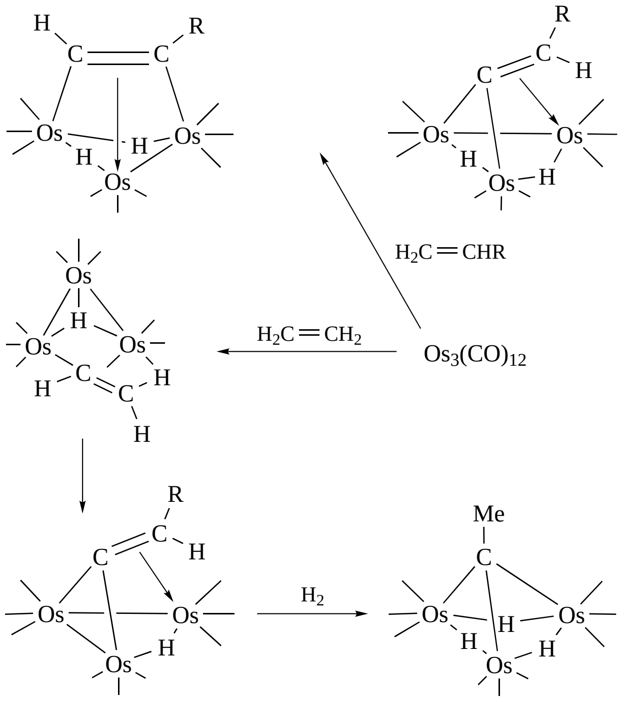
(**20**) μ_4-η^2

One of the most interesting transformations involving a coordinated alkyne is the cleavage of the carbon–carbon bond to form two alkylidyne ligands. This reaction, which is induced by loss of a two-electron donor ligand, is remarkably facile. Reversible cleavage has been demonstrated, as shown in equation (28).[36]



(28)

Thermolysis of metal carbonyl clusters in the presence of alkenes frequently leads to C–H addition, forming 1,1-alkenylidene or alkyne ligands.[9] Pyrolysis of $HOs_3(\mu$-η^2-$CH{=}CH_2)(CO)_{10}$ forms $H_2Os_3(\mu_3$-η^2-$C{=}CH_2)(CO)_9$. Hydrogenation of the alkenylidene yields $H_3Os_3(\mu_3$-$CMe)(CO)_9$. On the other hand, pyrolysis of propene and $Os_3(CO)_{12}$ forms both $H_2Os_3(\mu_3$-η^2-$C{=}CHMe)(CO)_9$ and $H_2Os_3(\mu_3$-η^2-$HC{=}CMe)(CO)_9$. These structures are shown in Scheme 7. Less stable alkene or alkenyl complexes can be formed using the techniques described in Section 2. Insertion of an alkyne into a metal–hydride bond produces an alkenyl ligand. Interconversions of C_2 ligands between μ-ethylidene, μ_3-ethylidyne, and μ_3-vinylidene fragments have been observed on many trimetallic clusters, including iron, cobalt,[43] ruthenium, and osmium,[9,44]



Scheme 7

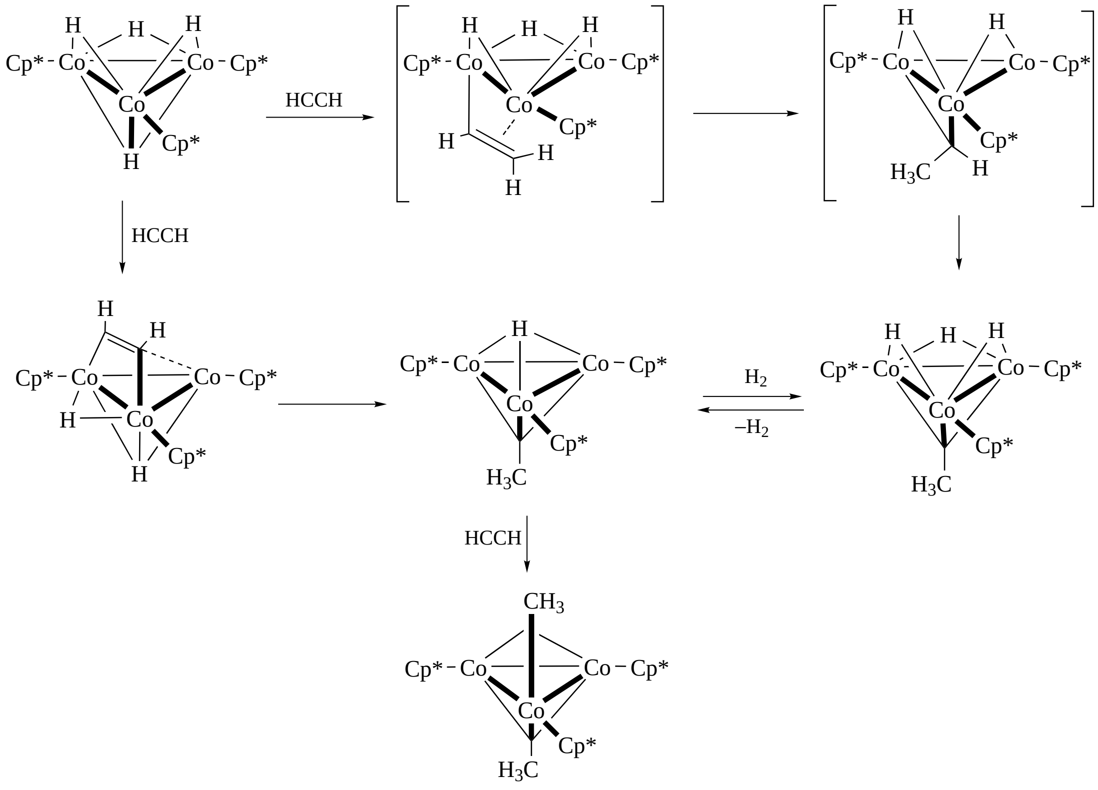
and also heterometallic clusters;[45] one example is shown in Scheme 8.

Ketene and ketenylidene ligands bound to trimetallic frameworks undergo very interesting chemistry.[9,36] The transformations involving these ligands may have some relevance to the chemistry of carbon atoms on metal surfaces.

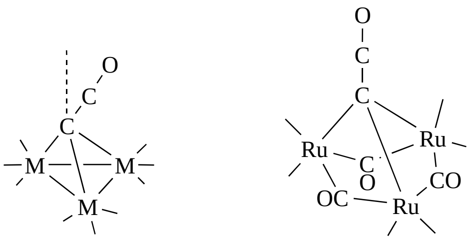
The first examples of ketene complexes were prepared by carbonyl–methylene coupling (equation 29). The ketene complex $Os_3(CH_2C(O))(CO)_{12}$ reacts with methanol, water, and hydrogen to give methyl acetate, acetic acid, and acetaldehyde, respectively. However, $[Os_3(\mu$-$I)(\mu$-$CH_2)(CO)_{10}]^-$ reacts slowly with methanol to give the enolate $[Os_3(CO)_{11}(CH_2C(O)OMe)]^-$ when the reaction is conducted under carbon monoxide. Electrophiles (E = BF_3 or methyl cation) attack at oxygen, forming $Os_3(\mu$-$I)(\mu$ -η^2-$C(OE){=}CH_2)(CO)_{10}$.[9]

$$[Os_3(\mu\text{-}I)(\mu\text{-}CH_2)(CO)_{10}]^- + CO \longrightarrow [Os_3(\mu\text{-}I)\{\mu\text{-}CH_2C(O)\}(CO)_{10}]^- \quad (29)$$

Ketenylidenes have been obtained by removal of oxygen from carbonyl ligands, which results in CO migration to the reactive carbon atom, and by methylene–carbonyl coupling and C–H oxidative addition (Scheme 9).[9,36] The ketenylidene ligand adopts two geometries as a face-capping ligand. The CCO axis of the ligand is tilted toward one metal atom in $[M_3(\mu_3$-$CCO)(CO)_9]^{2-}$ (M = Fe (33°; from the normal) and Os (26°; from the normal)) (**21**), but the CCO axis



Scheme 8 (Reproduced from T. Takao, T. Takemori, M. Moriya, and H. Suzuki, *Organometallics*, 2002, **21**, 5190)



(**21**) (**22**)

$[M_3(CO)_{11}]^{2-}$ + MeC(O)Cl ⟶ $[M_3\{\mu_3\text{-COC(O)Me}\}(CO)_{11}]^-$

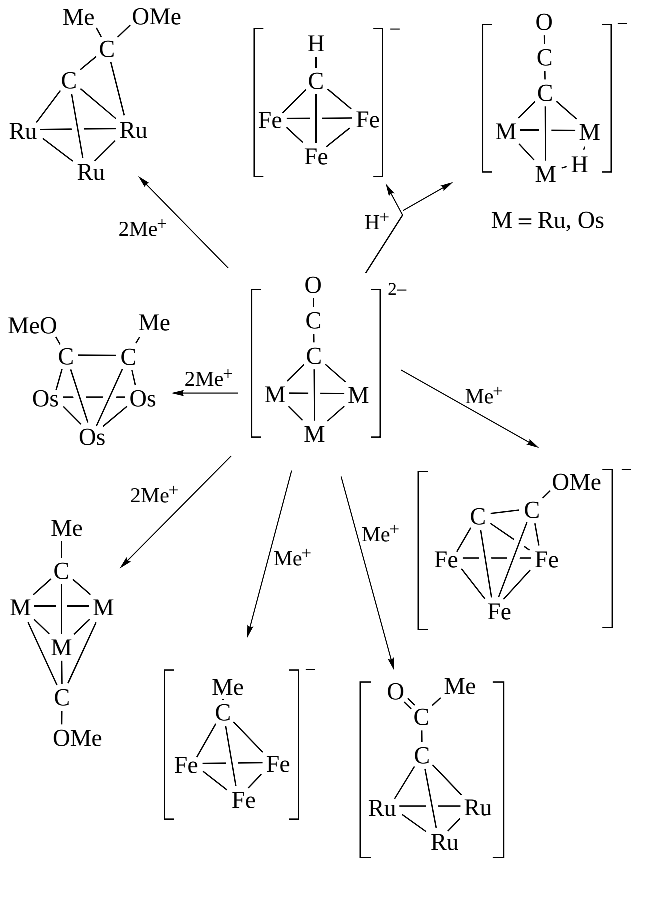
$[M_3\{\mu_3\text{-COC(O)Me}\}(CO)_{11}]^-$ + Na/benzophenone ⟶ $[M_3\{\mu_3\text{-CCO})(CO)_9]^{2-}$

Scheme 9

is almost normal to the trimetallic plane (12°; tilt with respect to the vertical) in $[Ru_3(\mu_3\text{-CCO})(CO)_9]^{2-}$ (**22**). The Ru_3 cluster has a different arrangement of carbonyl ligands as well, having three bridging carbonyls (*see Bridging Ligand*) (cf. only terminal carbonyls for the Os_3 and Fe_3 clusters).

The ketenylidene dianions $[M_3(CO)_9(CCO)]^{2-}$ (M = Fe, Ru, or Os) react as nucleophiles. Products derived from the reactions of ketenylidenes with electrophiles H^+ or Me^+ include methylidyne, alkylidynes, 1,1-alkenylidenes, and acetylides. Some of these reactions are shown in Scheme 10.[36] Carbon–carbon bond cleavage seems to be more facile when the CCO axis is tilted toward one of the metal atoms.

The carbonyl of the ketenylidene ligand undergoes a very interesting substitution reaction with phosphine ligands. Initial



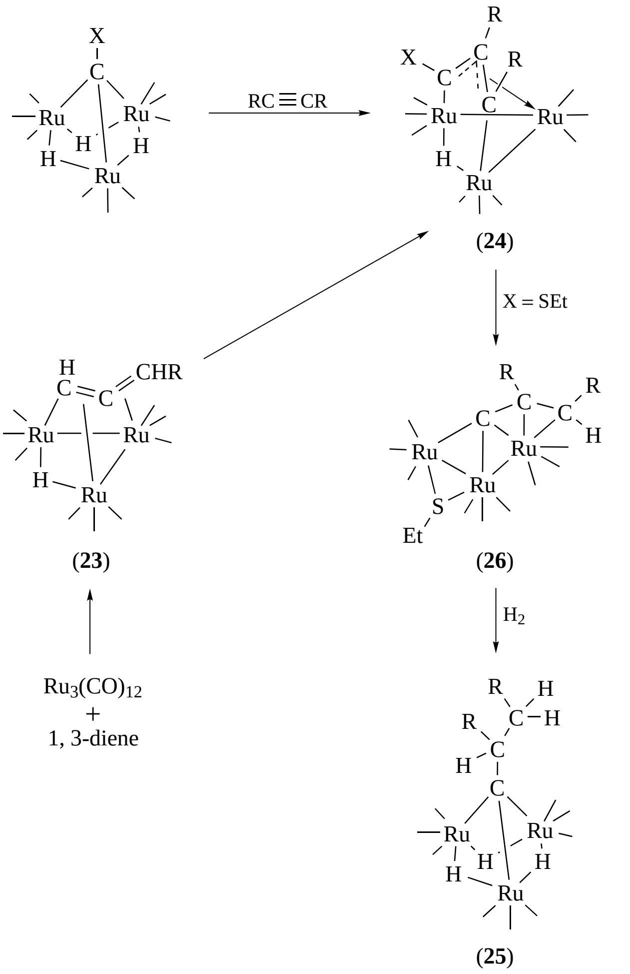
Scheme 10

substitution of $[Fe_2Co(\mu\text{-}CCO)(CO)_9]^-$ by PR_3 occurs at a Co atom by an associative substitution mechanism (*see Associative Substitution*).[46] Subsequently, the substituted product isomerizes to $[Fe_2Co(\mu_3\text{-}CPR_3)(CO)_9]^-$. The mechanism for isomerization is proposed to involve pairwise CO and PR_3 migration through metal–carbon bridging.

5.3 C_3 Units on Clusters

The most common C_3 ligands for monometallic complexes are allyl ligands, but these have not seen extensive use in cluster chemistry. More commonly, hydrogen migrations generate μ_3-η^3-allenyl and μ_3-η^3-1,3-dimetalloallyl ligands, which presumably are more favorable because of the polymetallic coordination.[9,36] Some of these clusters are shown in Scheme 11. Clusters containing allenyl ligands (**23**) have been produced in reactions of 1,3-dienes with metal carbonyl clusters. These clusters rearrange by a 1,2-hydrogen shift to more stable isomers, $HRu_3(\mu_3\text{-}\eta^3\text{-}RCCHCR')(CO)_9$ (**24**).

The $M_3(\mu_3\text{-}\eta^3\text{-}RCCRCR'')$ cluster core is a very stable one which is formed from a variety of unrelated transformations. The cluster is described as a nido form (*see Nido Cluster*) derived by removal of one vertex from a pentagonal bipyramid.

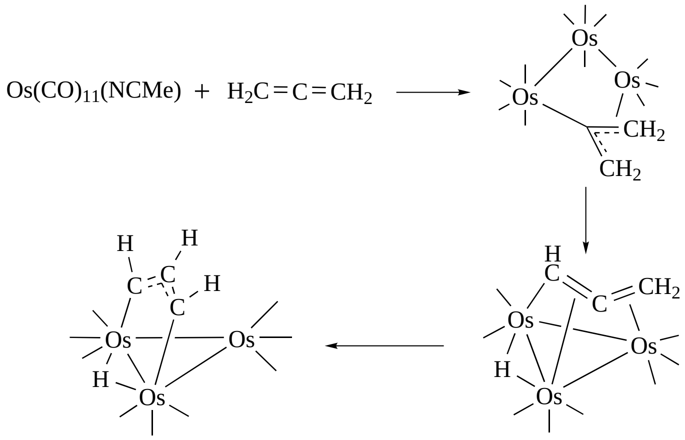


Scheme 11

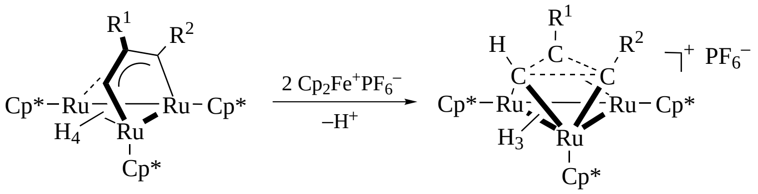
The first examples were prepared in reactions of alkynes with $M_3(CO)_{12}$, M = Ru and Os. The C_3 unit can also be produced by alkylidyne–alkyne coupling.

Other than hydrogen migrations, few reactions involving the μ_3-η^3-RCCRCR″ ligand have been noted. Hydrogenation of $HRu_3(\mu_3\text{-}\eta^3\text{-}MeOCCRCR')(CO)_9$ (see **24**) produces $H_3Ru_3(\mu_3\text{-}CCHRCH_2R')(CO)_9$ (**25**). Isomerization of $HRu_3(\mu_3\text{-}\eta^3\text{-}EtSCCRCR')(CO)_9$ yields $Ru_3(\mu_3\text{-}\eta^3\text{-}CCRCHR')(\mu\text{-}SEt)(CO)_9$ (**26**); this structure may be analogous to an intermediate in the hydrogenation reaction. Hydrogenation of $Ru_3(\mu_3\text{-}\eta^3\text{-}CCRCHR')(\mu\text{-}SEt)(CO)_9$ forms $H_3Ru_3(\mu_3\text{-}CCHRCH_2R')(CO)_9$, in addition to $HRu_3(\mu\text{-}SEt)(CO)_{10}$.

Rearrangement of allene on an Os_3 cluster also produces a $M_3(\mu_3\text{-}\eta^3\text{-}HCCHCH)$ species (Scheme 12). The reaction of the very labile $Os_3(CO)_{11}(NCMe)$ with allene gives as the initial product $Os_3(\mu\text{-}\eta^3\text{-}C(CH_2)_2)(CO)_{11}$. Photolysis of this product causes CO loss and C–H activation, forming $HOs_3(\mu_3\text{-}\eta^3\text{-}CH{=}C{=}CH_2)(CO)_9$. Finally, thermolysis of the allenyl cluster at 125 °C produces the more stable isomer $HOs_3(\mu_3\text{-}\eta^3\text{-}CHCHCH)(CO)_9$.[9]



Scheme 12



Scheme 13 (Reproduced from T. Takao, A. Inagaki, E. Murotani, T. Imamura, and H. Suzuki, *Organometallics*, 2003, **22**, 1361)

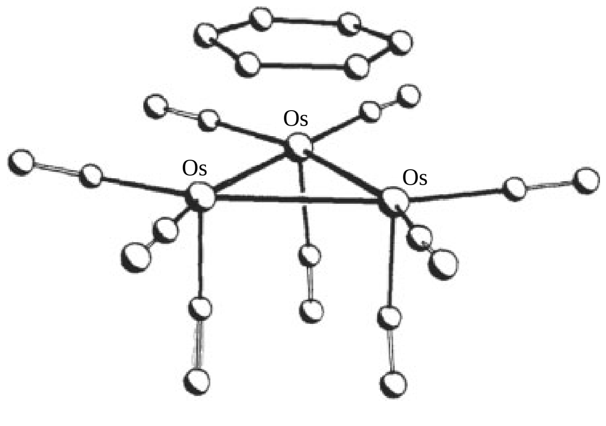
One very unusual reaction involving the μ_3-η^3-RCCRCR″ ligand is shown in Scheme 13. Oxidation of the {Cp* Ru}$_3$(H)$_4$(μ_3-η^3-HCCRCR) by treatment with ferricenium ion gives the cationic complex with a closed C_3 ring, which may be considered to be a η^3-cyclopropenyl. This is a rare example of a C–C reductive elimination initiated by a two-electron oxidation.[47]

6 OTHER HYDROCARBYL LIGANDS

6.1 Arenes

Arene ligands (*see Arene Complexes*) bond to monometallic complexes as η^6-, η^4-, and η^2-C_6R_6 species. Unique to trimetallic or larger clusters is the μ_3-η^2:η^2:η^2-C_6R_6 ligand.[48] This coordination mode is believed to model the geometry of benzene nondissociatively chemisorbed on the surface of a close-packed metal lattice. The prototypical cluster Os_3(μ_3-η^2:η^2:η^2-C_6H_6)(CO)$_9$ (**27**) is prepared by treatment of HOs_3(μ_3-η^5-cyclohexadienyl)(CO)$_9$ with trityl cation and then deprotonation of [HOs_3(μ_3-η^2:η^2:η^2-C_6H_6)(CO)$_9$]$^+$. Fluxionality of the μ_3-η^2:η^2:η^2-C_6H_6 ligand has been noted in Section 4.3.

An interesting example of the effect of electron count upon ligand bonding is the series (Cp*Ru)$_3$(H)$_3$(C_6H_6)$^{0/1+/2+}$. The neutral, 48-e cluster and the 47-e cationic cluster contain η^2:η^2:η^2-C_6H_6 ligands, whereas the 46-e dicationic cluster contains a η^3:η^3-C_6H_6 ligand.[49]



(**27**)

6.2 Fullerenes

Similar face-coordinated fullerene (*see* ***Carbon: Fullerenes***) complexes have been synthesized; also known

are complexes of η^2-C_{60}, μ-η^2:η^2-C_{60}, and μ_3-η^1:η^1:η^2-C_{60}.[50] One example, $Ru_3(CO)_9(\mu_3$-η^2:η^2:η^2-$C_{60})$ (**28**), is shown below.

6.3 Dienes

Conjugated 1,3-dienes can coordinate to a single metal atom or may bridge two metals of the cluster.[9] Most commonly the diene coordinates to a single metal atom in the cis conformation, as in (**29**). The diene is found in the s-trans conformation bridging two metals in $Os_3(CO)_{10}$(1,3-butadiene) (**30**).

7 ORGANOMETALLIC CLUSTERS AS CATALYSTS

Since the discovery of the first metal clusters, researchers have followed the promise of these compounds to serve as improved catalysts for known organic transformations and as catalysts for new transformations. Many clusters have been shown to serve as precursors for both homogeneous and heterogeneous catalysts.[51–53] Unfortunately, it has proven difficult to determine unequivocally that the active catalyst retains the cluster core. Additionally, the 'unique' catalytic properties of clusters have proven elusive. In view of these difficulties and the large number of reviews which have treated various aspects of cluster catalysis, the subject will not be summarized in this article. For further information (*see* ***Carbonylation Processes by Homogeneous Catalysis***; ***Hydrogenation & Isomerization of Alkenes***; ***Organic Synthesis using Transition Metal Carbonyl Complexes***; ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***, and ***Supported Organotransition Metal Compounds***).

8 ORGANOMETALLIC CLUSTERS AS MODELS FOR METAL SURFACE-BOUND HYDROCARBYLS

Molecular transition metal clusters have long been proposed as models for some aspects of the chemistry at metal surfaces. Earl Muetterties was one of the first to promote this 'cluster-surface analogy'.[54,55]

The most successful application of the cluster-surface analogy has been the use of spectroscopic signatures of cluster-bound hydrocarbyl ligands to identify vibrational spectra of chemisorbed hydrocarbons. Hydrocarbon fragments which have been identified on metal surfaces in this way include alkylidynes, alkylidenes, vinylidenes, and carboxylates. The μ_3-CR unit has been identified on numerous metal surfaces, including the Pt(111), Ru(001), Rh(111), and Pd surfaces. Chemisorption of ethylene, acetylene, propene, and other small hydrocarbons can give rise to alkylidyne fragments through C–H cleavage and hydrogen migration, common reactions for molecular metal clusters. The methylene fragment has been identified on the Ru(001) surface by comparison of vibrational data with data from cluster models. C_2 fragments identified by comparison with cluster models include acetylene, acetylide, and vinylidene. Vibrational data for $HOs_3(\mu$-$O_2CH)(CO)_{10}$ are similar to bands observed for formate adsorbed on to a silver surface.

In light of the utility of spectroscopic comparisons between surface adsorbed species and cluster models, it is surprising that so few of the more unique cluster-bound hydrocarbyl ligands have been spectroscopically characterized. Given the exceptional stabilities of structures such as μ_3-η^3-RCCR′CR″ in cluster systems, it is to be expected that such fragments are also to be found on metal surfaces.

Glossary

Addendum: predominant positive-valent element in a polyoxoanion
Heteroatom: nonaddendum positive-valent element in a heteropolyanion
Heteropolyanion: polyoxoanion with at least one kind of positive-valent element (other than hydrogen) in addition to the addenda
Heteropoly blue, heteropoly brown: mixed-valence polyoxoanion formed by partial reduction of the addenda
Isopolyanion: polyoxoanion with one kind of positive-valent element
Lacunary polyoxoanion: polyoxoanion with a surface cavity formed by removal of one or more addenda

1 INTRODUCTION

The elements, M, of groups 5 and 6 form an astonishing variety of polyoxoanions, $[(X)_xM_mO_y]^{n-}$ ($m > x$), where X (if present) can be one or a mixture of atoms from almost all other regions of the periodic table.[1–6] By far the most, polyoxoanions are formed by Mo, W, and V, usually in their highest (d^0) oxidation states. To date, only limited numbers of polyoxoanions of Nb, Ta, and Cr are known.

The first examples of polyoxoanions are considered to have been described by Berzelius in 1826 (yellow ammonium 12-molybdophosphate and -arsenate, and their reduced 'blue' derivatives), but it was not until the last third of the nineteenth century that detailed descriptive chemistry of many polymolybdates and polytungstates began to be reported. Although lacking any structural perspective, much of the early work published between 1865 and 1930, and reviewed in the 8th edition of Gmelin,[7] has been validated by subsequent investigations.

In 1933, Keggin's determination of the structure of the tungstophosphate anion in $H_3[PW_{12}O_{40}]\cdot 6H_2O$ opened the era of structurally characterized polyoxoanions. The 'Keggin Structure' confirmed the general principles that had been earlier suggested by Pauling, although the actual structural details were different. Subsequent structural investigations of polyoxoanions appeared relatively slowly for the next 25 years (only 12 structural types were listed in a 1971 review),[8] but that situation has now completely changed with the virtually routine use of X-ray diffraction and multinuclear NMR spectroscopy for solids and solutions.

Conversion of mononuclear oxoanions into polyoxoanions requires the consumption of acid. Simple examples involving Brønsted acids (*see Acids & Acidity*) in aqueous solutions are given in equations (1–3), although alternative routes to polyoxoanions have been developed, for example, through the use of acidic oxides in aqueous and nonaqueous solvents, or by hydrothermal methods.

$$CrO_4^{2-} + 2H^+ \longrightarrow [Cr_2O_7]^{2-} + H_2O \quad (1)$$

$$7MoO_4^{2-} + 8H^+ \longrightarrow [Mo_7O_{24}]^{6-} + 4H_2O \quad (2)$$

$$SiO_3^{2-} + 12WO_4^{2-} + 22H^+ \longrightarrow [SiW_{12}O_{40}]^{4-} + 11H_2O \quad (3)$$

In principle, all polyoxoanions should be, and most are, subject to decomposition by alkali, although occasionally the pH required for degradation may not be achieved in aqueous media. For example, $[Nb_6O_{19}]^{8-}$ and $[Ta_6O_{19}]^{8-}$ are the simplest oxoanions of Nb and Ta to be formed in water.

The polymerization of simple tetrahedral oxoanions involves (1) the corner linkage of tetrahedra, as with the chromates and some vanadates, and (2), much more commonly, especially with Mo and W, an expansion of coordination number to six, and the edge- and corner linkage of MO_6 octahedra. The ability of Mo^{VI}, W^{VI}, and V^V to display variable (four-, five-, six-, and occasionally seven-fold) coordination by an oxide ion is responsible in part for the large numbers of polyoxoanions formed by these elements. In contrast, hexavalent chromium is effectively limited to four coordination, and Nb^V and Ta^V to six coordination by the oxide ion.

The polyhedral (MO_n) building blocks of virtually all polyoxoanions are linked in such a way as to result in each polyhedron having either one or two (mutually *cis*) unshared vertices. The metal atoms are displaced from the centers of their coordination polyhedra toward these unshared vertices. These displacements correspond to the formation of short metal–oxygen terminal bonds resulting from oxygen p_π donation into the metal's vacant d-orbitals. Such terminal oxygens, which are very weakly basic, form part of the external surfaces of the polyoxoanions and effectively prevent further polymerization. Very rarely (about three examples

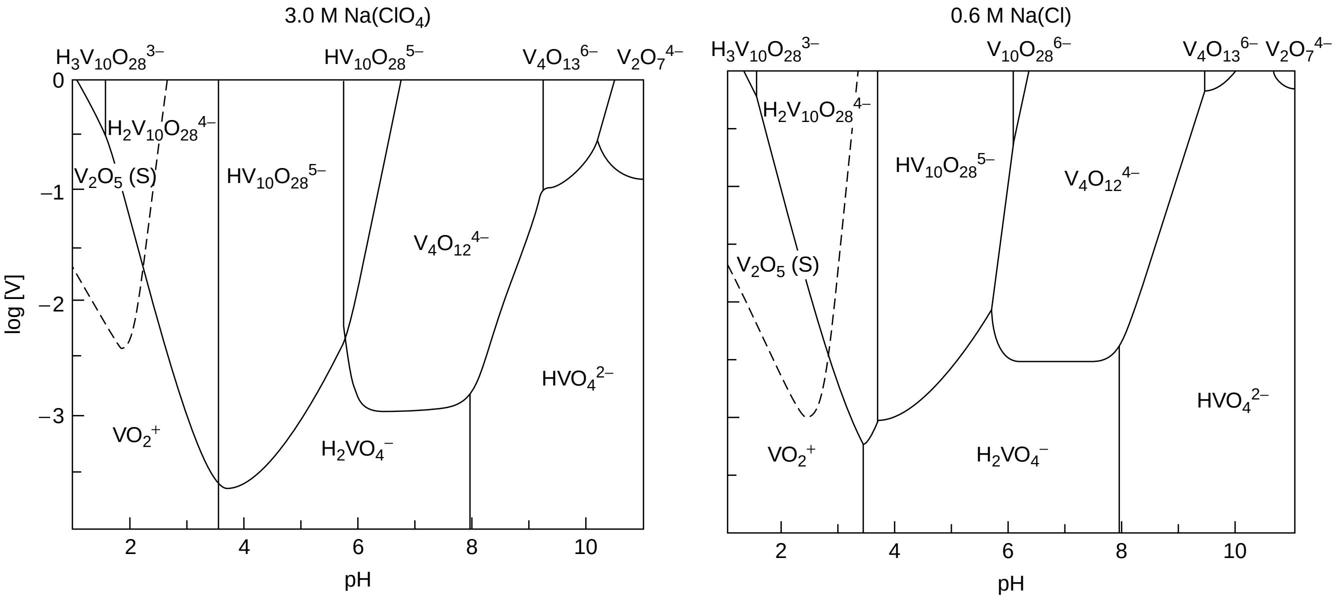

Figure 1 Predominance diagrams for aqueous polyvanadate species. (With kind permissions of Kluwer Academic Publishers)

are currently known), a polyanion may contain an MO_6 octahedron with three (*fac*) unshared vertices. As observed for mononuclear *fac*-trioxo complexes of Mo and W, the oxo oxygens are more basic and nucleophilic than those of the monooxo and *cis*-dioxo species, and polyoxoanions that contain such a structural feature tend to become protonated or undergo further condensation.

2 AQUEOUS OXOANION HYDROLYSIS: ISOPOLYANIONS

The conversion of mononuclear tetrahedral oxoanions to polyoxoanions (equation 4)

$$qMO_4{}^{n-} + pH^+ \longrightarrow [M_qO_y]^{m-} + \frac{p}{2}H_2O \qquad (4)$$

is governed by equilibria that are strongly dependent upon ionic strength, the nature of the countercation, temperature, and so on. Furthermore, equilibria involving some vanadates and tungstates are complicated by slow kinetics. With these caveats, we can make the following generalizations.

2.1 Isopolyanions of Group 5 Elements

Of the group 5 elements, only V^V forms a significant range of polyoxoanions. Speciation in aqueous solutions has been investigated by a combination of precise EMF measurements and ^{17}O and ^{51}V NMR spectroscopy; see Figure 1. In the ‘alkaline’ region (pH ca. 6 and above) are species based on tetrahedral coordination of V: $[V_2O_7]^{4-}$, traces of $[V_3O_{10}]^{5-}$, *cyclo*-$[V_4O_{12}]^{4-}$, and *cyclo*-$[V_5O_{15}]^{5-}$, and protonated forms of these anions. Interconversion between these species is rapid, but some kinetic data have been acquired via NMR. In the ‘acidic’ region (pH ca. 4–6), the orange decavanadates, $[H_xV_{10}O_{28}]^{(6-x)-}$ (Figure 2), with six-coordinate V, predominate. Other reported polyvanadates(V) are species that are either generated in, and isolated from, a nonaqueous solution, for example, $[V_5O_{14}]^{3-}$, the bowl-shaped $[V_{12}O_{32}]^{4-}$ (Figure 3), and $[V_{13}O_{34}]^{3-}$, or are kinetically metastable aqueous species, for example, $[H_{12}V_{13}O_{40}]^{3-}$ and $[V_{15}O_{42}]^{9-}$.

The aqueous chemistry of oxoniobates and tantalates is limited to the hexametalate anions, $[M_6O_{19}]^{8-}$ (Figure 4), although a niobium analog of decavanadate has been prepared by hydrolysis of $Nb(OEt)_5$.

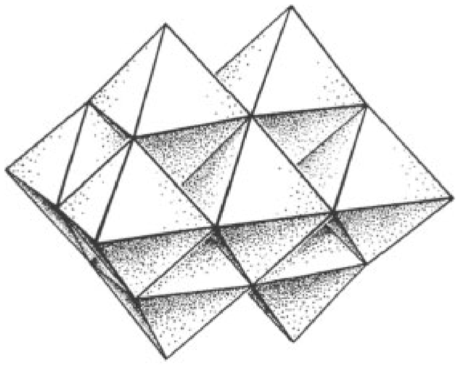

Figure 2 The D_{2h} structure of $[V_{10}O_{28}]^{6-}$ as an arrangement of VO_6 octahedra

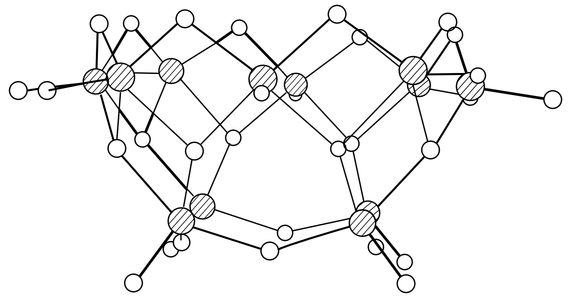

Figure 3 $[V_{12}O_{32}]^{4-}$

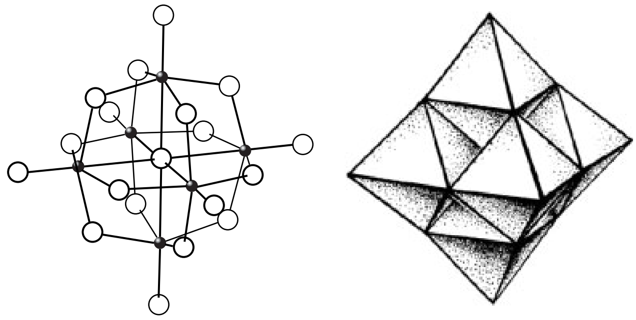

(a) (b)

Figure 4 Bond and polyhedral representations of $[M_6O_{19}]^{n-}$ ($M = Nb^V, Ta^V, Mo^{VI}, W^{VI}$)

2.2 Isopolyanions of Group 6 Elements

In group 6, Cr^{VI} polyoxoanions are based entirely on CrO_4 tetrahedra and are limited effectively to $[Cr_2O_7]^{2-}$ and $[Cr_3O_{10}]^{2-}$. Molybdenum(VI) and tungsten(VI), on the other hand, form many isopolyanions, most of which incorporate six-coordinate metal centers: $[Mo_2O_7]^{2-}$ exists only in the absence of alkali metal counter ions (*see Counter Ions*), and must be generated in nonaqueous solvents. In aqueous solution, the first stable polyanions formed (pH ca. 5) are the heptametalates, so-called 'paramolybdate' and 'paratungstate-A', $[M_7O_{24}]^{6-}$ (Figure 5). Subsequent hydrolysis differs for Mo and W: (β-)$[Mo_8O_{26}]^{4-}$ has been identified in solutions of relatively low $[Na^+]$ (see Figure 6) and an Mo_{36} species (see below) is isolated from more acidic solutions, whereas tungstates ultimately are converted to the Keggin structure 'metatungstate', (α-)$[(H_2)W_{12}O_{40}]^{6-}$ (Figure 7), although several other kinetically metastable species are known, for example, 'paratungtate-B', $[H_2W_{12}O_{42}]^{10-}$, and 'tungstate-X', (β-)$[(H_2)W_{12}O_{40}]^{6-}$. In nonaqueous solvents, other structures can be synthesized; these include $[Mo_5O_{17}H]^{3-}$, α-$[Mo_8O_{26}]^{4-}$, $[W_{10}O_{32}]^{4-}$ (Figure 8), and hexametalate species (Figure 4).

3 HETEROPOLYANION STRUCTURES

3.1 'Tetrahedral' Heteroatoms: the Keggin- and Related Structures

The stereochemical requirements of the heteroatoms generally determine the architecture of the heteropolyanions formed. This is illustrated by the Keggin structure (Figure 7) (and its numerous derivatives), which encloses a central tetrahedral unit ranging from $\{SO_4\}^{2-}$ to '$\{Cu^IO_4\}^{7-}$' (see Table 1).

Table 1 Heteroatoms, X, in Keggin heteropolyanions α-$[\{XO_4\}M_{12}O_{36}]^{n-}$

M = Mo	M = W	Net anion charge
S^{VI}		2−
P^V, As^V, Sb^V, V^V	P^V, As^V, V^V	3−
Si^{IV}, Ge^{IV}	C, Si^{IV}, Ge^{IV}, (?Mn^{IV})	4−
Ga	B, Al, Ga, Cr^{III}, Fe^{III}, Co^{III}	5−
	2H, Be, Zn, Co^{II}, Cu^{II}	6−
	H, Cu^I	7−

Structural isomers of the Keggin anion are possible, and have been confirmed in some cases. The best-known are those of C_{3v} symmetry, in which of one of the four equivalent groups of three edge-shared MO_6 octahedra of the parent anion have been rotated by $\pi/3$ radians. This structure is designated β, following α for the original Keggin anion, and has kinetic stability only. According to density functional calculations, the relative stabilities of the two isomers depends upon the oxidation state of the central heteroatom.[9] In one case, $[(AlO_4)W_{12}O_{36}]^{5-}$, an equilibrium is established between the two isomers.[10] 'Rotation' of two, three, and all four edge-shared groups yield γ,δ, and ε structures respectively. Whereas β isomers of $[(SiO_4)W_{12}O_{36}]^{4-}$ and the corresponding germanate are well established, and an unstable γ isomer of the silicate has been confirmed, no δ or ε isomers are known (but the ε configuration is recognizable as a part of other polyvanadate ($[H_3Mn^{IV}{}_3V_{12}O_{40}]^{5-}$) and polymolybdenum ($[(Cp^*Rh^{III})_8(Mo^V{}_{12}O_{36})(MoO_4)]^{2+}$, $[H_{14}Mo^V{}_{12}Mo^{VI}{}_4O_{52}]^{6-}$) structures, and is observed for the polycation in $[Al_{13}O_{40}H_{36}]^{5+}$). In so-called β-isomers several Keggin molybdates have been identified in solution, and although it is reasonable to presume that they have structures analogous to the β-tungstates, no unambiguous structural data are available for the fully oxidized species (but see below for a heteropoly blue structure). Possibilities for isomerism (*see Isomer*, *Types of*) increase enormously when 'mixed-addenda' polyoxoanions are considered, for example, $[\{PO_4\}V_2W_{10}O_{36}]^{5-}$. This example has five 'positional' isomers if the whole anion has an α configuration, and 13 isomers if the anion is β. That such isomers exist has been well established by NMR spectroscopy. In some cases, unique mixed-addenda anions may be synthesized and characterized; in others, mixtures of isomers are observed. Isomerization reactions generally are quite slow, but no successful method of separation of positional isomers has yet been developed.

The heteropolyanions $[\{XO_4\}_2M_{18}O_{54}]^{n-}$ (M = Mo, W; X = P, As, S) have a structure (of the so-called 'Dawson' type) formed by fusion of two Keggin fragments generated by the loss of three adjacent corner-shared MO_6 octahedra (see

Figure 9). The Dawson anions are formed spontaneously in molybdophosphate and -arsenate solutions of the appropriate stoichiometry and acidity, but the tungstates are formed slowly in solutions with a large excess of phosphate or arsenate. Several structural isomers (α, β, etc.) are known, especially for the tungstates. These involve 'rotation' of the edge-shared triad groups at the ends of the anion, and/or rotation of the two half-units. Further (positional) isomerism has been demonstrated for mixed-addenda species such as α-$[\{PO_4\}_2W_{12}Mo_6O_{54}]^{6-}$.

The Keggin and Dawson structures incorporate internal XO_4 tetrahedra that are attached to the oxometalate shell through each oxygen atom (μ_4 type), but structures are also known in which a tetrahedral coordination polyhedron occupies an exterior site (i.e. μ_3, one vertex is unshared). Examples are $[\{PO_4\}_2Mo_5O_{15}]^{6-}$ (Figure 10) and $[\{MoO_4\}_2Mo_6O_{18}]^{4-}$. Analogous structures are observed for polyanions in which the heteroatoms are trivalent P, As, Sb, tetravalent S, Se, and organo derivatives, $RXO_3{}^{n-}$. In the structures of $[P_6W_{18}O_{79}]^{20-}$ and $[P_5W_{18}O_{78}H_3]^{20-}$, both μ_3 and μ_4 phosphate tetrahedra are observed.

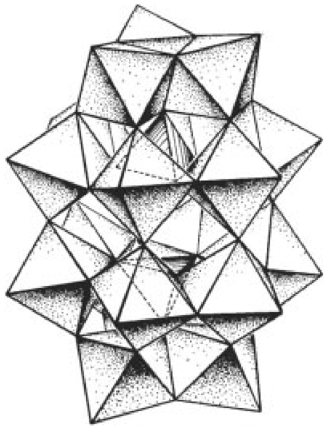

Figure 9 $[\{XO_4\}_2M_{18}O_{54}]^{n-}$, the D_{3h} 'Dawson' structure

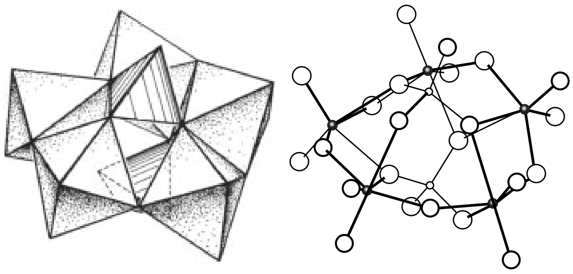

Figure 10 Polyhedral and bond representations of $[\{PO_4\}_2$-$Mo_5O_{15}]^{6-}$

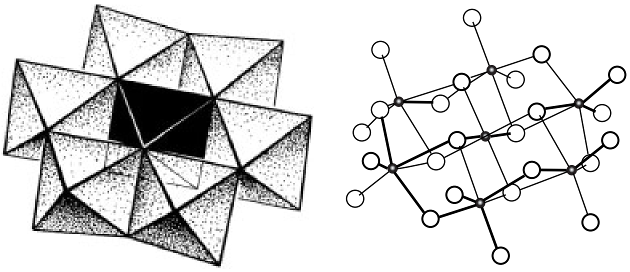

Figure 11 Polyhedral and bond representations of the 'Anderson' structure, $[\{XO_6\}M_6O_{18}]^{n-}$

3.2 Six-, Eight-, and Twelve-coordinate Heteroatoms

Several heteropolyanion structures accommodate central octahedral heteroatoms: an especially widespread type is the D_{3d} 'Anderson' structure (Figure 11 and Table 2). Note that two versions of the structure are known: with or without protonation of the central XO_6 octahedron, depending upon the oxidation state of X. Although the heptametalate anions, $[M_7O_{24}]^{6-}$ (Figure 5), can be considered to be C_{2v} isomers of the Anderson anions, few heteropolyanions have so far been shown to adopt the former structure.

Higher heteroatom coordination numbers are seen for the derivatives of lanthanide and actinide cations, which adopt the structures of $[\{CeO_8\}W_{10}O_{28}]^{8-}$ (square antiprism, *see Square Antiprism*) and $[\{UO_{12}\}Mo_{12}O_{30}]^{8-}$ (icosahedron, *see Icosahedron*), illustrated in Figures 12 and 13.

4 LACUNARY SPECIES AND THEIR DERIVATIVES

Although all polyoxoanions are ultimately decomposed to monomeric species in basic solution, control of pH leads in

Table 2 Anderson heteropolyanions: $[\{X(OH)_6\}M_6O_{18}]^{n-}$ or $[\{YO_6\}M_6O_{18}]^{n-}$

Heteroatom type	M = Mo	M = W	Net anion charge
X	Al, Ga, Cr^{III}, Fe^{III}, Co^{III}, Rh^{III}	–	3−
X	Mn^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn	Ni^{II}	4−
Y	I^{VII}	I^{VII}	5−
Y	Te^{VI}	Te^{VI}	6−
Y	Sb^{V}	Sb^{V}	7−
Y	Pt^{IV}	Mn^{IV}, Ni^{IV}, Pt^{IV}	8−

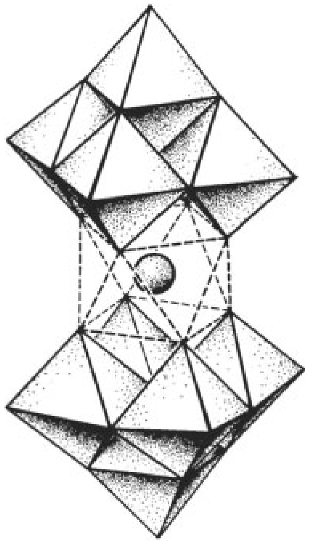

Figure 12 $[\{CeO_8\}W_{10}O_{28}]^{8-}$

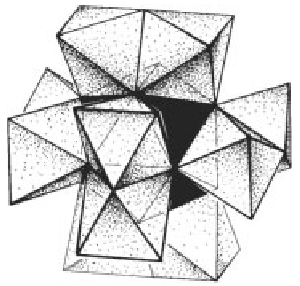

Figure 13 $[\{UO_{12}\}Mo_{12}O_{30}]^{4-}$

many cases to the formation, isolation, and characterization of ‘defect’ or ‘lacunary’ structures. These are best illustrated with the Keggin anion (Figure 7), which can form species $[XM_{11}O_{39}]^{n-}$ and $[XM_9O_{34}]^{n-}$ by the ‘removal’ of one or three (adjacent) MO_6 octahedra respectively. An intermediate structure in which two adjacent octahedra have been removed has not been observed; it would contain an MO_6 octahedron with three fac terminal oxygen atoms and is therefore expected to be quite reactive. Two kinds of XM_9 anions can be formed, both with C_{3v} symmetry: A-type, in which three corner-shared octahedra have been lost, and B-type, in which three edge-shared octahedra have been lost. Neither of these structures appears to be thermodynamically stable in solution, although both have been isolated as solid salts, and have been used to synthesize derivatives. In addition, both A- and B-type XM_9 structural units are recognizable in larger polyoxoanions. Examples are: $[P_2M_{18}O_{62}]^{6-}$, the D_{3h} Dawson structure formed by fusion of two A-PM_9 units; $[As^{III}_2W_{21}O_{69}(aq)]^{6-}$ and $[P^{V}_2W_{21}O_{71}(aq)]^{6-}$, two B- and A-type XW_9 respectively, separated by a ‘belt’ of three WO_6 octahedra; $[Co_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ with two B-type PW_9; and $[(NH_4)As^{III}_4W_{40}O_{140}]^{27-}$, containing four B-type AsW_9 units. Many of these larger structures can be further converted to lacunary species, for example, X_2M_{18} (X = P, As) (‘Dawson structure’) yields X_2M_{17}, X_2M_{15}, and X_2W_{12} anions.

Derivatives of lacunary polyoxometalate structures are legion. Most investigations have been made with ‘monovacant’ XM_{11} species, which function as tetra- or pentadentate ligands. Typically, metal cations are bound into the cavity generated by the loss of MO^{4+} from the Keggin structure, with formation constants of 10^2–10^5 (for divalent first-row transition metal cations). The resulting complexes may contain an exchangeable ligand attached to the incorporated cation; examples are $[BW_{11}O_{39}Co(NO_2)]^{7-}$ and $[PW_{11}O_{39}Ru(\eta^2\text{-}MeCHCHCO_2H)]^{5-}$. In other cases, especially for higher-valent cations, covalently attached atoms or groups may be present. Table 3 summarizes some of the possibilities for these types of complexes.

Lacunary anions with more than one surface ‘vacancy’ also may be derivatized by cation complexation. The results are not always predictable. Thus, XW_9 species may yield the expected ‘plenary’ Keggin structures, for example, $[PW_9V_3O_{40}]^{6-}$ and $[SiW_9O_{37}\{Cr(H_2O)\}_3]^{7-}$, but in other cases ‘sandwich’ structures based on either XW_9 arrangement are produced, for example, $[Co_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ (B-type), $[(OCe)_3(H_2O)_2(PW_9O_{34})_2]^{12-}$ and $[(H_2OCo)_3(PW_9O_{34})_2]^{12-}$ (A-type).

5 REDOX BEHAVIOR

Since polyoxometalates contain fully oxidized (d^0) metal atoms, they are resistant to oxidation, and high-valent states

Table 3 Derivatives of monovacant lacunary polyoxoanions, {P} (= e.g. $[PW_{11}O_{39}]^{7-}$)

A. Stoichiometry $[\{P\}M(L)]^{n-}$
- 1. M formally six coordinate:
  - L exchangeable:
    - M = di- and trivalent cations of Groups 3–13, alkali, alkaline-earth cations
    - L = especially H_2O, OH^-, but also numerous other ligands
  - L multiply bonded or otherwise nonexchangeable:
    - L = O^{2-}; M = tetra-, penta-, hexa-, and heptavalent species, e.g. $VO^{2+,3+}$, MnO^{2+}, CrO^{3+}, RuO^{3+}, TcO^{3+}, MoO^{4+}, ReO^{5+}
  - Other ML^{n+} combinations: SnR^{3+}, GeR^{3+}, OsN^{3+}, $RuNO^{3+}$, $MoNO^{3+}$, $Ti(Cp)^{3+}$
- 2. M formally four coordinate, L absent or weakly bonded, e.g. Cu^{2+}, Pd^{2+}, Pt^{2+}, Sn^{II}

B. Stoichiometry $[M(\{P\})_2]^{n-}$
- M formally eight coordinate (square antiprism), e.g. lanthanide(3+,4+) and many actinide(4+) cations; alkaline-earth cations (?)

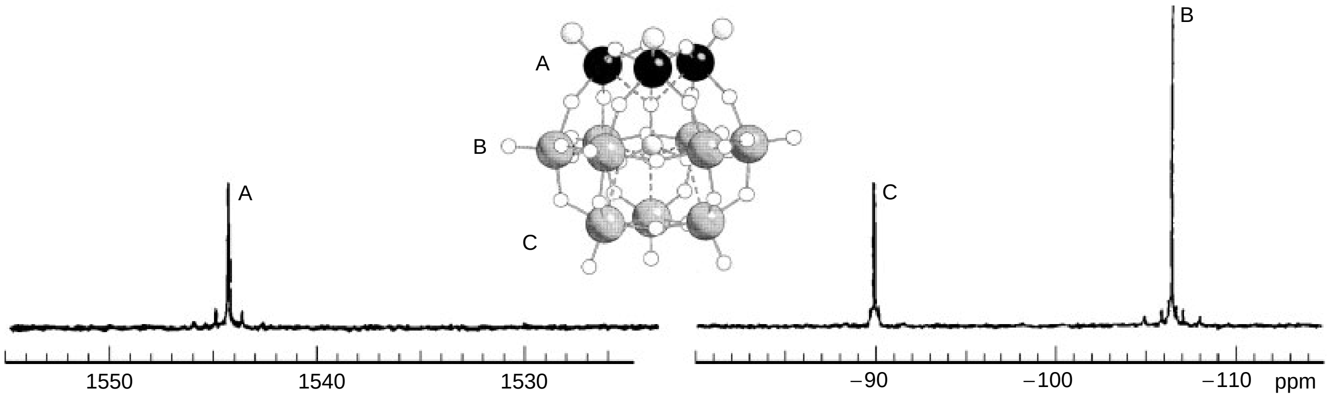

Figure 14 Tungsten-183 NMR spectrum of the heteropoly 'brown' α-$[\{SiO_4\}W_9^{VI}O_{33}(W^{IV}H_2O)_3]^{4-}$

of the heteroatoms can therefore be stabilized. Examples include tetravalent Ni, pentavalent Cr, Ru, and U, and hexa- and heptavalent Re. Such species have been used as electron transfer oxidants for organic substrates. By virtue of their structures, unusual coordination geometry–oxidation state combinations are observed, for example, tetrahedral high-spin Co^{III}, reversible $Cu^{I/II}$ couples, both in Keggin structure anions, and icosahedral f^1 species (Ce^{III}, U^V). The transition metal ion-substituted polyoxoanions (cf. Section 4) can be viewed as oxidation-resistant analogs of metalloporphyrins (*see Metalloporphyrin*) and indeed much of their reactivity, especially in nonaqueous solvents, is found to parallel that of the porphyrins, for example, as epoxidation catalysts, and the binding and activation of O_2, and so on.

Many polyoxoanions undergo facile and reversible reductions, which are conveniently studied by electrochemical methods, to yield mixed-valence heteropoly 'blues' and 'browns'.[1] The necessary feature for such behavior is the presence of (d^0) metal atoms with single (rather than two) terminal oxo oxygens, as found, for example, in the Keggin structure (Figure 7), but not in the Anderson structure (Figure 12). The strong axial ligand field generated by the monooxo arrangement produces a nonbonding orbital ('d_{xy}') on each metal atom. Heteropoly blues typically contain one to six Mo^V or W^V centers per anion as a result of partial occupation of these orbitals. Variable-temperature electron spin resonance (ESR) spectroscopy demonstrates for the paramagnetic one-electron reduced blues that the added electron undergoes a thermally activated 'hopping' between metal centers, that is, it is trapped on a single metal at sufficiently low temperature.[11–13] The blue colors of these species are the result of intensity-enhanced d–d transitions and intervalence charge transfer bands (*see Intervalence Transfer Transition*). Subsequently added 'blue' electrons couple with the first via multipath antiferromagnetic interactions (*see Antiferromagnetism*), and the delocalization of the blue electron pairs generate enhanced diamagnetism (*see Diamagnetism*) as a consequence of ring currents within the heteropolyanions.[14] The molybdate blues especially have long been used for colorimetric determination of trace levels of phosphate, silicate, and so on.

Heteropoly 'browns' are more highly reduced tungstates, generated by intraionic disproportionation of the blues under acidic conditions. Such species contain metal–metal bonded triangular clusters of three edge-shared $W^{IV}O_6$ octahedra (see Figure 14). The Keggin structure can therefore accommodate as many as 24 additional electrons in this fashion. Indeed, an additional eight electrons (32 in all!) can be accommodated in nonbonding molecular orbitals, two electrons per trimeric unit. Each W^{IV} bears a terminal exchangeable water ligand (thereby keeping the anion charge low), and the browns have been shown to participate in atom-transfer processes, for example, equation (5).

$$[(SiO_4)W_9O_{33}\{W^{IV}(H_2O)\}_3]^{4-} + 3Me_2SO \longrightarrow [(SiO_4)W_{12}O_{36}]^{4-} + 3Me_2S + 3H_2O \quad (5)$$

6 POLYOXOANION DERIVATIVES AND FUNCTIONALIZATION[15]

Organic and organometallic derivatives of polyoxometalates have been synthesized by direct or indirect routes.

6.1 From Lacunary Anions

Lacunary structures such as $[PW_{11}O_{39}]^{7-}$ react straightforwardly with RMX_n (M = Ge, Sn, As, and so on, that is, atoms that can undergo an expansion of the coordination number from four to six) to yield $[PW_{11}O_{39}MR]^{m-}$ species. Examples of such products are $[PW_{11}O_{39}Ti(Cp)]^{4-}$, $[BW_{11}O_{39}GeC_2H_4CO_2H]^{6-}$, and $[P_2W_{15}O_{56}\{SnBu\}_3]^{9-}$. With organophosphorus and -silicon reagents, the products retain four-coordinate P and Si, for example, $[\{PhP(O)\}_2XW_{11}O_{39}]^{n-}$ and $[\{RP(O)\}_2PW_9O_{34}]^{5-}$.

An alternative route to the organostannate derivatives involves the reaction of preformed Sn^{II} polyanions, for example, $[SiW_{11}O_{39}Sn:]^{6-}$, as nucleophiles with alkyl or organometallic halides.

6.2 From 'Complete' Polyanions

Direct attachment of organometallic moieties to the surface oxygen atoms of 'complete' (plenary) polyoxoanion structures is often possible. Generally, the relative basicity of the surface oxygen atoms is increased by partial substitution of W^{VI} atoms by Nb^V or V^V. In most cases, the organometallic group is attached in a ν^3 mode employing oxygen atoms that bridge the groups of three edge-shared MO_6 octahedra of the hexametalate (Figure 5), Keggin (Figure 7), or Dawson (Figure 10) structures. Simple examples include *cis*- and *trans*-forms of $[Nb_6O_{19}\{Re(CO)_3\}_2]^{6-}$, $[1,5\text{-(cod)}IrP_2W_{15}O_{62}]^{8-}$ and $[(CpTi)SiW_9V_3O_{40}]^{4-}$, but more elaborate constructions, for example, $[\{(C_7H_8)Rh\}_5(Nb_2W_4O_{19})_2]^{3-}$, are possible. Polyoxoanions may also be derivatized at the Nb–O terminal oxygen, for example, $[Cp_3U(NbW_5O_{19})_2]^{5-}$.

6.3 Oxoalkoxo Anions

Alkoxide derivatives have mostly been prepared indirectly, although thermal treatment of $[Me_3O]_3[PMo_{12}O_{40}]$ has yielded a methyl derivative of the Keggin anion (methylation at oxygen atom bridging edge-shared MoO_6 octahedra). Through the use of polyalcohols such as pentaerythritol and $RC\{(CH_2)_2OH\}_3$, several examples of polyoxoalkoxoanions have been synthesized by solution or hydrothermal methods. Of particular note are vanadate(IV) species based on the hexametalate (Figure 4) and decavanadate (Figure 1) cores with alkoxy oxygens in surface bridging positions. Although not within the purview of this article, it should be recognized that the neutral oligomeric (*see Oligomer*) alkoxides of the early transition elements such as titanium(IV) have structures comparable, and in some instances identical ($[Ti_7O_4(OEt)_{20}]$ versus $[Mo_7O_{24}]^{6-}$, Figure 5), to those of polyoxometalates.

6.4 Functionalized Heteroatoms

Complexes in which the heteroatom bears an organic group form another class of heteropolyanion derivatives. Several analogues of the structure illustrated in Figure 10 with phosphonates, arsonates, and phosphate monoesters have been synthesized. Other examples include the zwitterionic species $[\{H_3NC_6H_4AsO_3\}_4Mo_{12}O_{34}]$, and acetal and arsinate derivatives, $[\{R_2XO_2\}Mo_4O_{12}(OH)]^{n-}$ (X = C, As). With some of these complexes, it has been possible to demonstrate rapid intramolecular rearrangements, pseudorotation, hydration, and group transfer.

7 GIANT POLYOXOANION ASSEMBLIES[16]

In the decade or so since the first edition of this encyclopedia, there has been a considerable growth in the synthesis and structural characterization of unusually large polyoxometalates. In most cases, these have stability in solution (NMR spectroscopy) as well as in the solid state, and can be considered as linked assemblies of polyoxoanion building blocks.

7.1 Vanadates

Most 'large' polyvanadates contain both V^{IV} and V^V centers and frequently enclose small anions as clathrate guests. Examples are $[H_4V^{IV}_{18}O_{42}\{X\}]^{9-}$ (X = Cl, Br, I) and $[V^{IV,V}_{15}O_{36}\{CO_3\}]^{7-}$. The largest reported polyvanadate cluster is $[V^{IV,V}_{34}O_{82}]^{10-}$, which encapsulates a $\{V_4O_8\}$ cubane template.

7.2 Niobates

Clusters of approximately D_3 symmetry containing 30 niobium centers have been reported. These consist of five $[Nb_6O_{19}]^{8-}$ anions attached in trigonal bipyramidal fashion to a central oxocluster containing two Al^{3+} and six Ln^{3+} (Ln = Eu, Er, Lu) cations.

7.3 Molybdates

The first examples of very large polyoxomolybdates to be structurally characterized were the Mo_{36} isopolyanion noted above (Section 2.2) and an Eu_4Mo_{29} anion. Both of these anions contain $[Mo_7O_{24}]$ groups, two in the case of Mo_{36} and four in Eu_4Mo_{29}. The latter anion probably only has an identity in the solid state. In Mo_{36}, two of the molybdenum(VI) centers in each heptamolybdate have become seven-coordinate (quasi pentagonal bipyramidal), and a structural building block $\{Mo_8\}$ consisting of the bipyramid sharing equatorial edges with five MoO_6 octahedra, and two additional corner-shared octahedra, Figure 15, can be defined.

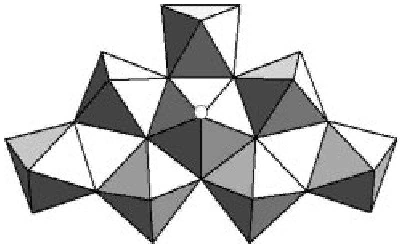

Figure 15 $\{Mo_8\}$ building block present in several large polyoxomolybdates. (Reprinted with permission from Ref. 16. © 1998 American Chemical Society)

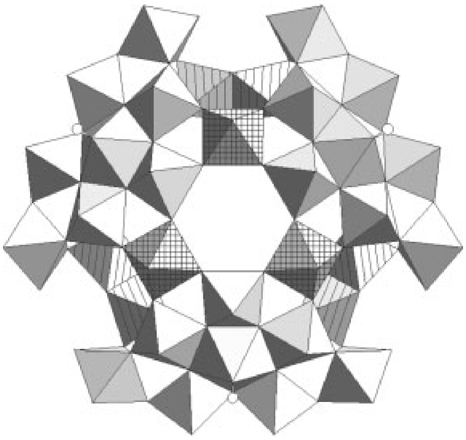

Figure 16 $[X_6\{Mo^V(\mu\text{-}H_2O)_2(\mu\text{-}OH)Mo^V\}_3\{Mo^{VI}_{15}(MoNO)_2\text{-}O_{58}(H_2O)_3\}]^{21-}$ ($X = V^{IV}O(H_2O)$; $Fe^{III}(H_2O)_2$). (Reprinted with permission from Ref. 16. © 1998 American Chemical Society)

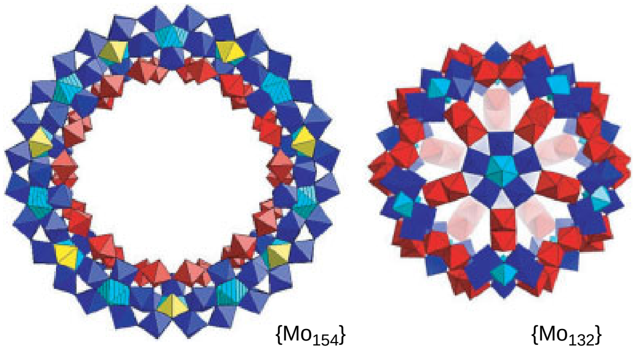

Figure 17 $[Mo_{154}O_{420}(NO)_{14}(OH)_{28}(H_2O)_{70}]^{28-}$ and $[\{Mo^V{}_2O_4\text{-}(CH_3COO)\}_{30}\{(Mo)Mo_5O_{21}(H_2O)_6\}_{12}]^{42-}$. (Reproduced by permission of Wiley-VCH)

The $\{Mo_8\}$ unit is observed in many of the spectacular polymolybdate clusters that have been reported by Müller during the last decade. These include the $\{Mo_{57}M_6\}$ anions (Figure 16), the ‘giant wheels’, $\{Mo_{154}\}$ (Figure 17) and $\{Mo_{176}\}$, the icosahedral ‘ball’ $\{Mo_{132}\}$ (Figure 17),[17] and the ‘hedgehog’ $\{Mo_{368}\}$ (Figure 18).[18]

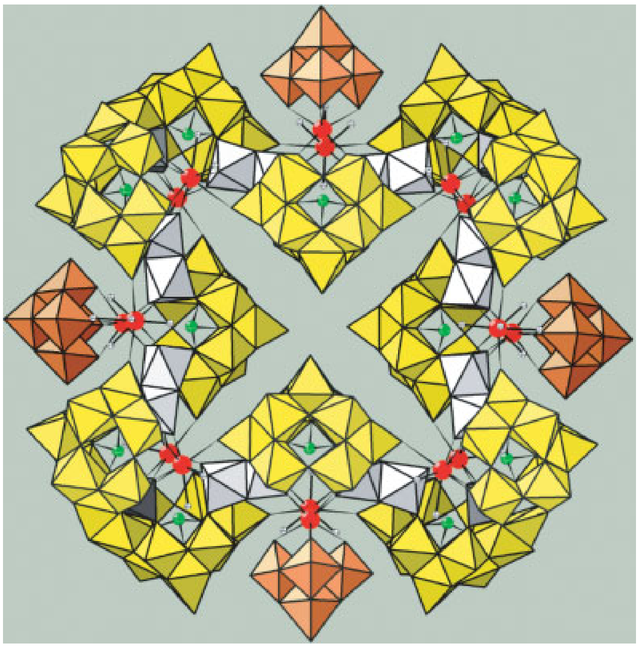

Figure 19 $[Ln_{16}(H_2O)_{36}(WO_2)_4(W_2O_6)_8(AsW_9O_{33})_{12}\text{-}(W_5O_{18})_4]^{76}$

7.4 Tungstates

Unlike the majority of the large polyoxomolybdates, which are mixed-valence $Mo^{V,VI}$ species, the tungstates are based on assemblies of lacunary W^{VI} units. Common building blocks are the B-type trivacant lacunary anions $[X^{III}W_9O_{33}]^{9-}$ ($X =$ As, Sb) and $[P_2W_{15}O_{56}]^{12-}$. The long-known As_4W_{40} anion contains four AsW_9 groups linked by WO_6 octahedra; more recent examples include $[As_6W_{65}O_{217}(H_2O)_7]^{26-}$ with six,[19] and $[Ln_{16}(H_2O)_{36}(WO_2)_4(W_2O_6)_8(AsW_9O_{33})_{12}(W_5O_{18})_4]^{76}$. (Figure 19) with twelve.[20] The latter anion includes lacunary W_5 groups derived from the hexatungstate anion (Figure 4), also seen in species like $[Eu_3(H_2O)_3(SbW_9O_{33})(W_5O_{18})_3]^{18-}$.

Examples of complexes incorporating $[P_2W_{15}O_{56}]^{12-}$ are the ‘tetrahedral’ assemblies $[\{(TiOH)_{12}O_6\}(P_2W_{15}O_{56})_4]^{24-}$ and $[(UO_2)_{12}(\mu_3O)_4(\mu_2H_2O)_{12}(P_2W_{15}O_{56})_4]^{32-}$ (Figure 20).[21,22]

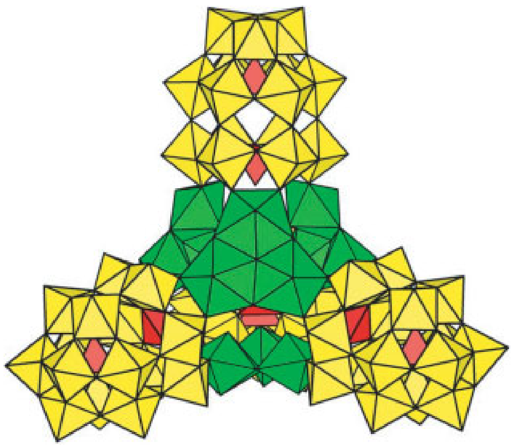

Figure 20 $[(UO_2)_{12}(\mu_3O)_4(\mu_2H_2O)_{12}(P_2W_{15}O_{56})_4]^{32}$

8 APPLICATIONS

The special properties of polyoxoanions (their large sizes, high molecular weights, solubilities in polar and nonpolar solvents, electron, and proton transfer and 'storage' capacities, high thermal stabilities, etc.) lead to numerous applications in several fields. These have been recently reviewed.[23] The earliest applications were in analytical chemistry, and it is probably true that the majority of publications involving polyoxometalates concern their analytical uses, especially for phosphate and silicate determinations via heteropoly blue formation. Another early application has been the use of tungstophosphoric acid, $H_3PW_{12}O_{40}$, as a general negative or positive stain for electron microscopy. With the development of covalently attached organic derivatives, this use is now expanded to highly selective species that target specific sites for imaging. Recently, polyoxometalates have proved to be successful phasing agents in the structural crystallography of large biomolecules such as the ribosome.[24]

Polyoxoanions have many desirable features that lead to their use as catalysts, both homogeneous and heterogeneous, and this use has expanded dramatically in recent years.[25–30] Molybdophosphates are used heterogeneously in the large-scale commercial oxidation of methacrolein to methacrylic acid, and in methane oxidation. Molybdovanadophosphates, mostly $[PMo_{10}V_2O_{40}]^{5-}$ and $[PMo_9V_3O_{40}]^{6-}$, have been developed as homogeneous reoxidants in Wacker chemistry (oxidation of alkenes, coupling of aromatics, *see Wacker Process*) and allow the process to be carried out at much lower chloride concentrations. Tungstophosphoric acids are used heterogeneously as Brønsted acid catalysts for the production of 2-propanol, 2-butanol, and *t*-butanol by alkene hydration. Numerous laboratory-scale catalytic systems have been developed. These include the use of transition metal derivatives of lacunary anions as 'metalloporphyrin analogs' for epoxidations and other oxidations; $[PMo_{10}V_2O_{40}]^{5-}/Br^-/O_2$ for brominations; polytungstates as photochemically activated oxidation catalysts.

Many polyoxometalate salts have been shown to be biologically active. Such activity includes a highly selective inhibition of enzyme function (phosphatases, dehydrogenases, isomerases), especially with the smaller vanadate and molybdate oligomers (V_4, Mo_4, Mo_5). In some cases, the selectivity seems to depend upon shape.

A large fraction of polytungstates that have been tested prove to have potent antitumoral and antiviral activity (rabies, influenza, scrapie, and the retroviruses responsible for AIDS and SAIDS).[31] Toxicity varies widely, but some species are less toxic than azidothymidine (AZT) and are effective against AZT-resistant cell lines. The polyoxoanions bind to the gp120 envelope glycoprotein of the retrovirus, and in some cases inhibit the function of the rus reverse transcriptase (cf. AZT). Reviews of Structure and Reactivity of Polyoxometalates have recently appeared.[32,33]

Polyphosphazenes

Harry R. Allcock
The Pennsylvania Sate University, University Park, PA, USA

1 Synthesis 1
2 Structure–Property Relationships 4
3 Uses 5
4 Summary 7
5 References 7

Most synthetic polymers are totally organic macromolecules derived from petroleum. One of the exceptions is the broad class of polymers with an inorganic backbone – called polyphosphazenes.

These polymers exist with a number of different architectures, as shown in Figure 1, but they all contain a backbone or rings of alternating phosphorus and nitrogen atoms, with two organic, organometallic, or inorganic side groups linked to each phosphorous atom. Most examples have a linear or lightly branched structure (**1**) (Figure 1). However, in recent years the development of star or dendritic species (**2**) and hybrid phosphazene-organic macromolecules such as (**3–6**) has widened the scope of this field and has stimulated numerous applications in addition to those known for pure polyphosphazenes.[1]

The first stable polyphosphazenes, of type (**1**), were synthesized in the mid-1960s, and in the intervening years this field has grown into a major area of polymer science that is the largest inorganic-based system. Its chemistry is broader than that of poly(organosiloxanes) (silicones) and larger than many areas of classical organic polymer science. More than 700 different polyphosphazenes are now known, with over 250 different types of organic or organometallic side groups, extremely diverse properties, and a widening list of actual and potential applications. Major developments have occurred during the past 10 years that have enhanced interest in these materials used in fields as diverse as biomedicine, fuel cell and battery technology, advanced elastomers, and optical and opto-electronic (photonic) materials. Moreover, the fundamental chemistry has been expanded to provide valuable information about polymerization mechanisms, macromolecular substitution chemistry, and structure–property relationships. The following account emphasizes this recent work and includes selected references since 1993. For a more comprehensive overview, the reader is referred to a recent monograph[1] and to an edited volume.[2]

1 SYNTHESIS

The original synthesis pathway to poly(organophosphazenes) is shown in Scheme 1.

The starting material is hexachlorocyclotriphosphazene (**7**) prepared from phosphorus pentachloride and ammonium chloride. Thermal ring-opening polymerization of this cyclic trimer in the molten phase at 250 °C in a sealed system brings about its slow conversion to poly(dichlorophosphazene) (**8**). The same reaction can be carried out in solution in dichlorobenzene at slightly lower temperatures, provided a catalyst such as boron trichloride is used. Poly(dichlorophosphazene) is a colorless elastomeric material that is soluble in organic solvents such as benzene, toluene, tetrahydrofuran, or cyclohexane. It is also highly reactive to nucleophiles such as alkoxides, aryloxides, and primary or secondary amines, which bring about replacement of the chlorine atoms by organic groups. A few organometallic reagents behave in the same way. The most remarkable feature of this reaction is the fact that all the halogen atoms can be replaced to give polymers that are in most cases stable to air, water, and radiation. Thus, typically 30 000 chlorine atoms per polymer molecule are replaced by organic groups, often within a few hours of reaction at 25–70 °C. Two or more different types of side groups may be introduced by sequential or simultaneous substitutions and this further widens the range of properties. In general, the long chain length of the poly(dichlorophosphazene) is carried forward into the structure of the substituted macromolecules. One disadvantage of this route is that the ring-opening polymerization process does not allow control of the chain lengths or of the molecular weight distribution. Nevertheless, it is the method that has been used to produce most of the known polyphosphazenes mainly because the starting materials are readily available and standard wet-chemistry techniques are employed. This process is also used to polymerize cyclic phosphazenes that bear short, linear phosphazene side chains (so-called *phosphazophosphazenes*)[1,3] and cyclophosphazenes that have carbon or sulfur in the ring in place of one of the phosphorus atoms.[1,4] All these polymers can then be subjected to halogen-replacement reactions in the same way as poly(dichlorophosphazene). Poly(dichlorophosphazene) is also produced via an inexpensive condensation reaction of $Cl_3P{=}NP(O)Cl_2$[2], but the molecular weights tend to be lower than those generated via the ring-opening route

However, the same polymeric intermediate can now be synthesized by an alternative method, which allows considerable control over the structure of the final product.[5–9] This is a living cationic polymerization process, which takes place at room temperature in solution, and which allows excellent control of the chain lengths, gives narrow molecular weight distributions and provides access to a wide rage of block, graft, and comb copolymers with organic macromolecules or poly(organosiloxanes). The monomer for this reaction is an N-silylchlorophosphoranimine (**9**), which may be prepared from Me_3SiCl and PCl_5, $(Me_3Si)_3N$ and PCl_5,

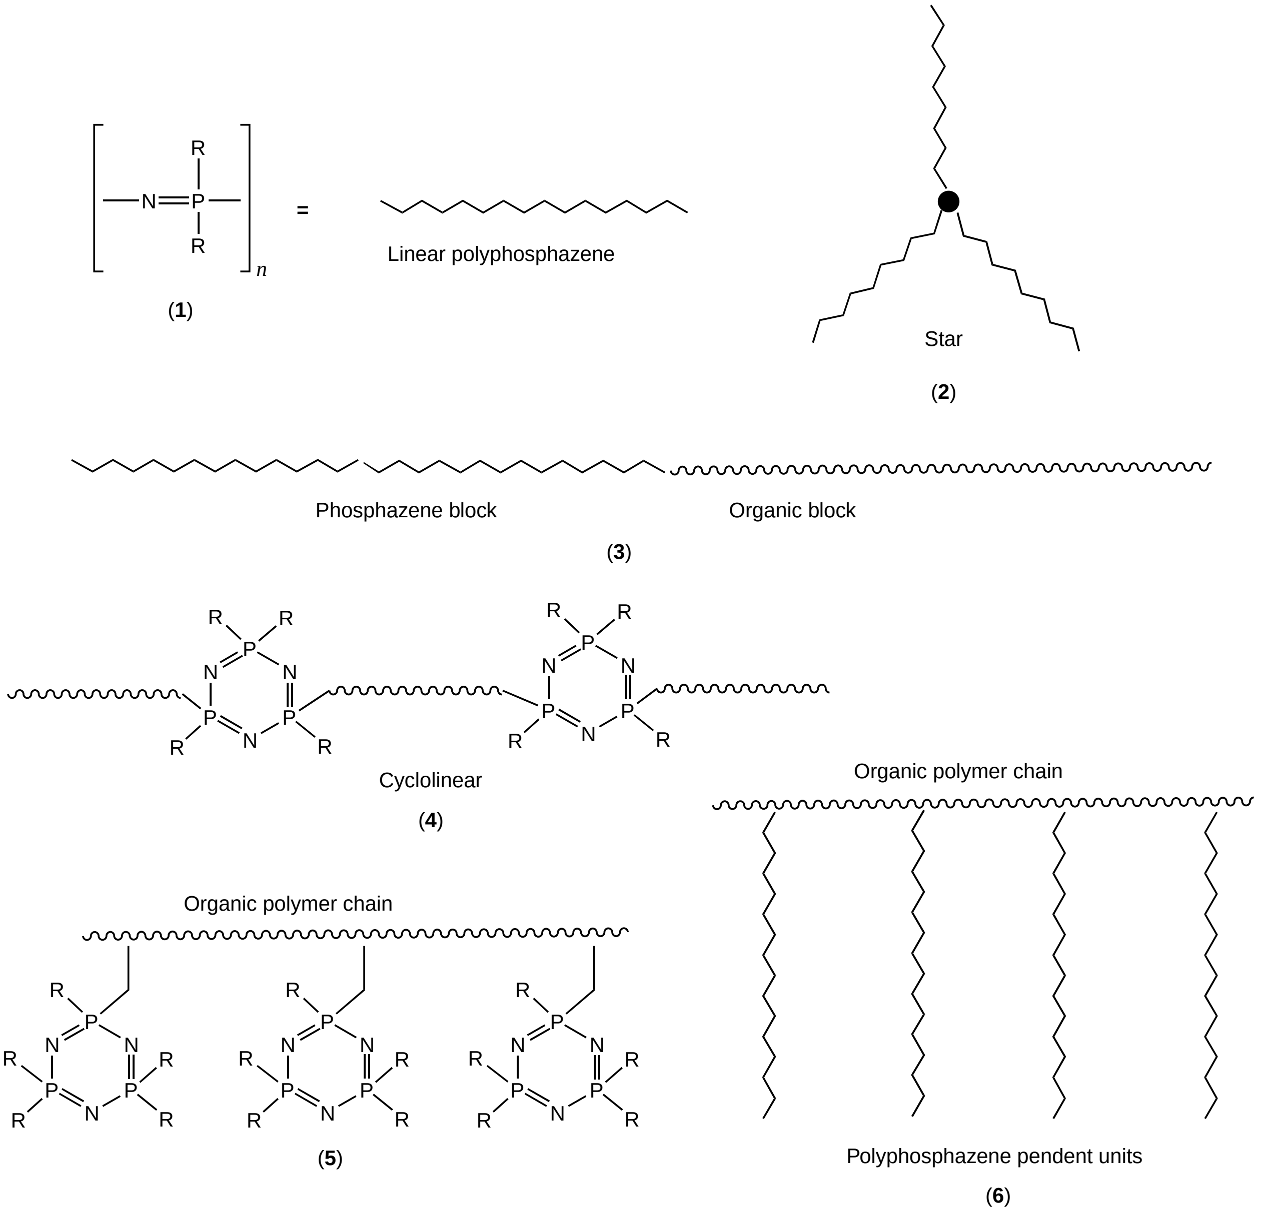

Figure 1 Different types of polyphosphazenes including linear classical macromolecules (**1**), star structures (**2**), block copolymers (**3**), cyclolinear polymers (**4**), and comb or graft copolymers (**5**) and (**6**). Not shown are cyclomatrix materials in which cyclic trimeric rings are connected in three dimensions[1]

or most recently from PCl_3 and $S(O)Cl_2$.[10] Polymerization of (**9**) occurs in the presence of an initiator such as phosphorus pentachloride, with trimethylchlorosilane being eliminated during the reaction. The overall sequence and a possible mechanism are shown in reactions (1)–(3).

Initiation

$$Cl_3P{=}NSiMe_3 \xrightarrow[-Me_3SiCl]{2PCl_5} Cl_3P{=}N{-}PCl_3^+\ PCl_6^- \quad (1)$$

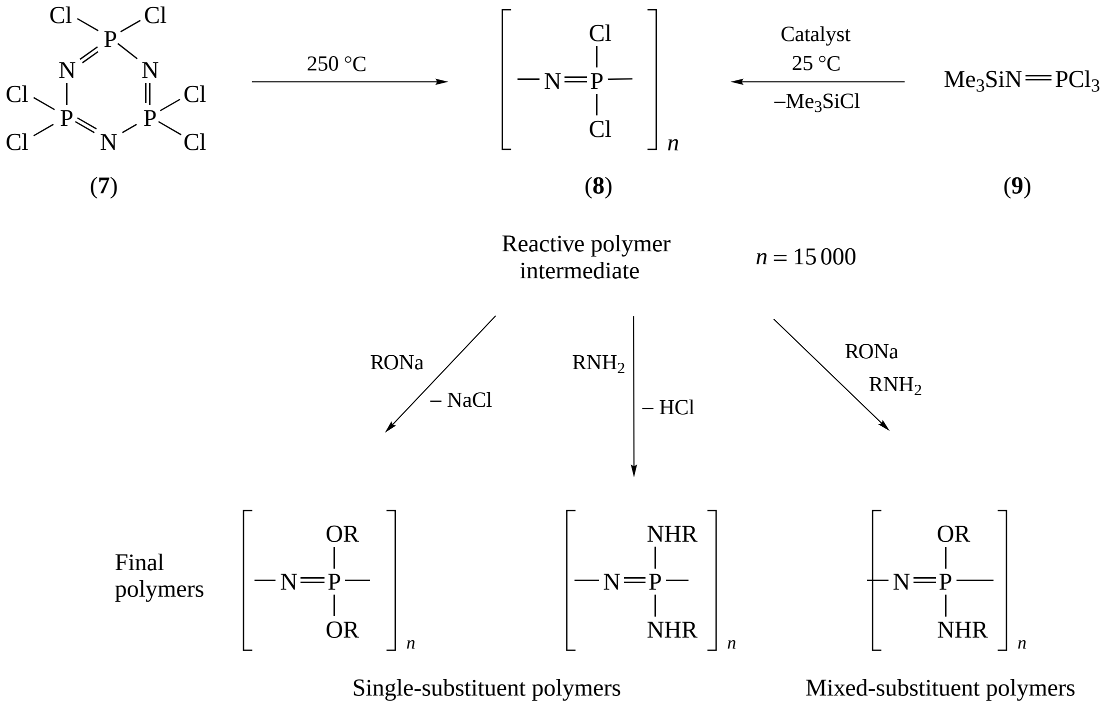
$$Cl_3P{=}N{-}PCl_3^+\ PCl_6^- \xrightarrow[-Me_3SiCl]{2PCl_5} [Cl_3P{=}N{-}PCl_2{-}N{=}PCl_3]^+\ PCl_6^- \quad (2)$$

Propagation

$$[Cl_3P{=}N{-}PCl_2{-}N{=}PCl_3]^+\ PCl_6^- \xrightarrow[-ClSiMe_3]{Cl_3P{=}NSiMe_3} Cl_3P{=}(PCl_2{=}N)_n - PCl_3^+\ PCl_6^- \quad (3)$$

''The living'' polymer end unit initiates more of same monomer, a different phosphoranimine monomer, or is coupled to a phosphoranimine-terminated organic polymer.

A major advantage of the living cationic polymerization process is that, because the chain ends are still active after



Scheme 1

polymerization, they can be used to couple the polyphosphazene to other polymers to produce block copolymers with polysiloxanes or organic polymers. Moreover, the living chain ends can be quenched with species that link organic unsaturated units to the chain ends. Polymerization of these allows the preparation of comb and graft copolymers such as (**6**).

Several synthetic pathways exist for the direct preparation of poly(organophosphazenes) that are based on the polymerization of phosphoranimines that already bear organic side groups. For example, various poly(organophosphazenes) are accessible via the polymerization of $Me_3Si–N{=}PR_2(OCH_2CF_3)$ as shown in reaction (4),[11–13] and others have been produced using anionic initiators (reaction 5).[14] Other synthesis routes involve the careful, controlled decomposition of diorganophosphorus azides (reaction 6).

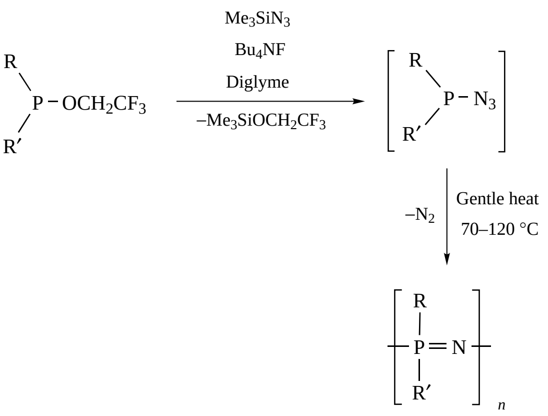
$OR^1 = OCH_2CH_2OCH_3$ or $OCH_2CH_2OCH_2CH_2OCH_3$

$OR^2 = OCH_2CF_3$



(6)

A number of recently reported synthetic methods include the formation of organic polymers with pendent cyclic or linear phosphazene side groups (reactions 7–9)[15–17] and a process for the preparation of linear polymers in which phosphazene rings are linked together by organic oligomer chains using acyclic diene metathesis (ADMET) techniques (reaction 10).[18]

2 STRUCTURE–PROPERTY RELATIONSHIPS

The synthesis of a large number of polyphosphazenes and an investigation of their properties has provided an almost unique opportunity to understand the relationship between the structure and properties in these systems.[1] A long-range objective is to be able to predict the properties of yet-unsynthesized polymers.

The properties of these polymers can best be understood in terms of three factors: (1) the special characteristics of the polyphosphazene backbone and its architecture, (2) the structure of the side groups linked to the skeletal phosphorus atoms, and (3) the ways in which the polymer molecules are packed together in the solid state.

1. *The Backbone.* The linear inorganic backbone imparts an unusual combination of properties. First, perhaps unexpectedly in view of the unsaturated structure, the skeletal bonds have a low barrier to torsion (perhaps as low as 0.1–0.5 Kcal/ repeating unit), which becomes translated into one of the most flexible backbones known throughout polymer chemistry. This means that some polyphosphazenes have glass-transition temperatures (T_g) as low as −100 °C. It also means that, in the absence of microcrystallinity, numerous polymers of this type are rubbery elastomers. This is a key property for

many applications. Second, the inorganic backbone is fire resistant. Small-molecule phosphorus compounds have been used for many years as fire retardants, but polyphosphazenes have this property built into their basic structure. Third, the phosphazene skeleton is transparent throughout the visible region of the spectrum and down to ∼220 mμ in the ultraviolet. This is the reason why polyphosphazenes are much more resistant to photolysis and thermolysis than most organic polymers. The backbone is also unusually resistant to cleavage by X-rays and γ-rays. It is believed that this stability is connected with the reluctance of the polar P–N bonds to split into free radicals when heated or irradiated. One other factor that depends on the backbone is the refractive index. The high-electron density in the skeleton generates a higher-base refractive index than found in most other polymers, and this is important for several optical and electro-optical applications.

2. *The Polymer Architecture.* Most of the known polyphosphazenes are linear or have lightly branched chains (**1**). However, as mentioned above, other geometries exist, including highly branched, star, or dendritic structures, comb polymers, a variety of block-copolymer structures and macromolecules that contain six-membered rings. Two polymers with approximately the same molecular weight, one linear and the other with star-geometry, both with the same side groups, will have very different properties. For example, for species with trifluoroethoxy side groups, the linear polymer has a high viscosity in solution, readily crystallizes, and gives films and fibers, but the more compact tri-star structure has a lower solution viscosity and is a noncrystalline gum.[19] Block copolymers tend to have properties that have some combination of the properties of the two component homopolymers, and this is especially true when one of the blocks is a phosphazene and the other is an organic polymer or a polysiloxane. This enables the design of polymers that combine the advantages of each while possibly minimizing the disadvantages of both. Block copolymers with, say, a hydrophilic phosphazene block and a hydrophobic organic block can form micelles in aqueous media.[20] The same is true of species that contain two different phosphazene blocks – one hydrophobic and the other hydrophilic.[21] Organic polymers with cyclophosphazene-pendent groups tend to have higher T_g's than the corresponding organic polymer and are much more resistant to combustion. Cyclolinear polymers of structure (**4**) typically have properties that are entirely different from those of the corresponding organic polymer. These too may be fire resistant.
3. *The Side Groups.* The side groups linked to phosphorus play an equally important role, as shown schematically in Figure 2. They influence not only chemical properties and solubility but solid-state properties as well.

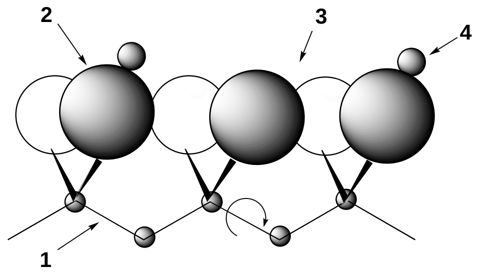

Figure 2 Properties in polyphosphazenes are determined by: (1) the backbone bonds that control the inherent flexibility of the polymer via their influence on bond torsional freedom, and also provide photo- and thermo-oxidative stability; (2) the side groups control polymer solubility, reactivity, thermal stability, crystallinity, cross-linking, and (indirectly) polymer flexibility; (3) 'free volume' between the side groups affects polymer motion, solvent penetration, membrane behavior, and density; (4) functional groups (usually introduced by secondary reactions) affect solubility, biological behavior, proton conduction, cross-linking, and many other properties

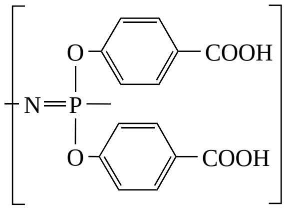
Small side groups, such as methoxy or ethoxy, or those that themselves are highly flexible, such as methoxyethoxyethoxy groups, do not impede the conformational reorientation of the backbone. Hence, they give rise to low glass transition temperatures and elastomeric materials. On the other hand, if the side groups are bulky (ferrocenyl, carboranyl, phenoxy, biphenyleneoxy, naphthaleneoxy, adamantyl) or capable of hydrogen bonding (phenylamino), the chain motions are restricted, the glass-transition temperatures rise, and the materials become glasses rather than elastomers. If the side group arrangement is symmetric (as for example in $[NP(OCH_2CF_3)_2]_n$), the polymer chains may crystallize and this changes what might otherwise be an elastomer to a flexible, film- or fiber-forming thermoplastic. Crystallization is inhibited if two or more different side groups (say OCH_2CF_3 and $OCH_2(CF_2)_xCF_3$) are randomly distributed along the chains because the resultant disruption of order prevents the chains from forming colinear arrays. The side groups are also the sites of secondary-reaction chemistry in which functional groups such as SO_3H, NH_2, OH, or COOH are introduced. Note that the functional units on organic side groups are responsible for properties such as hydrophobicity or hydrophilicity, color, electrical conductivity, and coordination to metal ions. For example, organic side groups that bear amino or phosphino functional units coordinate to transition metal compounds, and the oxygen atoms of alkyl ether side groups coordinate loosely to lithium ions. The side groups are also the components that participate in cross-linking reactions.

3 USES

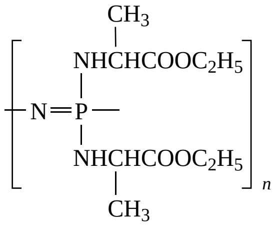
Applications that have been or are being developed for polyphosphazenes include several diverse biomedical

applications, elastomers for aerospace applications, optical materials, solid electrolytes for lithium batteries or fuel cells, gas separation membranes, and a host of applications in fire resistant technology.

1. *Biomedical Applications.* Biomedicine is a field where the tunability of materials' properties is crucial to new developments. Polyphosphazenes almost uniquely provide this versatility. Only three of the many applications will be mentioned here. First, the polymer shown as (**10**) is soluble in water as its sodium salt but is insoluble when the sodium ions are replaced by calcium. This is because the Ca^{+2} ions cross-link the chains. This phenomenon has been used to produce microspheres that encapsulate vaccine molecules for oral vaccinations.[22] Each calcium-cross-linked microsphere protects the vaccine during its passage through the stomach but releases it as the phosphazene polymer is de-cross-linked by sodium ions in the small intestine. Second, polyphosphazenes with amino acid ester side groups, such as (**11**), are hydrolytically unstable and decompose in the body to amino acid, alcohol, phosphate, and ammonia. This property is being used in the field of tissue regeneration, especially for materials that facilitate the regeneration of bone.[23] Nanofiber mats of polyphosphazenes are produced by the process of electrospinning.[24] These are then seeded with osteoblasts, which spread throughout the material and form new bone at the same rate as the polymer erodes. The ease with which the rate of polymer hydrolysis can be controlled by the type of amino acid–ester side group is crucial for the success of this approach. Third, specific polyphosphazenes with hydrophilic side groups are water-soluble but, after being cross-linked, form hydrogels. Side groups that give rise to this property are alkyl ether units such as $–OCH_2CH_2OCH_2CH_2OCH_3$ or its branched analogues, or $–NHCH_3$ and $–OC_6H_4COONa$. Combinations of these side groups give rise to responsive hydrogels in which the swelling or contraction of a hydrogel membrane occurs in response to changes in temperature, pH, or cation charge.[25] This is the basis of membranes that control the delivery of drugs or which turn on or off the activity of encapsulated enzymes.

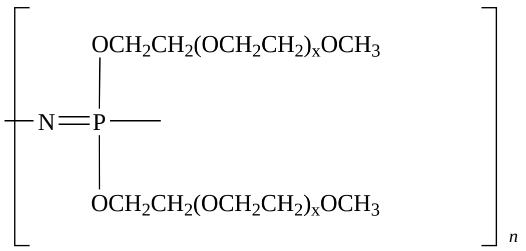


(**10**)

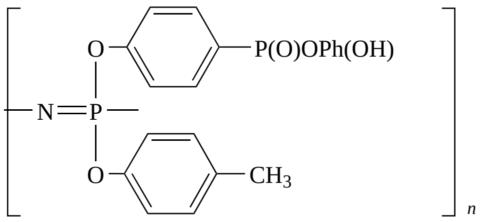


(**11**)

2. *Solid Ionic Conductors.* Membranes that provide a medium for the transport of lithium ions or protons are important components of liquid-free rechargeable lithium batteries and advanced fuel cells. Two classes of polyphosphazenes have been developed for these applications. First, polymers with oligo-ethyleneoxy side chains, such as (**12**), are good solid-state lithium ion conductors that have been examined in detail for liquid-free or gel battery applications.[26–29] Second, poly(aryloxyphosphazenes) with sulfonic, phosphonic, or sulfinimide functional groups on the aryl rings (such as **13**) show advantages for fuel cell applications, particularly for direct methanol fuel cells[30,31] for which there is an acute scarcity of suitable membrane materials.



(**12**)



(**13**)

3. *Optical Materials.* The polyphosphazene skeleton is electron-rich, which means that it provides a refractive index increment compared to conventional saturated organic backbones. In addition, the macromolecular substitution synthesis allows highly unsaturated organic side groups to be linked to the skeleton in ways that allow the refractive index, the color, the liquid crystalline, and nonlinear optical characteristics of the polymer to be finely tuned.[32,33] Thus, the use of these polymers in opto-electronic (photonic) switches and lens systems is a subject of growing interest.
4. *Elastomers.* The most advanced applications from a commercial viewpoint are found in the use of polyphosphazenes as elastomers that remain flexible at low temperatures, are resistant to hot oil and hydraulic fluids, and resist combustion. Polymers with both trifluoroethoxy and heptafluorobutoxy side groups were originally developed for aerospace and automotive applications,[1] but other elastomers that bear both trifluoroethoxy and organosilicon side groups are now

known.[34–37] Species with two different aryloxy side groups (e.g. phenoxy and *p*-ethylphenoxy) are fire resistant elastomers that are useful as thermal and sound insulation materials.

4 SUMMARY

The impact of inorganic chemistry on technology in recent years has been confined mainly to catalysis, ceramics, and electronics. The polyphosphazenes illustrate how inorganic reaction chemistry can be used to create a new major area of polymer science and one that has the potential to bring about much needed improvements in biomedicine, membrane technology, energy generation and storage, and in aerospace engineering. The challenge for the future is to apply these or similar techniques to the development of other inorganic polymer systems with backbone elements other than phosphorus and nitrogen.

1 INTRODUCTION

Many kinds of polymers containing silicon atoms in the main chain have been synthesized. A few examples are shown in Figure 1. By a wide margin, the most important are the polysiloxanes, commonly called silicones, which are now the basis for a worldwide industry.[1–5] Also described in this article are the polysilane polymers, which are of interest because of their special properties reflecting extensive delocalization of the σ-electrons along the Si–Si backbone (*see* σ*-Bond*).[6–9]

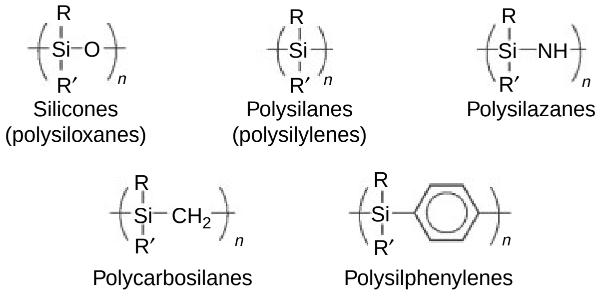

Figure 1 Some types of silicon-containing polymers

2 POLYSILOXANES: INTRODUCTION

2.1 A Brief History of Silicones

Organosilicon compounds were first synthesized in the 1860s, by the reaction of silicon tetrachloride with organozinc compounds (*see* ***Silicon: Organosilicon Chemistry***). Major advances took place only after 1900, when the more convenient *Grignard Reagents* became available. The first polysiloxanes were made by F. S. Kipping and his students in a classic series of experiments in the early part of the 20th century.[10] These workers prepared diorganodichlorosilanes, R_2SiCl_2, which, like other halosilanes, are easily hydrolyzed, initially to silanediols, $R_2Si(OH)_2$. It was anticipated that these compounds might eliminate water to give silicon analogs to ketones, $R_2Si{=}O$, hence ‘silicones’. Kipping soon realized, however, that the actual products of dehydration were cyclic or linear polymers containing Si–O–Si single bonds, rather than Si=O linkages. Nevertheless, the name silicone, applied to these polymeric materials, persists in usage even today.

The earliest commercial syntheses of silicone materials were also carried out by reactions of Grignard reagents with $SiCl_4$, followed by hydrolysis of the dichlorosilanes. This route has now been displaced by the ‘direct reaction’ between methyl chloride and silicon to give methylchlorosilanes, described more fully in Section 4.1.[11] Silicones were first introduced commercially in the late 1930s and production has increased continuously since that time.

At the beginning of this millennium, the worldwide sales of silicones were more than 10 billion dollars[12] per year. The United States is both the largest producer and consumer of silicones. Silicone manufacturers in the United States are Dow Corning, General Electric, OSi Specialties, and Wacker Companies. Basic producers in other countries include Bayer, Goldschmidt, and Wacker in Germany; Shin-Etsu, Toray, and Toshiba in Japan; Rhone-Poulenc in France; and Rhone-Poulenc and Dow-Corning in the United Kingdom. Other countries in which silicone production is known to take place are the People’s Republic of China, the Czech Republic, and the former USSR.

2.2 General Properties of Silicones

The silicone polymers can be considered inorganic–organic hybrid materials. Their structure, with a very flexible and thermally stable polymer backbone of alternating silicon and oxygen atoms, is closely related to that of silicate minerals. The alkyl or aryl side groups, however, confer hydrocarbon-like character. The polyorganosiloxane structure, unprecedented in nature, gives the silicones special properties that make them valuable in a myriad of end products. They find application in uses affecting most aspects of modern life, and nearly every branch of manufacturing.[13]

The silicones comprise a broad class of materials, including oils, elastomers, and resins. Because of backbone flexibility,

silicones have the lowest viscosities in fluids and most flexibility at lowest temperatures in elastomers of any commercial materials. Silicone oils, because of their great thermal stability and inertness, are excellent heat-transfer and hydraulic fluids. The water repellency of silicones makes them invaluable for the treatment of stone and masonry. The low surface energy of polysiloxanes makes them useful in release liners, used, for example, against adhesive labels. Special formulations are used as antifoaming additives, and conversely, others make good foam stabilizers. They are extensively used in textile treating; many modern fabrics contain 0.5–1%, and some specialty fabrics up to 5%, silicone. Because silicone oils are bland and biologically inert, they are now used in most cosmetic formulations, and within the body as implants and prostheses. Silicones resist high temperatures and oxidation, and silicone resins are therefore important in finishes for smoke stacks, and so on.

The high diffusion rate of oxygen through silicone polymers makes them useful in contact lenses. Siloxanes have excellent dielectric properties, and therefore silicone oils are used to fill transformers, and silicone rubber insulation is extensively used in electronic equipment and electrical machinery. The inertness to weathering and oxidation resistance of silicones makes them excellent sealants for building construction. Because silicones have good properties at low as well as high temperatures, they are vital materials in spacecraft and high-performance aircraft. For one historic example, the boots worn by astronaut Neil Armstrong when he first stepped on to the moon were made of silicone rubber.

2.3 Polysiloxane Structures

It will be useful to consider the structure of a generalized silicone polymer, shown in Figure 2. The structure shown is that for a linear polysiloxane, such as a silicone oil or a rubber gum before cross-linking. As mentioned earlier, the backbone is constructed of alternating silicon and oxygen atoms, forming siloxane, Si–O–Si, linkages. In the terminating groups, the R substituent can be and most commonly is methyl, giving unreactive Me_3Si–O terminations. Reactive terminating substituents, –OH, –OR, –H, –CH=CH_2, are introduced, especially in low-molecular weight oligomers, to permit elaboration of the structure by further reactions (*see Oligomer*).

Side chain substituent groups R′ may also be methyl, giving the pure polydimethylsiloxane polymers, the most widely used silicones. Other groups are introduced to provide special properties. The most important are phenyl groups, which lower the crystallization temperature so that the polysiloxane will maintain flexibility at extremely low temperatures. Phenyl substituents also increase heat and oxidation resistance, and so are usually introduced in polysiloxanes designed for high-temperature service. Trifluoropropyl groups, $CF_3CH_2CH_2$–, are employed to increase oil and solvent resistance, and to further lower the (already very low) surface energy of siloxanes. Experimentally, silicones are also being produced with longer fluoroalkyl substituents such as $CF_3CF_2CF_2CF_2CH_2CH_2$–. Alkyl groups such as n-C_8H_{17} are sometimes included to increase compatibility of the silicone with organic media. Finally, the reactive substituents H– or CH_2=CH– are often introduced, usually in very small amounts, to provide the possibility for cross-linking.

Substituents R′ other than methyl are used in the minimum amount needed to confer the desired property, since all other side groups are more expensive than methyl.

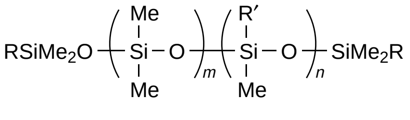

Figure 2 A typical polysiloxane

2.4 Naming and Notation

Polysiloxanes are named as derivatives of disiloxane, $H_3SiOSiH_3$. Thus $Me_3SiOSiMe_2OSiMe_3$ is octamethyltrisiloxane and $(PhMeSiO)_3$ is 1,3,5-triphenyltrimethylcyclotrisiloxane. Special notation used in the silicone industry will be important in the discussion to follow. In this shorthand system, silicon centers are designated as M, D, T, or Q. M represents a monofunctional trimethylsilyl group, with its share of the attached oxygen atom, $Me_3SiO_{0.5}$; D is a chain-extending difunctional Me_2SiO group; T is a cross-linking site, $MeSiO_{3/2}$; and Q represents a quaternary silicon atom, $SiO_{4/2}$. Some typical siloxane structures, with names and designations according to the silicone notation system, are given in Table 1.

Other substituents than methyl are sometimes designated by primes or superscripts following the letter. Thus D^H is often used for the MeSiHO unit, and D^F for the $CF_3CH_2CH_2SiHO$ unit. The useful intermediate tetramethylcyclotetrasiloxane, $(MeSiHO)_4$, can then be designated as $D^H{}_4$.

Table 1 Some typical siloxane structures

Structure	Name	Designation
$Me_3SiOSiMe_3$	Hexamethyldisiloxane	MM
$Me_3SiOSiMe_2OSiMe_2OSiMe_3$	Decamethyltetrasiloxane	MD_2M
$Me_3SiO(SiMe_2O)_nSiMe_3$	Poly(dimethylsiloxane)	MD_nM
$(Me_2SiO)_3$	Hexamethylcyclotrisiloxane	D_3
$MeSi(OSiMe_3)_3$	–	TM_3

3 SYNTHESIS OF POLYSILOXANES

3.1 The Direct Process

Silicon differs from carbon in that all of the element existing in nature is in an oxidized form, as SiO_2 or silicate minerals. The first step in the synthesis of silicones then becomes the reduction of silica to an active reduced form of silicon. The usual starting point is the electrothermal reduction of SiO_2 with carbon (equation 1). The elemental silicon can be converted to reactive $SiCl_4$ by chlorination (equation 2) or to hydrochlorosilanes by reaction with HCl (equation 3). The importance of the latter materials in silicone technology will be described later.

$$SiO_2 + C \longrightarrow Si + CO \tag{1}$$

$$Si + Cl_2 \longrightarrow SiCl_4 \tag{2}$$

$$Si + HCl \xrightarrow{Fe} HSiCl_3 + H_2SiCl_2 + SiCl_4 \tag{3}$$

A cornerstone of the modern silicone industry is the direct reaction of methyl chloride with silicon, discovered in the early 1940s by E. G. Rochow in the United States and independently by R. Müller in Germany.[11] The direct reaction, carried out by all basic producers of silicones, is done in a fluidized bed reactor using finely divided silicon with particle size ≈30–300 µm, at about 300 °C. In spite of decades of research in many laboratories, the exact course of the reaction is not yet known.[14–18]

Copper is an indispensable catalyst, usually supplied in the form of oxidized copper having a mean composition Cu_2O (but containing both Cu and CuO), in amounts of about 5%. In the reactions, it is believed that copper is converted first to CuCl, and then to the intermetallic phase Cu_3Si, which is probably the catalytically active material (equations 4–7). The Cu_3Si may react with methyl chloride to give methylchlorosilanes and copper, which diffuses into the silicon to form more Cu_3Si. Gaseous methylcopper, MeCu, has also been suggested as a transient intermediate species. As the exothermic reaction proceeds, the silicon grains become gradually smaller until they are so fine that they become swept out of the reactor in the gas stream.

$$Cu_2O + 2MeCl \longrightarrow 2CuCl + \text{by-products} \tag{4}$$

$$CuCl + Si \longrightarrow Cu + SiCl \tag{5}$$

$$3Cu + Si \longrightarrow Cu_3Si \tag{6}$$

$$Cu_3Si + 2MeCl \longrightarrow Me_2SiCl_2 + 3Cu \tag{7}$$

Besides copper, the principal catalyst, other materials are added to the direct reaction. About 0.1–1% of an electropositive element (Al, Mg, or Ca) is added to speed the reaction with methyl chloride, and to shorten the induction period before chlorosilanes begin to be produced in good yield. An element which forms a low-melting chloride (usually zinc) is also added in amounts of 0.1–1%, apparently to form a flux which helps to remove oxide coatings from the reaction mass. Finally, very small amounts (0.001–0.005%) of a group 15 element, As, Sb, or Bi, are added as ‘promoters’. The reason why the latter elements aid the direct reaction is not clear; perhaps they serve as dopants to provide reactive electron-excess sites in the silicon lattice. However, lead was found to be a poison for the catalyst.

The major, and most desired, product from the direct reaction is dimethyldichlorosilane, $(CH_3)_2SiCl_2$. Other principal products and their boiling points are shown in Table 2. Good separation of these products, which have similar volatilities, is important for further processing. It follows that large, efficient fractionating towers are an essential part of a silicone production plant.

The yields of the main products vary, as indicated in Table 2. The relative amounts depend on the purity and particle size of the silicon and the copper catalyst, the amount and nature of the additives, the temperature profile and flow velocity in the reactor, and the history of the particular contact mass. A major consideration is to maximize the selectivity for the desired Me_2SiCl_2 over $MeSiCl_3$, which is often obtained in more than useful amounts. Early in the reaction, selectivity for Me_2SiCl_2 is high; as the silicon becomes largely consumed, this selectivity decreases. The by-products Me_3SiCl and $MeSiHCl_2$ are both useful in further processing.

Minor products from the direct reaction, all normally produced in amounts less than 1%, include $SiCl_4$, $HSiCl_3$, Me_4Si, $Me(Et)SiCl_2$, disilanes, especially $Me_2Si(Cl)Si(Me)Cl_2$ and $(MeSiCl_2)_2$, disiloxanes, CH_4 and other hydrocarbons, and H_2. The reaction effluent contains all of these, plus excess MeCl, and finely divided silicon particles containing up to 20% copper as well as other metals. These solids are separated, and usually treated to recover the copper. Unreacted MeCl is separated, purified, and recycled. The monosilane fraction is distilled out and then separated into its components by careful fractional distillation. The disilane fraction can also be distilled out, and may be upgraded into useful chloromonosilanes by cleavage reactions, as shown in equation (8).

$$Me_2SiClSiMeCl_2 + HCl \xrightarrow{cat.} Me_2SiCl_2 + MeSiHCl_2 \tag{8}$$

3.2 Other Monomer-forming Reactions

The direct reaction can also be used to make phenylchlorosilanes, starting with chlorobenzene and using

Table 2 Main products from the MeCl–Si direct reaction

Product	(%)	Bp (°C)
Me_2SiCl_2	80–90	70.0
$MeSiCl_3$	5–15	65.7
$MeSiHCl_2$	3–5	40.7
Me_3SiCl	3–5	57.3

silver as catalyst (equation 9). This reaction is, however, no longer used in the United States, because traces of highly toxic polychorobiphenyls are produced as by-products. Instead, phenyl groups are introduced by the liquid phase reaction of benzene with $HSiCl_3$ or $HMeSiCl_2$, catalyzed by boron trichloride (equations 10 and 11). This reaction proceeds through the intermediate formation of B–H bonds, and then of phenylboron chlorides, which transfer phenyl groups to the silicon.

$$PhCl + Si \xrightarrow{Ag} Ph_2SiCl_2, PhSiCl_3, Ph_3SiCl, \text{etc.} \quad (9)$$

$$C_6H_6 + HSiCl_3 \xrightarrow{BCl_3} PhSiCl_3 \quad (10)$$

$$C_6H_6 + HMeSiCl_2 \xrightarrow{BCl_3} PhSiMeCl_2 \quad (11)$$

Other substituent groups are usually introduced via *Hydrosilation* reactions.[19,20] In this important reaction, Si–H bonds add across C=C or C≡C bonds in 1,2 fashion to give products. Many transition metals and their complexes will catalyze hydrosilation, but the usual catalyst is platinum (*see* ***Hydrosilation Catalysis***). Thus $CF_3CH_2CH_2Si(Me)Cl_2$ is made by hydrosilation of 3,3,3-trifluoropropene with methyldichlorosilane (equation 12). *n*-Alkylmethyldichlorosilanes can be made similarly, by hydrosilation of 1-alkenes. Vinylmethyldichlorosilane may be obtained in analogous fashion by hydrosilation of acetylene, as shown in equation (13). An alternate route to the same compound is hydrosilation of vinyl chloride, followed by dehydrochlorination (equations 14 and 15).

$$CF_3CH{=}CH_2 + MeSiHCl_2 \xrightarrow{Pt} CF_3CH_2CH_2SiMeCl_2 \quad (12)$$

$$HC{\equiv}CH + MeSiHCl_2 \longrightarrow H_2C{=}CHSiMeCl_2 \quad (13)$$

$$H_2C{=}CHCl + MeSiHCl_2 \longrightarrow H_2C{=}CHSiMeCl_2 \quad (14)$$

$$MeCHClSiMeCl_2 \xrightarrow[-HCl]{\Delta} H_2C{=}CHSiMeCl_2 \quad (15)$$

The platinum catalyst is effective in very small amounts, and can be introduced as H_2PtCl_6 or as elemental platinum on an inert support. A particularly active catalyst is the soluble platinum complex of divinyltetramethyldisiloxane, $CH_2{=}CHSiMe_2{-}O{-}SiMe_2CH{=}CH_2$. The hydrosilylation reaction operates through the Chalk-Harrod mechanism or one of its variants.[21,22] In these mechanisms, the first step involves the conversion of a metal alkene complex to a metal alkene silyl hydride complex. In addition to platinum, recently ruthenium, rhodium, palladium, copper, and zinc complexes are being studied as hydrosilation catalysts.[23–28]

3.3 Hydrolysis

The next step in the synthesis of silicone polymers is the hydrolysis of dimethyldichlorosilane, giving HCl and a mixture of cyclic and linear oligomeric polysiloxanes (equation 16). The rate of reaction between Me_2SiCl_2 and water is rapid, and is limited by the transfer across the aqueous–organic phase boundary.[2] Accordingly the hydrolysis is best carried out under highly turbulent conditions, often in a continuous loop reactor, with the aqueous phase being a concentrated HCl solution. A typical product mix from the hydrolysis is given in Table 3.

$$MeSiCl_2 \xrightarrow{H_2O} (Me_2SiO)_n + HO(SiMe_2O)_mH + HCl \quad (16)$$

It is interesting to note that the eight-membered ring compound D_4 is the major product in the cyclic fraction, with only small amounts of the six-ring D_3 being formed. This is because of ring strain in D_3 (discussed in Section 5). An inert organic diluent (heptane) is sometimes added to facilitate separation of the siloxane and aqueous phases; this increases the yield of cyclic products since dilution favors intramolecular cyclization. The degree of polymerization of the α, ω-dihydroxysiloxane oligomer portion is typically $\approx$18, but depends on the exact hydrolysis conditions. In practice, the hydrolysis conditions can be varied to produce a larger amount of cyclic or of linear oligomers, depending on plant requirements at the time.

If desired, the linear oligosiloxanes, and indeed any linear polydimethylsiloxane, can be converted into cyclosiloxanes by base-catalyzed pyrolysis. If this reaction is carried out under equilibrating conditions and the products are fractionally distilled with removal only of the most volatile compound, D_3, the entire mixture can be converted to this valuable intermediate. This procedure is frequently used to obtain pure D_3 and D_4, useful for polymer synthesis by ring-opening polymerization.

Sometimes, prior to aqueous hydrolysis, chlorosilanes are converted to methoxysilanes by treatment with methanol (equations 17 and 18). Hydrolysis of methoxysilanes is much slower than for chlorosilanes, but has the advantage that no HCl is formed in the reaction.

$$Me_2SiCl_2 + 2MeOH \longrightarrow Me_2Si(OMe)_2 + 2HCl \quad (17)$$

$$Me_2Si(OMe)_2 + H_2O \longrightarrow (Me_2SiO)_n + MeOH \quad (18)$$

3.4 Polymerization

The usual method for obtaining linear silicone polymers is by ring-opening polymerization[3,29–31] reactions on cyclic

Table 3 Typical products from hydrolysis of dimethyldichlorosilane

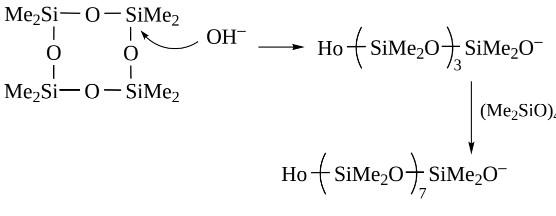
	%	Mp (°C)	Bp (°C)
D3	1	64	134
D4	42	17	175
D5	7	−38	210
D6	2	−3	245
Linear oligomers	47		

siloxanes such as D_4 or D_3, or mixed D_n oligomers. Such polymerization can be carried out under acidic or basic conditions, but base catalysis is generally preferred. Suitable catalysts are KOH or tetraalkylammonium hydroxides. Molecular weight is controlled by addition of chain-blocking substituents such as hexamethyldisiloxane, MM. Thus to make a dimethylsilicone oil of a selected average molecular weight, D_4 can be equilibrated with the calculated amount of MM, as shown in equation (19).

$$\underset{\text{MM}}{Me_3SiOSiMe_3} + \underset{D_4}{(Me_2SiO)_4} \xrightarrow[150\,^\circ\text{C}]{\text{KOH}} \underset{\text{MD}_n\text{M}}{Me_3SiO(SiMe_2O)_nSiMe_3} \quad (19)$$

In the absence of chain-terminating additives, an equilibrium mixture of cyclic and linear siloxanes is obtained, containing about 13% of rings from D_4 to D_{10}, about 3% of molecules from D_{10} to D_{1000}, the remaining 84% being high polymer with DP $>$ 1000. (The ring-strained D_3 molecule is not present at equilibrium, except at very high temperatures.) This is the process used to make the gum stock for silicone elastomers. The equilibrium mixture is neutralized to destroy the catalyst and the low-molecular weight cyclic compounds are distilled out under vacuum, leaving a polymer with average molecular weight greater than one million. The kinetics and mechanism of the ring-opening reaction have been investigated in some detail.[3,29–31]

The initial step in base-catalyzed ring opening is cleavage of a cyclosiloxane ring to form a silanolate anion; attack of silanolate on cyclic molecules is then the chain-extending reaction (equation 20). Polar solvents or additives (DMSO, crown ethers, HMPA) promote the reaction by solvating the cation of the ion pair. Chain cleavage by back biting can take place, however, to give an equilibrium mixture containing both cyclic and linear polymeric siloxanes. If two different cyclosiloxanes are mixed and ring opened, the initially formed polymer is likely to be block-like, because the rates of ring opening depend on substitution at silicon. Long heating with catalyst present will ultimately produce a random copolymer.



(20)

The rate of ring opening also depends on ring size. D_3, which contains strained Si–O–Si bonds, is much more reactive than D_4 or D_5 with lithium catalysts such as *n*-butyllithium. As shown in equation (21), D_3 undergoes ring-opening polymerization by successive addition of D_3 units without equilibration, to give a monodisperse ‘living polymer’. This reaction provides a useful means for generating block copolymers of two different silicon monomers, by using a second cyclotrisiloxane (equation 22).

$$n\text{-BuLi} + D_3 \longrightarrow \underset{(n\text{-BuD}_3^-)}{n\text{-Bu(SiMe}_2\text{O)}_2\text{SiMe}_2\overset{-}{\text{O}}\overset{+}{\text{Li}}} \xrightarrow{D_3}$$

$$n\text{-BuD}_6^- \xrightarrow{D_3} n\text{-BuD}_9^- \xrightarrow{D_3} n\text{-BuD}_{12}^- \quad (21)$$

$$n\text{-Bu(D}_3)_n^- + mD'_3 \longrightarrow n\text{-Bu(D}_3)_n(D'_3)_m \quad (22)$$

Silicon–hydrogen bonds react with strong bases, so cyclosiloxanes containing hydrogen attached to silicon, for example $(MeSiHO)_4$, $(D^H{}_4)$, cannot be polymerized under basic conditions. The Si–H bond, however, survives under acidic conditions, and therefore acid-catalyzed ring opening is used to make siloxane polymers with hydrogen bonded to silicon.[3] Catalysts include H_2SO_4 absorbed on clay or carbon, sulfonic acids, or the acid form of sulfonated polystyrene resins. Polymerization of siloxane monomers with Lewis acid catalysts such as phosphonitrile chloride has been the subject of study recently.[31,32]

Condensation reactions of silanols provides another method for polysiloxane synthesis. Hydroxy-terminated siloxane oligomers or polymers can be further condensed to polymers of higher molecular weight by condensation with loss of water (equation 23). This reaction is catalyzed by various metal salts; tin salts have been widely used. Mixtures of two different $\alpha,\ \omega$-dihydroxysiloxane oligomers may be condensed to give block copolymers.

$$\sim\!\sim\text{Si—OH} + \text{HO—Si}\sim\!\sim \xrightarrow{-H_2O} \sim\!\sim\text{SiOSi}\sim\!\sim \quad (23)$$

A relatively new process for siloxane manufacture is aqueous phase emulsion polymerization.[33,34] Cyclosiloxanes such as D_4 when mixed with water and alkylbenzenesulfonates as a surfactant, along with some free sulfonic acid, form an emulsion. When the mixture is heated to $>$60 °C, ring opening of the cyclosiloxane takes place to give α,ω-dihydroxy oligosiloxanes, which undergo acid-catalyzed condensation to form long-chain siloxanes.

4 SILICONE MATERIALS

4.1 Siloxane Fluids

The silicone fluids are normally chain-blocked linear polymers, manufactured by ring-opening polymerization, as described in Section 3.4. The dimethylsiloxane polymers are by far the most important, but to make fluids for high-temperature use, phenylmethylsiloxane units are also included in the polymer.

4.2 Silicone Elastomers: Heat-cured[35]

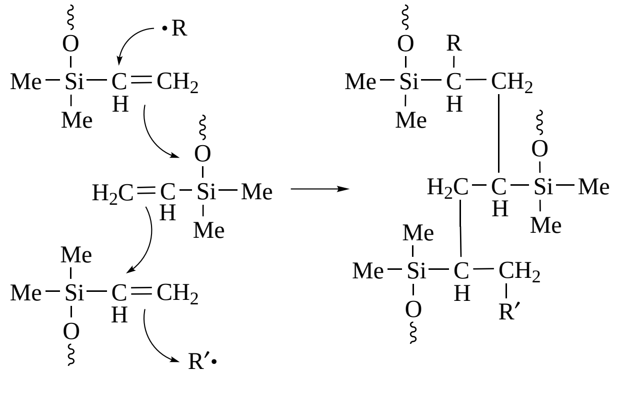
The starting material is a high molecular weight polysiloxane gum made by ring-opening polymerization. To convert the gum into a useful elastomer, cross-linking is essential. This can be brought about by radicals from the decomposition of organic peroxides. Abstraction of hydrogen atoms from methyl groups takes place, and the siloxane chains become joined by Si–CH_2–CH_2–Si linkages.

In a modern variant of this vulcanization reaction, polysiloxanes containing a small amount, <1%, of methylvinylsiloxane groups are the starting materials. Aryl or alkyl peroxides are again used to initiate cross-linking, but the chemistry now involves radical addition to vinyl groups on neighboring siloxane chains, depicted in Scheme 1.

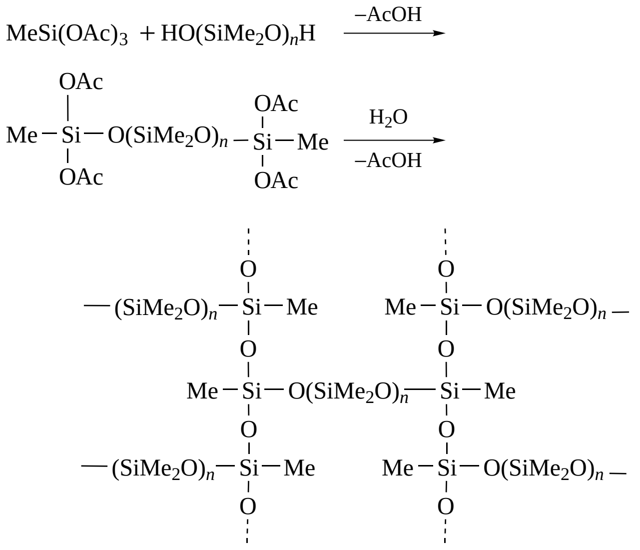
The tensile strength of cross-linked polysiloxane elastomers is low, but can be markedly improved by reinforcement with a filler. The material of choice is fumed silica with high surface area, which can increase the strength by a factor of 20. It is thought that the silica particles agglomerate to form a three-dimensional network within the siloxane, greatly reinforcing the structure.

The silica particles, however, contain reactive Si–OH groups, which can condense with Si–OH end units of the gum, forming a prematurely cross-linked elastomer during mixing. These sites can be tamed by reaction with hexamethyldisilazane, $Me_3SiNHSiMe_3$, which converts them to inactive trimethylsiloxy groups (equation 24). An even better method is pretreatment of the silica by heating it with short-chain, hydroxy-terminated siloxane oligomers. Presumably these condense with the Si–OH groups to form siloxane bonds, giving a siloxanized surface which is highly compatible with the elastomer.

$$2 \sim\!\sim\, Si-OH + Me_3SiNHSiMe_3 \longrightarrow 2 \sim\!\sim\, SiOSiMe_3 + NH_3 \qquad (24)$$



Scheme 1 Radical cross-linking of vinyl-containing polysiloxanes



Scheme 2 Formation and cross-linking of tetraacetoxy RTV silicone

4.3 Room Temperature Vulcanizing ('RTV') Elastomers

These are silicones in liquid or paste form that can be transformed into cross-linked elastomers at or near room temperature.[36] There are two basic types, one component and two component. The one-component room temperature vulcanizing (RTV) elastomers cure upon exposure to air. A typical material of this type is synthesized from a dihydroxy-terminated siloxane oligomer and methyltriacetoxysilane (Scheme 2). The resulting tetraacetoxy compound will flow as a paste and so can be molded into shape. Hydrolysis of the acetoxy groups takes place over a period of hours. Condensation of the resulting silanols gives a highly cross-linked end product.

RTV siloxanes with alkoxy groups in place of acetoxy groups are now being used, and offer the advantage that no acid is formed during the cure. The hydrolysis of alkoxy groups is slower, but can be catalyzed with metal salts.

Two-component RTV elastomers have been developed, based on a variety of chemical reactions. Three systems will be illustrated here:

1. Hydroxy-terminated siloxane oligomers are mixed with trialkoxysilanes; catalysis by Sn^{2+} leads to condensation and cross-linking through Si–O–Si bonds, with loss of ethanol (equation 25).

$$HO-Si\sim\!\sim Si-OH + RSi(OEt)_3 \xrightarrow{Sn^{2+}} \text{cross-linked polymer} + ROH \qquad (25)$$

2. Alkoxy-terminated siloxanes are treated with a trialkoxysilane, in the presence of *t*-butyl titanate and a little water. Solvolysis followed by condensation produces the cross-linked polymer (equation 26).

$$\text{ROSi}\sim\sim\text{Si—OR} + \text{R}'\text{Si(OR)}_3 \xrightarrow[\text{H}_2\text{O}]{(t\text{-BuO})_4\text{Ti}} \text{cross-linked polymer} + \text{ROH} \quad (26)$$

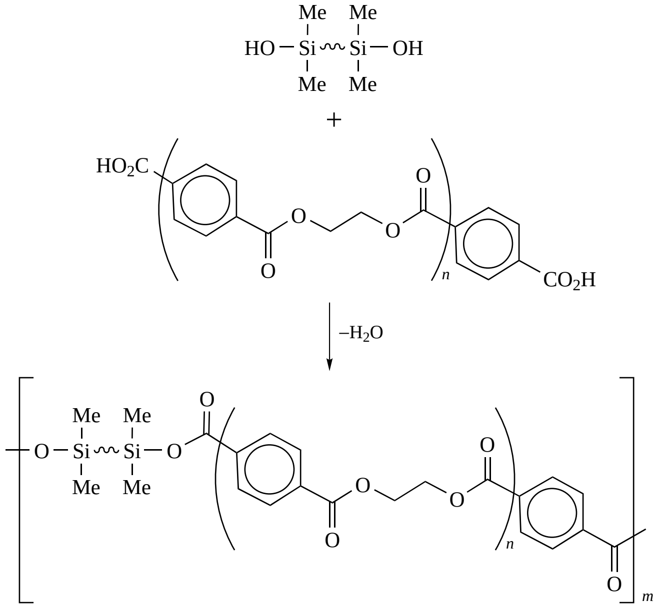
3. A vinyl-terminated siloxane polymer is mixed with a compound containing several Si–H groups, such as D_4^H, $(MeSiHO)_4$; in the presence of a platinum catalyst, hydrosilation takes place to give Si–CH_2–CH_2–Si cross-links (equation 27). A related platinum-catalyzed system employs two siloxane prepolymers, one containing some Si–H bonds and the other Si–vinyl groups. The platinum catalyst is active in extremely small amounts, so that its use is practical despite the high cost of platinum.

$$\text{H}_2\text{C}{=}\text{CH}-\text{Si}\sim\sim\text{Si}-\text{CH}{=}\text{CH}_2 + (\text{MeSiHO})_4 \xrightarrow{\text{Pt}} \text{cross-linked polymer} \quad (27)$$

4.4 Siloxane Copolymers

Specialty polymers in which siloxanes are combined with organic polymers are a growing part of the silicone industry.[37–39] Many compositions have been described, of which only a few will be mentioned here.

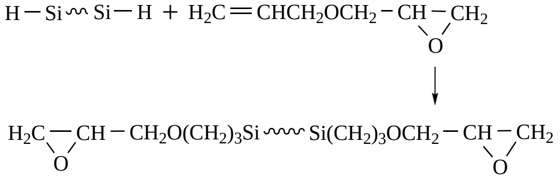
Linear polysiloxanes having reactive terminal groups are often condensed with reactive organic polymers. For example, hydroxy-terminated siloxanes can be condensed with a carboxy-terminated polyester, as illustrated in equation (28). The resulting polymers behave as thermoplastic elastomers, having some of the desirable properties of both siloxanes and polyesters. Similar condensation reactions have been used to synthesize siloxane copolymers with polyamides, polyethers, polycarbonates, and so on.



(28)

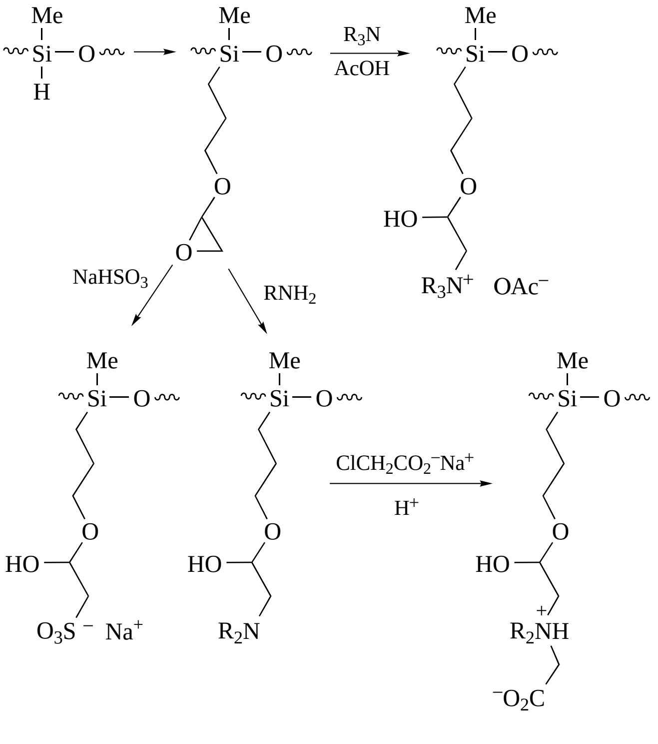
In another approach to copolymers, linear H-terminated polysiloxanes are hydrosilated to introduce reactive groups. Examples are the addition of allylamine to give reactive intermediates that can be converted to polysiloxane–polyimides or polyamides, and the hydrosilylation of allyl glycidyl ether to produce a silicone that can be copolymerized with epoxides or acrylates (equations 29 and 30).

$$\text{H}-\text{Si}\sim\sim\text{Si}-\text{H} + \text{H}_2\text{C}{=}\text{CHCH}_2\text{NH}_2 \longrightarrow \text{H}_2\text{N(CH}_2)_3\text{Si}\sim\sim\text{Si(CH}_2)_3\text{NH} \quad (29)$$



(30)

Polysiloxanes with hydrogen atoms on the main chain are also modified by hydrosilylation with allyl glycidyl ether. The epoxy side groups may then be transformed into ionic substituents, as illustrated in Scheme 3. The resulting polysiloxanes with ionic side groups have good properties as hair and textile conditioners.

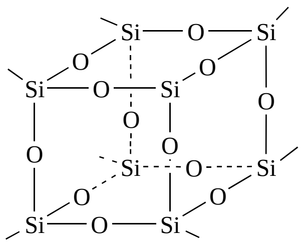


Scheme 3 Synthesis of polysiloxanes with ionic side chains

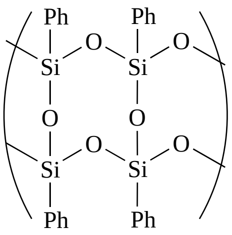
4.5 Silicone Resins

These are cross-linked compositions, containing trifunctional (T) or tetrafunctional (Q) silicon units. The simplest are produced from methyltrichlorosilane, by hydrolysis, either directly or after intermediate conversion to methyltrialkoxysilanes. Smaller amounts of dimethylsiloxane or trimethylsiloxane units may be introduced, as the corresponding chloro- or alkoxysilanes, to increase flexibility of the resin. Curing is brought about by aqueous solvolysis, usually catalyzed by metal salts, leading to highly cross-linked siloxane structures. More typical silicone resins contain mixtures of phenyl- or alkyltriethoxysilanes, mixed with $MeSi(OEt)_3$ and perhaps $Me_2Si(OEt)_2$ or Me_3SiOEt.

Depending on the composition, silicone resins may be soluble in organic solvents, or insoluble and therefore sold as aqueous emulsions. Because of their three-dimensional nature, the structures of silicone resins are complex and poorly understood. Under certain conditions cage molecules can be produced, such as the cubic structure $(RSiO)_8$ (**1**). The phenylsilicone resins, $(PhSiO)_{3/2}$, are often supposed to be ladder polymers (**2**), but the evidence for this structure is ambiguous.[40] Recent X-ray diffraction studies suggest that the resin is probably a mixture of two components: one amorphous and the other showing a regular structure in which the regular structure could be a mixture of partial cage or partial ladder structures.[41]



(**1**)



(**2**)

The single largest use of silicone resins is as water repellents for stone and masonry. The resins also find important applications in paints and finishes, especially for high-temperature use, and increasingly as additives to conventional paints. Among the numerous speciality uses which have also been developed, siloxane resins are used to coat pharmaceutical pills and as encapsulants for electronic components.

5 STRUCTURE AND PROPERTIES OF SILOXANES

The unique properties of the silicones undoubtedly reflect the structure, dynamics, and chemical bonding in these polymers, all of which are unusual. In the polydimethylsiloxane chain (Figure 3), the O–Si–O angles of 109° are nearly tetrahedral as expected, but the Si–O–Si angles have the abnormal value of 143°.[42] Large Si–O–Si bond angles of 140–145° are present in unhindered disiloxanes, so this value can be taken as the preferred unconstrained siloxane bond angle. Even larger bond angles up to 180° are found for hindered disiloxanes like $Ph_3SiOSiPh_3$. The O–Si–O and Si–O–Si angles in D_4, 109° and 143° show that this eight-membered ring is free of angle strain; larger cyclosiloxanes can also adopt strain-free conformations. In cyclotrisiloxanes, however, the O–Si–O angle is slightly decreased to 107°, and the Si–O–Si angle is strongly bent, down to 130–135°. Cyclotrisiloxanes therefore possess extra energy owing to angle strain, which accounts for their higher reactivity.

Along the random-coil polydimethylsiloxane chain, the trans arrangement is favored over *gauche*, but the rational barrier at oxygen is immeasurably low, probably less than $0.8\,kJ\,mol^{-1}$. In addition, the Si–O–Si bonds probably undergo bending deformation quite easily.[43] In model compounds, the restoring force for Si–O–Si bond bending is very small. These factors probably combine to make the polysiloxane chain extremely flexible. The high degree of motion of the siloxane chains can explain the very low glass transition temperatures, high permeability, low change of viscosity with temperature, and low surface tension, all important characteristics of silicones.

Although Si–O bonds are polar (*see Photoconductivity*), the silicones are nevertheless hydrophobic (*see Hydrophobicity*) and indeed are highly useful as water-repellent materials. This paradoxical behavior must mean that the extreme flexibility and motion within the polysiloxane chain is more important than the polar character of the bonds. Presumably, the methyl groups sweep out a large volume due to the motions of the siloxane chain, so that incoming polar molecules mainly contact methyl groups rather than Si–O bonds. In addition, there is evidence that the Si–O bonds in siloxanes are actually much less polar than would be expected from the large *Electronegativity* difference between Si and O. Evidence for this is that siloxanes are very weak Lewis bases compared to ethers or alkoxysilanes.[44,45] The present theoretical explanation for the reduced basicity and polarity of siloxanes is that lone pair electrons on oxygen are delocalized into antibonding Si–C orbitals ($n-\sigma^*$ overlap).[46]

Another paradoxical property of silicones is their activity as surfactants.[47] Conventional surfactant molecules contain a hydrophilic (*see Hydrophilicity*) as well as a hydrophobic portion, but for siloxanes no hydrophilic group is necessary;

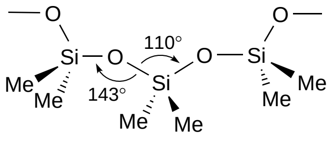


Figure 3 Segment of a dimethylpolysiloxane chain

silicones themselves can behave as surfactants. Probably the surface-active properties result because the siloxanes occupy a water–oil interface, with the more polar Si–O bonds at the aqueous surface and the organic groups in the hydrocarbon phase. The surfactant property of siloxanes makes them useful as foam stabilizers, for example, in the manufacture of polyurethane foam polymers. The molecular weight must be carefully controlled, however. If the molecular weight of the silicone is too high, it becomes insoluble, and then has the opposite effect of destroying the foam! Insoluble silicones, usually resins, are in fact employed as antifoam agents in various manufacturing processes.

Polysiloxanes with two different groups attached to silicon, such as $(PhSiMeO)_n$, contain stereogenic centers at silicon. Polymers having this type of substitution appear to be atactic or nearly so. However, stereoregular polysiloxanes have been synthesized recently by several research groups.[48–51]

6 POLYSILANES

6.1 General Introduction to Polysilane Polymers

As the name implies, polysilane polymers consist of chains made up exclusively of silicon atoms. (In the literature these polymers are named either as polysilanes or poly(silylenes); thus $(Et_2Si)_n$ can be called polydiethylsilane or poly(diethylsilylene).) Unlike the heteroatomic polysiloxanes, with alternating silicon and oxygen atoms in the polymer backbone, the polysilanes are homoatomic and therefore structurally closer to alkene polymers. However, because the atoms in the main chain are all silicon, the polysilanes show quite special properties.[6–9,52]

The cumulated silicon–silicon bonds in the polymer chain permit extensive electron delocalization to occur. The result is that the photochemical and electronic properties of polysilanes are very different from those of most other polymers, and somewhat resemble those of π-conjugated polymers such as polyacetylene, polyaniline, and polythiophene. The electron delocalization is unusual in that it involves the σ electrons of the polysilane chain, whereas in other electron-delocalized polymers the electron mobility depends on π conjugation (Figure 4). The polysilanes and related polygermanes are unique in displaying large effects owing to σ-electron conjugation. Many of the technological uses suggested for polysilanes are based on this remarkable property.

In linear polysilanes, silicon–silicon bonds occupy two of the four valences on each silicon atom; the other valences are taken up by bonds to substituent groups, which may be the same (**3**) or different (**4**). Exact silicon analogs to alkene polymers like polyethylene, with two hydrogen atoms on silicon, are little known because of their high reactivity. The reactivity is greatly reduced if the pendent groups are organic groups, which can include alkyl, aryl, substituted alkyl or aryl,

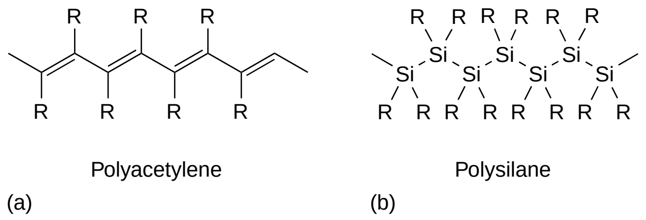

Figure 4 (a) Polyacetylene, π conjugated; (b) polysilane, σ conjugated

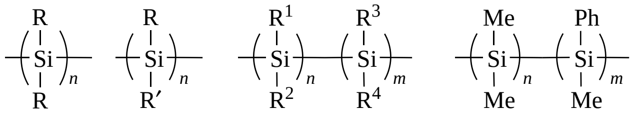
trimethylsilyl, ferrocenyl, and so on. Copolymers are also known (**5**). An example is the copolymer (**6**), which has the popular name ‘polysilastyrene’.



(**3**) (**4**) (**5**) (**6**)

The properties of polysilanes depend greatly on the nature of the substituent groups bonded to silicon. The range of properties varies from highly crystalline and insoluble, to partially crystalline or liquid crystalline, to glassy or rubbery amorphous materials. In general, the polysilane polymers are thermally stable to above 200 °C, and inert to water unless a hydrolyzable group such as halogen is present on the silicon. They are slowly degraded by UV light, a fact which limits their usefulness as structural materials.

The recent upsurge of interest in polysilanes stems from their uses in technology, both actual and potential. They are now being sold and used as precursors to silicon carbide ceramics.[53–57] Polysilanes are useful as photoresists[58–60] in the manufacture of microelectronic components, as shown especially by studies at IBM research laboratories.[7] These polymers are excellent charge-transport materials in an electric field[61] and so might find uses in electrophotography,[62] in novel printing technology, and in display devices. The polysilanes can serve as photoinitiators for radical reactions,[63,64] and have nonlinear optical properties, which makes them of interest for various uses in optical technology.[7,65–69] Some of these actual and potential applications will be discussed further in Section 9.

6.2 Historical Development

Oligomeric polysilanes, including the cyclic compounds $(Ph_2Si)_n, n = 4–6$, were prepared early in the 20th century, but high polymers were almost unknown until the late 1970s. Until quite recently, it was thought that silicon’s capability for chain formation was limited to a few atoms. The first description of a polysilane high polymer appeared in a 1949 paper by

Burkhard, who reported the synthesis of polydimethylsilane, $[Me_2Si]_n$, from sodium metal and dimethylchlorosilane in toluene (equation 31).[70] This polymer is a highly crystalline substance which decomposes without melting and is insoluble in all common solvents. Its intractable nature may have contributed to the relative neglect of polysilane polymers over the next three decades.

$$Me_2SiCl_2 + 2Na \xrightarrow[110\,°C]{\text{toluene}} (Me_2Si)_n + 2NaCl \qquad (31)$$

During this time, however, cyclic and linear oligomeric polysilanes were studied, especially compounds in the permethyl series. These compounds exhibit unusual properties, reflecting electron delocalization over the silicon–silicon bonds. The linear permethylpolysilanes $Me(SiMe_2)_nMe$, have UV absorption bands which increase in wavelength and intensity as the chain length increases, behavior which resembles that of linear polyenes. Cyclic polysilanes, for example $(Me_2Si)_5$, can be reduced to anion radicals in which the unpaired electron is fully delocalized over the ring (equation 32), as shown by electron spin resonance (ESR) measurements.[71]

$$\underset{\text{Colorless}}{(Me_2Si)_5} \xrightarrow[-60\,°C]{e^-,\ \text{THF}} \underset{\text{Blue}}{(Me_2Si)_5{}^{-\bullet}} \qquad (32)$$

Interest in polysilanes was reawakened in 1975, when Yajima and Hayashi found that permethylpolysilane could be transformed into silicon carbide by heating at high temperatures.[72,73] Soon afterward, papers on soluble, meltable polysilanes began to appear. The literature on polysilanes has grown rapidly since that time. The early focus on the synthesis and simple characterization of polysilanes has given way to detailed physical studies of the structure of these polymers, and of their electronic and photophysical properties.

7 POLYSILANES: SYNTHESIS

7.1 Sodium Condensation of Dichlorosilanes

The standard method for synthesis of polysilanes follows the original preparation of $(Me_2Si)_n$ by Burkhard. Diorganodichlorosilanes are treated with finely dispersed sodium metal in an inert diluent, usually above the melting point of sodium. Homopolymers are obtained from single dichlorosilanes, while cocondensation of mixtures of dichlorosilanes yields copolymers (equation 33). Toluene is the most commonly used solvent, but other aliphatic or aromatic solvents are also effective. After completion of the reaction, the mixture is quenched with alcohol and/or water to destroy any excess sodium and silyl anion, then filtered and the polymer is precipitated from hydrocarbon solution with a nonsolvent, usually 2-propanol.

$$Me_2SiCl_2 + PhMeSiCl_2 \xrightarrow[110\,°C]{Na,\ C_7H_8} \left(\underset{Me}{\overset{Me}{Si}} \right)_n \left(\underset{Me}{\overset{Ph}{Si}} \right)_m \qquad (33)$$

The yields of high polymer from this synthesis depend on the exact conditions and the nature of the substituent groups, but are typically low, from a few percent up to 60–70% in the most favorable cases. The by-products are mainly cyclosilanes, $(RR'Si)_n$ where $n = 4–6$. The molecular weight distributions of the polymers obtained by this procedure are usually bimodal, as shown in Figure 5.[74] Various attempts have been made to improve the sodium condensation, including sonication and the addition of crown ethers and other additives, with some success.[75,76]

Several studies of the mechanism of the sodium coupling reaction have been carried out, and a mechanistic model has emerged which accounts for most of the experimental observations.[6,77,78] The reaction chain appears to be anionic in nature. The first step is believed to be the slow reaction of the dichlorosilane with sodium to give an anion (equation 34). The chain-extending process is the reaction of polymer silyl anions with dichlorosilane molecules (equation 35), followed by rapid reduction of the chlorine-terminated polymer to the anion (equation 36). Reduction must take place at the surface of a sodium particle. As polymerization occurs, some molecules may break free from the sodium surface; once in solution away from the metal, chain extension would cease. This portion may give rise to the low-molecular weight polymer. Other molecules probably become entangled at the sodium surface and so cannot break free. They therefore continue to react with fresh dichlorosilane, and eventually

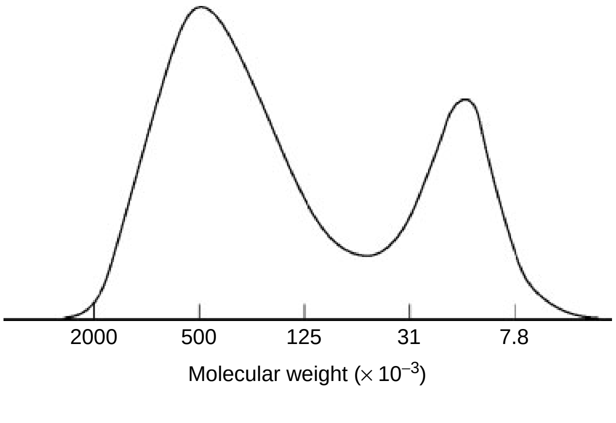


Figure 5 Gel permeation chromatograph of poly(methyl-*n*-hexylsilylene), showing bimodal molecular weight distribution

contribute the high molecular weight fraction.

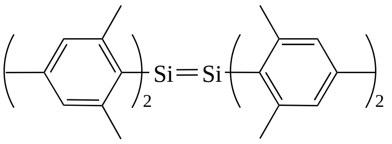
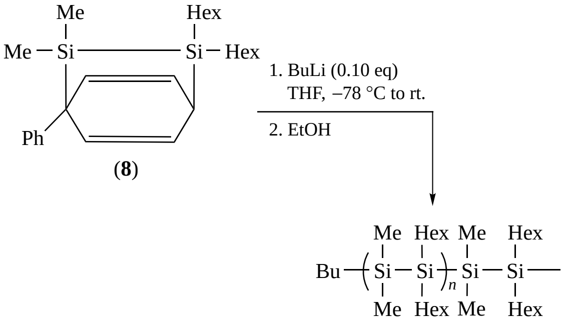
7.2 Polymerization of Masked Disilenes

Polyalkenes are invariably made by polymerization of alkenes. Why is an analogous route, the polymerization of disilenes, $R_2Si{=}SiR_2$, not used to make polysilanes? The reason is that the barrier to polymerization of disilenes is simply too low, so that in most cases they polymerize or oligomerize as soon as they are generated. Stable disilenes can be made and isolated, but only with very bulky substituents at the silicon which make the polymer less stable than the disilene.[79] An example is tetramesityldisilene (**7**), a highly reactive compound that undergoes many novel chemical reactions but does not polymerize.



(**7**)

Anionic polymerization of ‘masked disilenes’ has been used for the synthesis of polysilanes.[80,81] The monomers are bridged disilabicyclooctadienes such as (**8**). Treatment of these with an organolithium compound converts them to ‘living,’ anionically terminated polysilanes (equation 37). The anionic ends of the polymers may be quenched with water, or used in further reactions, for instance, to generate block copolymers with other monomers such as styrene or butadiene. Polymerization of masked disilenes can also be used to obtain ordered polysilane copolymers, which are difficult to obtain by other methods.



(37)

In addition to organolithium compounds, other reagents such as organomagnesium compounds and potassium alkoxides have also been used as initiator for anionic polymerization of masked disilenes.[82,83]

7.3 Ring-opening Polymerization

This method, which is the standard for polysiloxanes, is much less useful for polysilanes. One reason is that polysilane polymers are thermodynamically unstable compared to cyclosilanes. Thus, any method of polymerization leading to equilibration will produce cyclosilanes exclusively; the linear polymers can only be kinetic products.

Ring-opening polymerization can nevertheless be used to produce polysilanes, provided strained rings are used and the process does not proceed to equilibrium.[81] So far this method has been used to convert four-membered rings to polymers. Thermal ring opening transforms (MeSi-n-Hex)$_4$ to linear polymer (equation 38)[76] and anionic ring opening is effective for $(PhSiMe)_4$ (equation 39).[84,85] Photochemical technique has also been used recently for ring-opening polymerization to prepare polysilanes.[86]

$$(n\text{-HexSiMe})_4 \xrightarrow{\Delta} (n\text{-HexSiMe})_n \qquad (38)$$

$$(\text{PhSiMe})_4 \xrightarrow{\text{RLi}} (\text{PhSiMe})_n \qquad (39)$$

7.4 Dehydrogenative Coupling

Condensation of diorganosilanes, $RR'SiH_2$, with loss of dihydrogen could provide a useful polysilane synthesis. Such dehydrogenative coupling, catalyzed by transition metals, has been extensively investigated.[87–89] The best catalysts are dialkyltitanocenes, Cp_2TiR_2, or zirconocene alkyls or hydrides, Cp_2ZrR_2 or Cp_2ZrH_2, however, late transition metal complexes (e.g. Wilkinson’s catalyst) have also received attention lately. Diorganosilanes, R_2SiH_2, usually only undergo dimerization to $R_2SiH–SiHR_2$, but monoorganosilanes can be polymerized or oligomerized to moderate molecular weights. Arylsilanes are more reactive than alkyl derivatives, and the reaction has been best studied for phenylsilane (equation 40).

$$n\text{RR}'\text{SiH}_2 \xrightarrow{\text{catalyst}} \text{H(SiRR}')_n\text{H} + (n-1)\text{H}_2 \qquad (40)$$

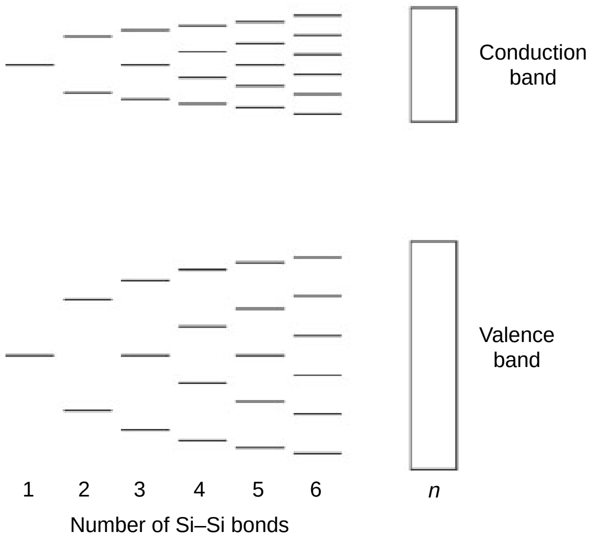


Figure 6 Schematic diagram showing splitting of filled and unfilled energy levels as the polysilane chain length increases, leading to formation of a valence band and a conduction band

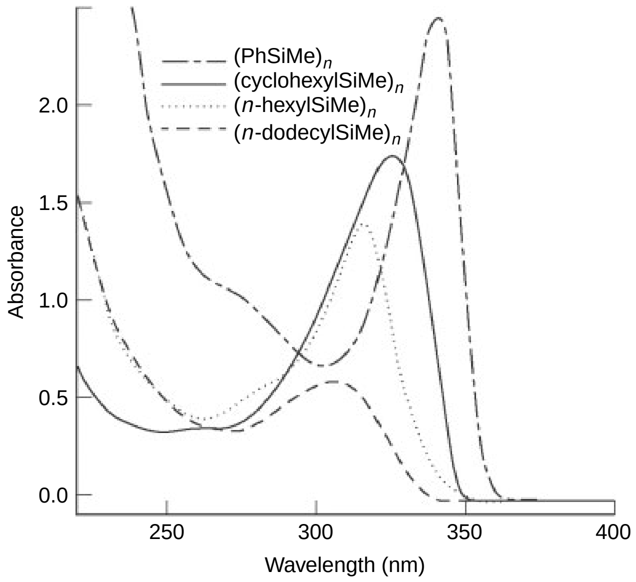

Figure 7 Typical UV spectra for polysilanes

8 POLYSILANES: ELECTRONIC PROPERTIES AND CONFORMATION

8.1 UV Absorption and Thermochromism

The σ-electron delocalization characteristic of polysilanes results in part from the low ionization potential for Si–Si σ electrons. The ionization potentials for polysilanes are often even lower than for alkenes. In addition, the resonance interaction between adjacent silicon orbitals is relatively large. The interaction can be viewed as one between neighboring Si–Si bonds, leading to an energy splitting. A similar interaction between antibonding Si–Si orbitals also takes place (Figure 6). As the number of silicon atoms increases, the energy gap between the filled σ and unfilled σ^* orbitals decreases. Eventually the filled orbitals combine to form a valence band, and the unfilled orbitals similarly generate a conduction band (*see Band Theory*).

The UV absorption by polysilanes involves promotion from the valence band to the conduction band, $\sigma \rightarrow \sigma^*$.[90] The absorption maxima for polysilanes typically lie between 300 and 400 nm (Figure 7), and are quite intense with $\varepsilon > 5000$ per Si–Si bond. In agreement with the model presented in Figure 6, the absorption maximum moves to a longer wavelength as the number of silicon atoms increases, eventually reaching a limit when the number of silicons is $\approx$30.

The polysilane σ–σ^* absorption wavelength, λ_{max}, depends on the nature of the substituents, and depends quite strongly on the conformation of the polymer chain. The absorption band is shifted to a longer wavelength as the length of all-trans segments in the polymer chain increases. The number of trans junctions often increases with decreasing temperature, and as a result the polysilanes are often thermochromic (*see Thermochromism*), both in solution and as solids.[91] Sometimes the thermochromism is manifested by a gradual shift of the absorption band to lower energy; in other cases an abrupt thermochromic transition can be observed over a rather narrow temperature range. An example is shown in Figure 8 for poly(di-*n*-butylsilylene). This observation indicates that two forms of the polymer with different conformations are present in equilibrium, a surprising result. Thermochromism in polysilanes have been found to cause change in refractive index in polysilane films.[92] Thermochromism in polysilanes are found to be affected by the variation in side chain.[93] The UV absorption in polysilanes is affected by the solvent giving rise to solvatochromism.[93–96]

Another interesting behavior observed in polysilane films is ionochromism where the thermochromic frequency shift is either inhibited (negative inonochromism) or accelerated (positive ionochromism) upon addition of lithium salts.[97]

8.2 Conformation and Configuration

The solid-state structures of symmetrical di-*n*-alkylpolysilanes $(R_2Si)_n$ have been studied in some detail by X-ray crystallography, vibrational spectroscopy, and so on, and a partial summary is given in Table 4.

The lower members of the series, where R = methyl to *n*-propyl, have all-trans conformations in the solid at ordinary temperatures, as do the polymers where R = *n*-hexyl, *n*-heptyl, and *n*-octyl. The two polymers with intermediate chain length, R = *n*-butyl and *n*-pentyl, instead have a 7/3 helical structure at room temperature.[7,98] Yet another conformation, alternating *trans–gauche* (TG–TG′), is found for the polymer where R = *n*-tetradecyl.[76] Above some

Table 4 Structures of Some polysilane polymers at 25 °C

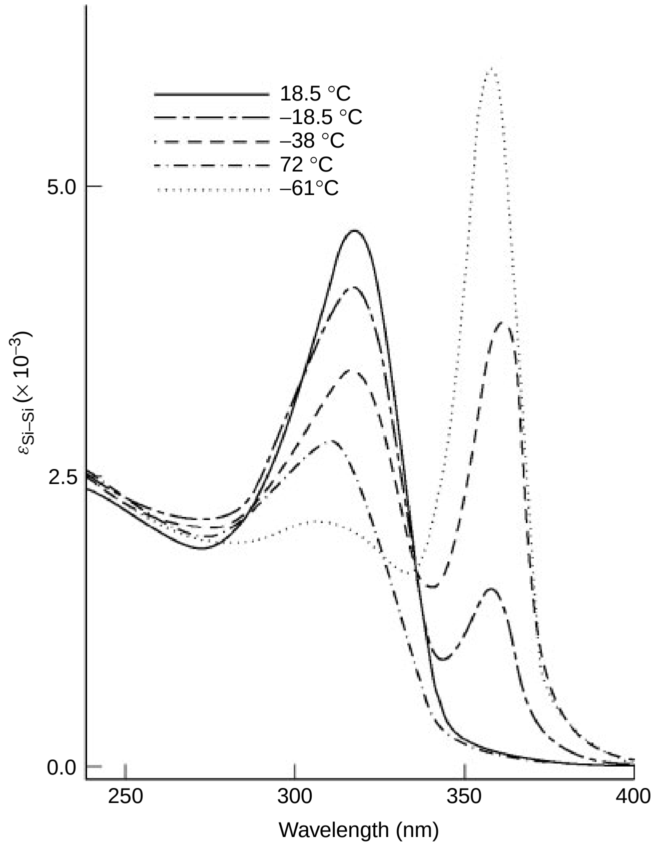

Figure 8 The UV spectrum for $(n\text{-butyl}_2Si)_n$ solutions in hexane as a function of temperature, showing an abrupt thermochromic transition

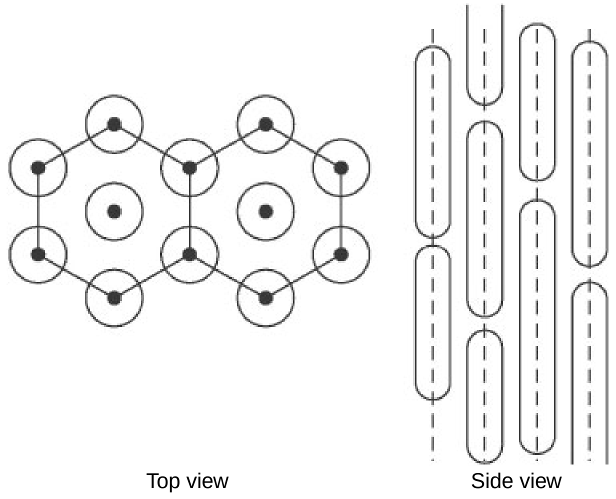

Figure 9 Schematic drawings showing the proposed arrangement of polysilane molecules in a hexagonal columnar liquid crystalline phase

transition temperature, many of the dialkylpolysilanes adopt a hexagonal, columnar liquid crystalline structure (Figure 9). For instance in poly(di-*n*-hexylsilylene), this transition takes place at 42 °C. Very recent studies indicate that polysilanes can exist in a variety of stable chain conformations.[99,100]

Polymers with two different alkyl substituents, $(RR'Si)_n$, are less crystalline. When the groups are very different in size the polymers are amorphous, as is the case for $(MeSi\text{-}n\text{-Hex})_n$, $(MeSi\text{-}n\text{-Bu})_n$, and $(MeSiPh)_n$. With groups of more nearly equal size, for example $(n\text{-BuSi-}n\text{-Hex})_n$, the columnar liquid crystalline structure is favored.[6,101] Copolymers, for example $(n\text{-Pr}_2Si)_n(n\text{-Hex}_2Si)_m$, $n/m \sim 1$, often also take the liquid crystalline arrangement. The many different structures which are observed for polysilanes reflects the great conformation flexibility in this class of polymers, consistent with theoretical calculations which indicate that the conformational preference is slight.

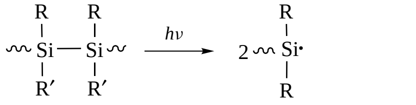
Less is known about the configurations of polysilane polymers. Dialkylpolysilanes such as $(MeSi\text{-}n\text{-Bu})_n$ made by sodium condensation appear to be atactic, from ^{29}Si NMR studies,[8] but arylalkylpolysilanes made by the same procedure appear to be partially tactic. Anionic ring-opening polymerization of $(PhSiMe)_4$ (Section 7.3) leads to a $(PhSiMe)_n$ polymer with greater, but still incomplete, stereoregularity.

8.3 Photophysics and Photochemistry

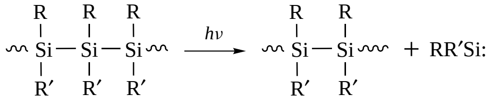
The polysilanes can be regarded as a series of loosely coupled chromophoric segments with mostly trans arrangement, separated by more pronounced kinks which break up the σ-conjugation. Transfer of energy from one segment to another in the polymer seems to be rapid, and the excitation thereby tends to become concentrated in the longer trans segments. Although the principal low-energy excitation is σ–σ^*, other excited states are undoubtedly present.[90]

The polysilanes generally exhibit intense, short-lived fluorescence. Competing with the fluorescence are photochemical reactions, of which three are most important. At high photon

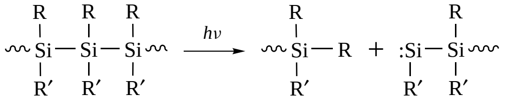
energy, the main reactions are silylene elimination (equation 41) and chain breaking to give silyl radicals (equation 42). A minor, but significant photoreaction is chain cleavage, with substituent migration to form a silylene (equation 43). At longer wavelengths, equation (41) does not take place and chain cleavage predominates.[102] The cross section (probability) for chain scission depends on the substituent groups, and is much greater in solution than in the solid state.



(41)



(42)



(43)

The various photoprocesses are important for several potential applications of polysilanes. Because of their intense fluorescence they have been suggested as scintillation materials for radiation detection. The chain-breaking reactions mean that polysilanes can be degraded by UV light; it is this property that makes them useful as photoresist materials.

9 TECHNOLOGICAL APPLICATIONS OF POLYSILANES

9.1 Silicon Carbide from Polysilanes

Polysilanes are now employed commercially as precursors for the synthesis of silicon carbide ceramics, either as fibers, foams, coatings, or solid monolithic objects.[7,8,55,56,103–106] This technology was initiated by the discovery in 1975 that silicon carbide could be made from $(Me_2Si)_n$, the original polysilane polymer.[2,10] In this process, $(Me_2Si)_n$ or the six-membered ring oligomer $(Me_2Si)_6$, are heated to near 450 °C. At this temperature complex rearrangement reactions take place. Methylene groups from the methyl substituents become inserted into the Si–Si bonds, so that the polysilane is largely transformed into a polymer with alternating silicon and carbon atoms, a polycarbosilane. This product is fractionated and can then be melt-spun into fibers. These are, however, meltable, so they must be rigidified by heating in air to form a thin coating of SiO_2 on the fiber surface. The heat-treated fibers are then reheated to high temperatures to obtain silicon carbide, with loss of CH_4 and H_2 (Scheme 4). Transformation to amorphous SiC is complete at about 280 °C; at still higher temperatures crystallites of β-SiC grow in the fiber, reinforcing and strengthening them. Maximum tensile strength is achieved at about 1300 °C.

This process is carried out in Japan by Nippon Carbon Co. to make NICALON silicon carbide fibers, with high tensile strength and excellent temperature and oxidation resistance. It can also be used to generate coatings and solid objects. Modifications of the basic process include the addition of borosiloxanes as catalysts, and the incorporation of titanium, in the form of titanium alkoxides, to produce fibers containing titanium and oxygen as well as silicon and carbon.

Of the other polysilanes which have been used as silicon carbide precursors, perhaps the best studied is 'polysilasytrene' (**6**). This polymer is used as a binder for finely divided silicon carbide powder, giving a mixture which can be injection molded. Firing then converts the molded object to silicon carbide.[6] The ceramic so produced is not fully dense, containing about 25% of void space from the hydrogen and hydrocarbons reheated during the firing. Although this reduces the ultimate strength somewhat, the microscopic 'bubbles' limit the growth of cracks, so that silicon carbide made by this process can be machined on a lathe.

Other more complex polymers have been employed as silicon carbide precursors. For instance, the mixture of methylchlorodisilanes obtained as a by-product in the direct synthesis of Me_2SiCl_2 can be redistributed with catalysts to give a polycyclic, partially cross-linked polymer with the approximate composition shown in equation (44). Pyrolysis of this precursor produces silicon carbide in good yield.[53] Partially cross-linked polymers made by condensing vinylmethyldichlorosilane and other methylchlorosilanes with sodium also are efficient precursors for silicon carbide.

Polysilanes have been used to prepare composite foams containing silicon carbide with aluminum nitride[103] or silicon nitride.[107]

$$MeCl_2SiSiCl_2Me + MeCl_2SiSiClMe_2 \xrightarrow[250^\circ]{Bu_4P^+Cl^-}$$

$$[(Me_2Si)_3(MeSi)_{17}Cl_5] \xrightarrow{\Delta} SiC \qquad (44)$$

9.2 Polysilanes as Photoresists for Microelectronics

In the manufacture of microchips and other microelectronic devices, the topography of the device is built up by sequential microlithography. A thin film of photosensitive material, a photoresist, is laid down on the substrate, usually a silicon wafer. The desired pattern is then transferred by exposing the wafer to light which causes a change in the photoresist layer. Because polysilanes are degraded by UV light, they are useful as positive-working photoresists.[7,108]

One application of polysilanes is in a bilayer construction, as shown in Figure 10. To cover existing topography on the wafer, a thin planarizing layer of a nonphotoactive polymer is deposited, followed by a very thin photoresist layer, about 0.5 to 0.2 μm in thickness. The wafer is exposed through a mask,

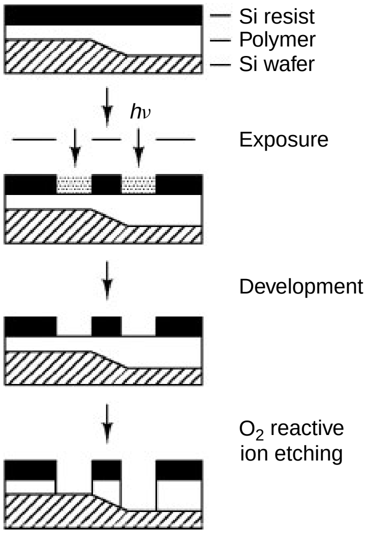


Figure 10 The use of a polysilane resist in a bilayer photolithographic process

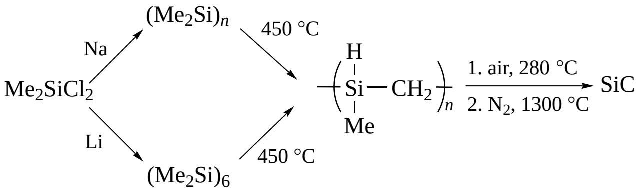

Scheme 4 Formation of silicon carbide from poly (dimethylsilylene)

with the result that the exposed portion of the polysilane is made more soluble than the unexposed polymer. The resist is then developed by a washing step in which the degraded polymer is removed, leaving the unexposed portion still in place. Next, the image is transferred through the planarizing layer by oxygen plasma etching. Polysilanes, and other silicon-containing photoresists, are advantageous because they form an inert coating of SiO_2 when contacted with the oxygen plasma, and so are not removed. The exposed planarizing layer is, however, etched away, down to the silicon surface, which can then be doped or otherwise altered. Following this processing all of the polymer can be removed, and the entire process repeated.

The wavelength of light used limits the resolution in microlithography, because at the present spacing of features diffraction effects are significant. The polysilanes, active in UV light, can provide greater resolution than visible-light photoresists. The light sensitivity of polysilanes is generally less than that of conventional photoresist materials which have light-amplifying properties. The polysilane light sensitivity can, however, be improved by careful design of the polymer and by the admixture of sensitizing additives.

9.3 Polysilanes as Photoinitiators

The photolytic cleavage of silanes to give silyl radicals can be used to induce radical chain reactions such as polymerization.[64,109] Several acrylate monomers have been polymerized with polysilanes as initiators, as well as styrene, and so on. The efficiency of polysilanes as radical photoinitiators is rather small, about an order of magnitude lower than conventional photoinitiators. The advantage of polysilanes lies in the fact that compared to most photoinitiators they are relatively insensitive to the effect of oxygen. This may be because oxygen-scavenging sites are generated along with radicals in the photolysis of polysilanes.[63]

9.4 Polysilanes as Hole Conductors in Electrophotography

In electrophotography, charges generated at a photoconductive surface are caused to migrate through a film under the influence of an electric field, and then used to produce an image. Because of the delocalization of Si–Si σ-electrons, the polysilanes show outstandingly good properties as hole conductors,[61] and are therefore promising materials for photocopying and printing applications.[62] Data for several materials are shown in Table 5. The films currently used in photocopiers are made of polycarbonate, doped with a triarylamine. The nitrogen atoms in the amine are the charge-carrying sites. Poly(phenylmethylsilylene) alone has hole mobility about as great as the materials now used commercially, and $(PhSiMe)_n$ with a triarylamine dopant added is about an order of magnitude faster.

By incorporating a charge-generating material onto a polysilane, a photoconductive film can be made. Very high photoconductivity has recently been observed for $(PhSiMe)_n$ doped with C_{60}, *Buckminsterfullerene*.[110] Photoconductive composite films of polysilane have been prepared by dispersing nanocrystalline silicon in the polymer.[111] Doping polysilanes with organic dyes have been used to prepare organic photoconductive films sensitive to particular wavelengths of light.[112]

The hole conducting property of silanes might made them very useful for preparing ‘molecular wires’.[113]

Table 5 Charge mobility and activation energy for charge transport for electrophotographic polymers

Polymer	Hole mobility ($cm^2\,V^{-1}\,s^{-1}$)	Activation energy (eV)
Polyvinylcarbazole	10^{-8}	0.6
Amine-doped polycarbonate	10^{-4}	0.3–0.7
$(PhSiMe)_n$	$>10^{-4}$	0.28
Amine-doped $(PhSiMe)_n$	10^{-3}	–

1 INTRODUCTION

Quasicrystals are solid materials exhibiting diffraction patterns with apparently sharp spots containing symmetry axes such as fivefold or eightfold axes, which are incompatible with the three-dimensional periodicity associated with crystal lattices.[1,2] Many such materials are aluminum alloys, which exhibit diffraction patterns with fivefold symmetry axes; such materials are called icosahedral quasicrystals.[3–7] Such quasicrystals[8–10] may be defined to have delta functions in their Fourier transforms, but their local point symmetries are incompatible with the periodic order of traditional crystallography. Structures with fivefold symmetry exhibit quasiperiodicity in two dimensions and periodicity in the third. Quasicrystals are thus seen to exhibit a lower order than in true crystals but a higher order than truly amorphous materials.

The structures of icosahedral quasicrystals may be viewed as three-dimensional analogues of Penrose tiling,[11–14] which is a geometric structure exhibiting fivefold symmetries and Bragg diffraction. Location of atoms in quasicrystals requires the use of six-dimensional crystallography,[15–18] in which the atoms correspond to three-dimensional hypersurfaces in six-dimensional periodic lattices rather than normal three-dimensional crystallography in which the atoms correspond to zero-dimensional points in three-dimensional periodic lattices. Note that in both the conventional three-dimensional crystallography used to determine the structures of regular crystals and in the six-dimensional crystallography required to determine the structures of quasicrystals, the dimensionality of the locations of the atoms is three less than the dimensionality of the lattice.

The complications of six-dimensional crystallography prevent the chemical structures of quasicrystals from being described in ways familiar to chemists. Instead, chemical models for quasicrystal structures are more readily developed by first considering closely related true crystalline materials, and then introducing appropriate perturbations destroying the periodic translational order but retaining the long-range translational and orientational order characteristics of quasicrystals.[5,6]

There are several classes of icosahedral quasicrystals with diverse compositions.[7,19] The following classes are the most important:

1. the i(Al–Mt) class (Mt = transition metal) including i($Al_{80}Mn_{20}$),[3] i($Al_{74}Mn_{20}Si_6$),[20,21] i($Al_{79}Cr_{17}Ru_4$),[22] and i($Al_{70}Pd_{20}Mn_{10}$);[23]
2. the i(AlZnMg) class including i($Al_{25}Zn_{38}Mg_{37}$),[24] i($Al_{44}Zn_{15}Cu_5Mg_{36}$),[25] and i($Al_{60}Cu_{10}Li_{30}$);[26]
3. the i(MMgRE) class (M = Zn or Cd; RE = rare earth metal) including $Zn_{60}Mg_{30}RE_{10}$[27] and $Cd_{65}Mg_{20}RE_{15}$;[28]
4. binary i(CdM) quasicrystals of approximate stoichiometry Cd_6M (M = Ca or Yb).[29]

Many of these phases contain relatively large amounts of aluminum suggesting the comparison of the structures of these materials with those of compounds with boron and gallium icosahedra including the icosahedral cage boranes, elemental boron, and boron-rich metal borides (*see* ***Borides: Solid-state Chemistry***), and gallium-rich intermetallic phases of alkali metals and gallium (*see* ***Gallium: Inorganic Chemistry***).

Consider the so-called T2 icosahedral quasicrystal i($Al_{60}Cu_{10}Li_{30}$) and related alloys containing aluminum, lithium, and copper and/or zinc, which have been studied by Audier and collaborators.[30] This system is significant since there are crystalline phases of stoichiometries similar to these T2 icosahedral quasicrystalline phases. Thus, the atom positions in the crystalline cubic R phase of approximate Al_5CuLi_3 stoichiometry are known so that the structure of this phase can provide some insight into the structure of the closely related T2 icosahedral phase of approximate stoichiometry $Al_{0.570}Cu_{0.108}Li_{0.322}$. Of interest in the structure of R-Al_5CuLi_3 is the presence of discrete Al_{12} icosahedra. Discrete molecules containing similar Al_{12} icosahedra are very rare although i-$Bu_{12}Al_{12}{}^{2-}$ containing an Al_{12} icosahedron, which is isoelectronic with $B_{12}H_{12}{}^{2-}$, has been reported as a low-yield product from the reduction of i-Bu_2AlCl with potassium metal.[31]

Audier and collaborators[20,32] have described a polyhedral shell structure for R-Al_5CuLi_3 using a number of polyhedra of icosahedral symmetry. This shell structure consists of the following layers:

1. a central $(Al,Cu)_{12}$ icosahedron;
2. an Li_{20} regular dodecahedron with the Li positions above the faces of the central $(Al,Cu)_{12}$ icosahedron (layer a) analogous to the construction of dual polyhedra (*see* ***Polyhedra***);
3. a larger $(Al,Cu)_{12}$ icosahedron formed from the external orbitals of the central $(Al,Cu)_{12}$ icosahedron (layer a) so that its atoms lie above the 12 faces of the Li_{20} dodecahedron in another ‘polyhedral dual construction’;
4. an $(Al,Cu)_{60}$ truncated icosahedron (Figure 1) distorted from I_h symmetry to O_h symmetry so that 12 vertices are of one type (circled in Figure 1) and 48 vertices are of another type (not circled in Figure 1). The atoms of

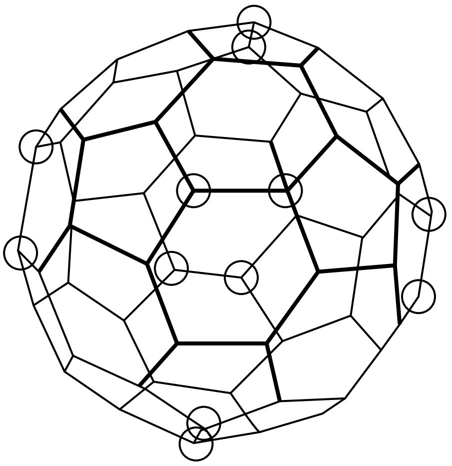

Figure 1 The two different types of vertices in the truncated icosahedron distorted from I_h to O_h symmetry as found in the structure of R-Al_5CuLi_3

this polyhedron lie above the midpoints of the faces of the omnicapped dodecahedron formed by combining the Li_{20} dodecahedron (layer b) with the larger $(Al,Cu)_{12}$ icosahedron (layer c) in still another 'polyhedral dual construction', since the truncated icosahedron is the dual of the omnicapped dodecahedron. Furthermore, the truncated icosahedron in layer d is the same polyhedron as that found in the structure of the C_{60} fullerene (*see* ***Carbon: Fullerenes***). The 84 atoms in layers a, c, and d taken together are known as a Samson complex.

A related model for quasicrystal structures has also been presented by Aslanov.[33]

The above discussion considers a model for the structure of the crystalline cubic R-Al_5CuLi_3. Now consider possible perturbations in this model to give the quasicrystalline T2-Al_5CuLi_3. In this connection, the 54-vertex Mackay icosahedron (Figure 2) appears as a structural unit in certain quasicrystals.[34] The Mackay icosahedron has a shell structure consisting of the following layers:

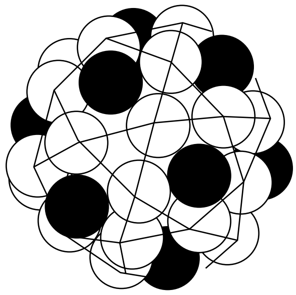

Figure 2 A view of the surface of a Mackay icosahedron showing the vertices of the larger icosahedron (layer b) as black circles and the vertices of the icosidodecahedron (layer c) as white circles. The vertices of the central icosahedron (layer a) are not visible

1. A central icosahedron (not visible in Figure 2);
2. A larger icosahedron formed from the external orbitals of the atoms in the central icosahedron (layer a) overlapping with an additional set of 12 atoms (black circles in Figure 2) that are located in the midpoints of the 12 pentagonal faces (6 visible) of the icosidodecahedron;
3. A 30-vertex icosidodecahedron formed by placing atoms above each of the 30 edges of the larger icosahedron (layer b). Layer c is shown as white circles in Figure 2.

Layers a and b of the Mackay icosahedron are identical to layers a and c in the Audier model for R-Al_5CuLi_3, whereas the outer icosidodecahedron layer of the Mackay icosahedron (layer c) has exactly half the number of atoms of the outer truncated icosahedron. Furthermore, the packing of the truncated icosahedra into the R-Al_5CuLi_3 lattice results in each of the peripheral truncated icosahedron atoms being shared between exactly two adjacent complexes (see above) so that a single Samson complex structural unit has the same 54 atoms as a corresponding Mackay icosahedron. This suggests a very close relationship between the packing of Samson complexes in the R-Al_5CuLi_3 crystal and a possible packing of Mackay icosahedra in a T2-Al_5CuLi_3 quasicrystal. In fact, a concerted 90° rotation about a tangential axis of each of the 30 edges connecting pairs of pentagonal faces in the peripheral truncated icosahedron in each Samson complex of the R-Al_5CuLi_3 crystalline lattice converts a lattice of 54-atom Samson complexes into a lattice of 54-atom Mackay icosahedra.

1 INTRODUCTION

Rhenium organometallic chemistry has witnessed a very fast and important development during the last decade. Previously following upon the footsteps of Mn organometallic chemistry, it has gained full independence, creating a number of new and highly productive areas of research and applications. Although this course of progress was predicted one decade ago when the first edition of this Encyclopedia was written, in fact, it has well overridden any logical expectations mainly because the major developments emerged in zones barely above surface in those days.

From a more fundamental standpoint, large progress was made in the field of Re clusters and polynuclear complexes related to heterogeneous catalysis models, and in the study of the transformations of unsaturated hydrocarbons mediated by the $ReCp'(CO)_2$ and $[ReCp'(NO)(PPh_3)]^+$ fragments. For the latter case, a very sophisticated understanding of the stereochemical control of the reactivity of unsaturated C=C and C=O ligands has been reached falling very short from practical extensive use. Moreover, Re has excelled in stabilizing a number of elusive 'primeval' molecules like HNO, H_2CNH, H_2N_2, linear carbon allotropes, and others. However, the most spectacular progress was achieved on the side of more applied research topics. The research around the room-temperature luminescent derivatives of the *fac*-$Re(CO)_3$ fragment attained a fantastic sum of published work opening the perspective for short-term real applications in fields like molecular sensors, optical responsive materials, and many others. Practical applications are now commonly used in the field of oxidation and oxygen-transfer catalysis, which arose in the wake of the discovery of $ReMeO_3$ (MTO). Last, but very, very far from the least, is the astonishing growth of the research on Re bioorganometallic chemistry. This topic, a frail blossom 10 years ago, grew toward immediate applied targets as imaging, radiotherapy, biological assaying, and biomarking and was responsible for

many spectacular results and applications while entailing a revolution of the whole synthetic establishment of Re organometallic chemistry. All taken together, these three areas account for the ca. 50% yearly increase in the publication rate of Re organometallic chemistry unabatedly registered from the mid-1990s onwards.

The following text is built upon the concept of descriptive organometallic chemistry, which uses the ligands rather than the oxidation states to organize the covered material. This includes all the material reviewed in the first edition[1] most of which is also covered by major comprehensive reference works until 1993.[2–4] All of the more recent material was taken directly from the primary literature as well as some annual surveys.[5–7] Therefore, in order to keep the number of references within an acceptable value, priority was given to the direct referencing of the material published from 1993, since the older material can be retrieved from the mentioned reference works and by cross referencing.

2 CHEMISTRY OF THE Re CARBONYL DERIVATIVES

2.1 Chemistry of $Re_2(CO)_{10}$

Dirhenium decacarbonyl $Re_2(CO)_{10}$ (**1**), the historical entry into the organometallic chemistry of Re, was discovered by Hieber and Fuchs in 1941. It can be prepared by carbonylation (*see also* ***Carbonyl Complexes of the Transition Metals***) of Re_2O_7, by reduction of $ReCl_5$ or K_2ReCl_6 under CO pressure, or at atmospheric pressure by the simple synthesis shown in equation (1).[8]

$$NaReO_4 \xrightarrow[\text{DIBAL-H, toluene } 80\,^\circ\text{C}]{\text{CO 1 atm}} Re_2(CO)_{10} \tag{1}$$

(**1**) is a white, volatile, air-stable complex structurally isomorphous with its analogs $M_2(CO)_{10}$ (M = Mn, Tc). A single metal–metal bond joins two $M(CO)_5$ moieties in a staggered conformation with approximate D_{4d} symmetry, having the radial CO groups slightly bent away from the M–M bond (4–6°). The molecule is not fluxional (*see Fluxional Molecule*) at room temperature. $MnRe(CO)_{10}$ (**2**) is best prepared by reaction of $[Mn(CO)_5]Na$ with $ReBr(CO)_5$ (see Section 14). The value obtained for the Mn–Re *Bond Length* in (**2**), 2.909 Å, is close to the value of 2.9038 Å measured for the Mn–Mn distance and is clearly shorter than the 3.0413 Å in (**1**).

2.1.1 *Homolytic Cleavage of $Re_2(CO)_{10}$ and the $Re(CO)_5$ Radical*

In addition to the typical chemistry of binary metal carbonyls, which centers on substitution and redox reactions, the presence and fate of the M–M bond adds to the variety of reactions and mechanistic pathways available to the $M_2(CO)_{10}$ complexes, namely through the photochemical or thermal formation of reactive $M(CO)_5$ radicals. Photolysis of a gas-phase molecular beam of (**1**) with 300 nm light produces $Re(CO)_5$ radicals translationally polarized along the Re–Re bond; this is in agreement with bond rupture being caused by the $1(\sigma 2) \rightarrow (1\sigma\sigma^*)$ transition. However, in solution and low-temperature matrices the situation is more complex due to the competing Re–Re bond dissociation and CO loss as primary steps. This competition also occurs for $Mn_2(CO)_{10}$ and (**2**). A wavelength dependency of M–M homolysis and CO loss processes has been first ascertained for $Mn_2(CO)_{10}$, but it is common to all three $MM'(CO)_{10}$ complexes (M, M′ = Mn, Re). The primary photochemical reaction of $MM'(CO)_{10}$ in solution has been shown to result in (1) homolytic fission of the metal–metal σ bond to form $M(CO)_5$ radicals, (2) dissociation of a CO ligand to form $MM'(CO)_9$, (3) nondissociative relaxation to the electronic ground state, as summarized in Scheme 1.

The branching ratios have been found to depend on the excitation wavelength by which pathway (1) is favored by lower energy excitation, whereas pathway (2) is favored by higher energy excitation.[9]

The chemistry that follows the generation of the active species $Re(CO)_5$ or $Re_2(CO)_9$ is quite different. The primarily formed $Re_2(CO)_9$ has a vacant equatorial coordination site, *eq*-$Re_2(CO)_9$, but it may be converted to the axially vacant isomer, *ax*-$Re_2(CO)_9$ upon irradiation with 546 nm light. This vacant site may coordinate solvents (S) or other ligands (L) to form substituted complexes $Re_2(CO)_9(L)$ (equation 2).

$$M_2(CO)_{10} + L \xrightarrow{h\nu} M_2(CO)_9L + CO \tag{2}$$

Flash photolysis of $MM'(CO)_{10}$ at 93 K leads to loss of CO and $MM'(CO)_9(S)$ as the sole net photochemical products.[10]

While $Mn_2(CO)_9(S)$ readily loses solvents at 93 K to form the semibridge form $Mn_2(CO)_8(\mu\text{-}\eta^1,\eta^2\text{-CO})$, $MnRe(CO)_9(S)$ only reverts to $MnRe(CO)_8(\mu\text{-}\eta^1,\eta^2\text{-CO})$ upon irradiation with visible light at 93 K. Upon warming

$$(OC)_5M{-}M'(CO)_5 \underset{}{\overset{h\nu}{\rightleftharpoons}} \begin{cases} {}^{\bullet}M(CO)_5 + {}^{\bullet}M'(CO)_5 & (1) \\ MM'(CO)_9 + CO & (2) \end{cases}$$

Scheme 1

of the glass, it recombines with CO to form $MnRe(CO)_{10}$. $Re_2(CO)_9(S)$ also reverts to (**1**) upon warming of the matrix but does not form any semibridged species upon irradiation either. A femtosecond infrared study of the dynamics of solvation and caging of these $Re(CO)_5$ (**3**) and *eq*-$Re(CO)_9$ (**4**) species is available.[9]

The $Re(CO)_5$ (**3**) radical, which may also be generated by several other methods, for example, deposition of Re atoms on a CO matrix at 10 K or *Pulse Radiolysis* of $ReBr(CO)_5$ in ethanol, has the theoretically predicted square-pyramidal structure that is maintained in solution at room temperature. Reactions where (**3**) may play a crucial role after photochemical generation from (**1**) include halogen abstraction, disproportionation, and electron transfer to an electron acceptor (EA) (Scheme 2).

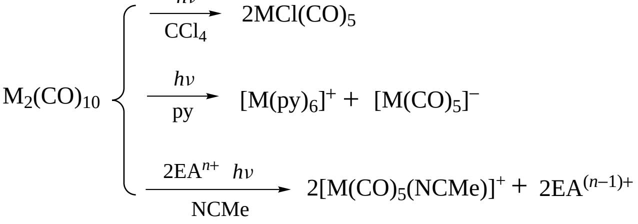
Competition experiments established the reactivity order of radicals generated by M–M bond homolysis as $Re(CO)_5 > Mn(CO)_5 > CpW(CO)_3 > CpMo(CO)_3 > CpFe(CO)_2 > Co(CO)_4$.

Electron-transfer reactions (*see* ***Electron Transfer in Coordination Compounds***) are important because (**3**) behaves as a better oxidizing and reducing agent than (**1**).

Persistent $Re(CO)_3(PR_3)_2$ radicals have been spectroscopically and even crystallographically characterized, for example, $Re(CO)_3(PCy_3)_2$ (**5**), suggesting the square-pyramidal structure to be the most favored one (*see* ***Diffraction Methods in Inorganic Chemistry***). Subcarbonyls like $Re(CO)_2$ have been studied in rare gas matrices.

2.1.2 Substitution Reactions of $Re_2(CO)_{10}$

Since many substitution reactions of (**1**) are done under thermal or photolytic conditions where Re–Re bond rupture may occur, $Re(CO)_5$ was first regarded as an intermediate in both types of substitution reactions. However, the mechanistic studies of photochemically induced substitutions suggest that: (1) photochemical substitution may not occur through the monomeric $M(CO)_5$ but from the longer-lived primary photointermediate $M_2(CO)_9$ (equation 2); (2) both primary photointermediates may give the same reaction products; and (3) substitution of CO in $M(CO)_5$ is most probably associative and not dissociative as in most substitution reactions of 17- and 19-electron metal carbonyl complexes (*see* ***Mechanisms of Reaction of Organometallic Complexes*** and ***Paramagnetic Organometallic Complexes***).

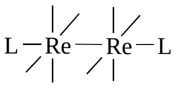


Scheme 2

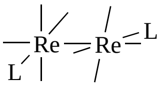
Independent of the mechanistic details involved, a host of *Ligand Substitution* products of (**1**) have been prepared. In monosubstituted products, $Re_2(CO)_9L$ ($L = PR_3$, py, NCMe), the axial position is normally occupied by the bulkier ligands (PPh_3) with equatorial substitution generally observed for the smaller ones, for example, py, PMe_3, and NCMe.

Coordination of the Si–H bond to $Re_2(CO)_9$ seems to be responsible for the catalytic activity of (**1**) in the synthesis of silyl ethers, $ROSiR'_3$ from R'_3SiH and ROH.[11]

Disubstituted complexes $Re_2(CO)_8L_2$ may have diaxial (**6**) or staggered transoid (**7**) isomers, while several other possibilities are found for trisubstituted $Re_2(CO)_7L_3$ ($L = PR_3$, CNR, $P(OR)_3$) (*see Isomer, Types of*).

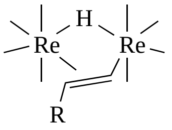


(**6**)

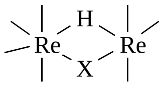


(**7**)

Further substitution with phosphines leads to monomeric radical products, for example, $Re(CO)_3(PR_3)_2$, but phosphite derivatives with a smaller *Cone Angle* may be prepared photolytically, for example, $Re_2(CO)_4\{P(OPh)_3\}_6$. In the bridged diphosphine complexes $Re_2(CO)_6(L\text{–}L)_2$ ($L\text{–}L = R_2P(CH_2)PR_2$), different photophysical properties arise because of the difficult breaking of the Re–Re bond. Photolysis of (**1**) in the presence of alkenes affords the dimers $[Re_2(\mu\text{-H})(\mu\text{-CH=CHR})(CO)_8]$ (**8**). These complexes are fluxional with the hydride and π-alkenyl bonds interchanging between the metals. The alkene in (**8**) may be displaced by two-electron ligands, for example, PR_3, $P(OR)_3$, alkenes, and H_2, in which case $[Re_2(\mu\text{-H})_2(CO)_8]$ is formed. This type of reaction is quite general and photolysis of (**1**) with HX ($X = H$, OH, OMe, C≡CPh, C(O)Me, PR_2) gives the products with the structural framework (**9**), quite common in Re and Mn carbonyl chemistry.[12] Scheme 3 exemplifies some of the reactivity of complex (**9**: $X = PPh_2$).

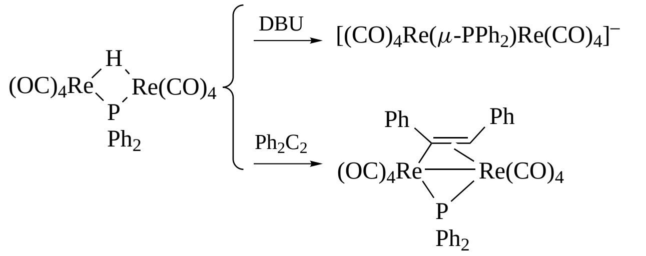


(**8**)

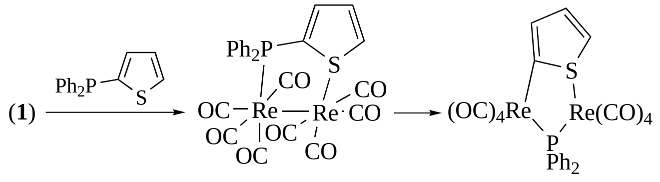


(**9**)

The complex (**9**; $X = CH_3$) prepared from $[Re_2(\mu\text{-H})_2(CO)_8]$ and N_2CH_2, decomposes above −20 °C to liberate CH_4 and form 1,2-*eq,eq*-$[Re_2(CO)_8(THF)_2]$ (**10**). The lability of the THF ligand makes (**10**) a versatile precursor to other



Scheme 3

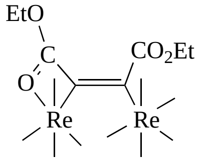


Scheme 4

complexes of type (**9**) by H–H and C–H activation, as well as polynuclear Re carbonyl hydride clusters (Section 3.2).[13]

Other bonds are cleaved by (**1**) under photolytic conditions, for example, the P–C bond in Scheme 4.

Thermal reaction of $Re_2(CO)_9(NCMe)$ with electrophilic alkynes $EtO_2C{\equiv}C(CO_2Et)$, $RC{\equiv}CCO_2R'$ inserts the alkyne across the Re–Re bond forming, for example, (**11**).[14]



(**11**)

The thiethane complex $Re_2(CO)_9(SCH_2CH_2CH_2\text{–})$ catalyzes the cyclooligomerization of thiethane to the sulfur macrocycles $12S_3$ and $24S_6$.[15]

The thermal substitution of CO is catalyzed by several supported transition metals and their oxides, for example, PdO (*see* ***Heterogeneous Catalysis by Metals*** and ***Oxide Catalysts in Solid-state Chemistry***).[16] Adsorption and reaction of (**1**) on MgO occurs according to Scheme 5.

The adsorption of (**1**) on Al_2O_3 is an important method of preparation of heterogeneous Re-containing catalysts, for example, hydrodesulfurization.[17]

(**10**) is an excellent starting material for the synthesis of molecular models of SiO_2-anchored Re carbonyls. An electron beam irradiation of (**1**) induces the formation of nanorods of Re (*see* ***Metallic Materials Deposition: Metal-organic Precursors***).

2.1.3 Redox Reactions of Re₂(CO)₁₀

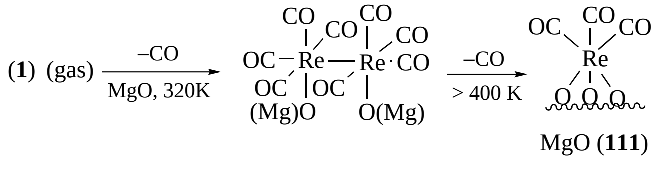
Chemical oxidation of (**1**) with $NOPF_6$ in MeCN gives the cation $[Re(CO)_5(NCMe)]^+$ (**12**), a convenient starting material for other $[Re(CO)_5L]^+$ derivatives (e.g. $L = PR_3$, py). Oxidation with halogens in MeCN gives $ReX(CO)_5$ and (**12**). The order of reactivity within the $M_2(CO)_{10}$ family varies according to the nature of the oxidant, the type of electron-transfer step (inner or outer sphere) (*see Inner-sphere Reaction* and *Outer-sphere Reaction*), and the nature of the solvent (to which the reactions are very sensitive). Strong anionic oxidants, for example, $[Fe(CN)_6]^{3-}$, do not oxidize $M_2(CO)_{10}$ but oxidizing cations do.

The anion $[Re(CO)_5]^-$ (**13**) is formed by reduction of (**1**) with Na/Hg. This extremely reactive species yields a variety of Re carbonyl clusters (*see* ***Polynuclear Organometallic Cluster Complexes***). Further reduction to $[Re(CO)_4]^{3-}$ is possible with Na in HMPA. The electrochemistry of $M_2(CO)_{10}$ shows that these species oxidize at the same potential and, in MeCN, give $[M(CO)_5(MeCN)]^+$. However, (**1**) is more difficult to reduce than $Mn_2(CO)_{10}$ and electrochemical reduction leads to the typical clusters obtained from (**13**) under chemical conditions.

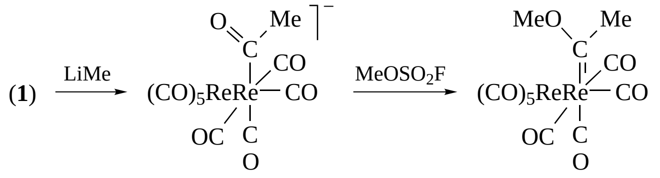
2.1.4 Nucleophilic Attack on Re₂(CO)₁₀

Reaction of Li alkyls with (**1**) gives acyl anions, which upon alkylation form Fischer-Type Carbene complexes (*see Fischer-type Carbene Complexes*) (Scheme 6).

This reactivity is very general for Re carbonyls. For instance, (**9**; $X = PCy_2$) is not deprotonated by LiPh at $-100\,°C$. Instead, the salt $Li[Re_2(\mu\text{-}H)(\mu\text{-}PCy_2)C(O)Ph]$ is obtained.[18]



Scheme 5



Scheme 6

In the context of the homogeneous modeling of the *Fischer-Tropsch Process*, the analogous formyls $[M_2(CO)_9(CHO)]Li$ were intensively studied. They were formed on addition of hydride (H^-) from $Li[BEt_3H]$ to $M_2(CO)_{10}$ (M = M, Re). The Re_2 derivative is the most stable of these rather sensitive complexes. They decarbonylate to $[Re_2(CO)_9H]^-$ via a radical chain mechanism and are stabilized by $SnBu_3H$, an H radical source. These formyls possess a strong hydridic character, that is, they behave as good H^- donors. $NaBH_4$ and OH^- additions to (**1**) lead to a wide variety of polynuclear Re carbonyl hydrides and Re carbonyl anions (see Section 3.2).

2.2 Chemistry of the Re Carbonyl Anions and Related Species

Among the mononuclear, $[Re(CO)_4]$ and $[Re(CO)_5]^-$ (**13**), and polynuclear, $[Re_2(CO)_9]^{2-}$ and $[Re_4(CO)_{16}]^{2-}$, carbonylate anions, (**13**) is the most important as it is a fundamental building block in Re organometallic chemistry. It is prepared by reduction of (**1**) with Na/Hg and may be conveniently metathesized to the unsolvated PPN salt, $[Re(CO)_5]PPN$.

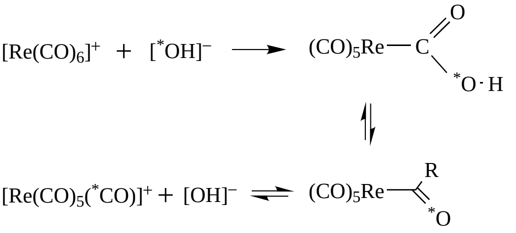
This very strong nucleophile reacts with a variety of organic and inorganic substrates forming Re–C, Re–Re, and Re–M′ bonds, as discussed in Sections 4.1 and 14. The mechanistic simplicity of these substitutions, however, may be misleading because electron-transfer processes may be involved in the initial stage of the reaction because $[Re(CO)_5]^-$ is also a good reducing agent.[19]

One example of this complex behavior is given by the reaction of (**13**) with C_{60} that, under photolysis, ends in $[Re(CO)_4(\eta^2\text{-}C_{60})]^-$. Its Mn analogue has a very strong Mn–C_{60} bond.[20]

Complex (**13**) is very easily protonated to form Re carbonyl clusters of low nuclearity (as discussed in Section 3.2).

2.3 The Chemistry of the Re Carbonyl Cations $[Re(CO)_nL_{6-n}]^+$

The parent cation $[Re(CO)_6]^+$ is inert in substitution reactions, and CO replacement may only be achieved under forcing conditions and does not happen with labeled *CO. However, the positive charge in the complex enhances the reactivity of coordinated CO toward nucleophiles, as the labeling experiment in equation (3) shows.

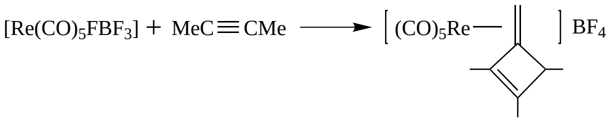


(3)

Nucleophilic attack of hydrazine, NH_2NH_2, or azide, $N_3{}^-$, on the coordinated CO of $[Re(CO)_6]^+$ is followed by rearrangement to give $Re(NCO)(CO)_5$ and NH_3 (or N_2). In a similar fashion to the first step in equation (3), OR^- and NHR_2 add to the CO of $[Re(CO)_nL_{5-n}]^+$ to give the adducts $[Re\{C(O)Z\}(CO)_3L_2]$ (Z = OR, NR_2). However, if the CO force constant is $<17 \times 10^{-8}$ N Å $^{-1}$ an equilibrium between reactants and adducts is observed. Structurally characterized neutral formyl complexes $[Re\{C(O)H\}(CO)_nL_{5-n}]$ result from H^- addition to the corresponding cations (L = $P(OR)_3$).

Substitutionally labile cations, $[Re(CO)_5(S)]^+$ (S = solvent) are available by oxidation of (**1**), by halide abstraction from $ReBr(CO)_5$ with Ag^+ salts, or by the reaction of $ReH(CO)_5$ or $ReMe(CO)_5$ with Ph_3CBF_4 or from the latter and HBF_4. The resulting $Re(CO)_5FBF_3$ is a strong Lewis acid that adds virtually any L donor to give $[Re(CO)_5L]^+$.[21]

Not unexpectedly, more reactive ligands like alkynes undergo acid-promoted transformations such as the cyclodimerization in equation (4) (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***).



(4)

Complexes $[Re(CO)_4PR_3]^+$ stabilized by the $[BArF]^-$ counterion coordinate CH_2Cl_2, H_2, and Si–H bonds activating H_2 heterolysis and C–Cl bond breaking.[22]

$[Re(CO)_4(OEt_2)_2]^+$ is a useful reagent for the synthesis of a variety of $[Re(CO)_4L_2]^+$ complexes with weak donors, including $[Re(CO)_4(OH_2)_2]^+$.[23]

These chemical properties allow the stabilization of otherwise elusive ligands. The cations $[Re(CO)_n(PR_3)_{5-n}]Y$ react with hydrazine to form $[Re(H_2N{=}NH_2)(CO)_n(PR_3)_{5-n}]Y$. This can be oxidized to the 1,2-diazene species $[Re(\eta^1\text{-}HN{=}NH)(CO)_n(PR_3)_{5-n}]Y$, a rare example of a stabilized HN=NH ligand on a mononuclear complex. More interestingly, oxidation of $[Re(H_2N{=}NHCH_3)(CO)_n(PR_3)_{5-n}]Y$, also with $Pb(OAc)_4$, leads to the methylenimine complex $[Re(HN{=}CH_2)(CO)_n(PR_3)_{5-n}]Y$. This is only the second example of the stabilization of this extremely unstable yet fundamental molecule.[24] Other examples of Re complexes with this type of diazo ligands can be found in the Section on Substitution Reactions and in a review.[25] The elusive nitroxyl molecule (HN=O), isoelectronic with 1,2-diazenes and methylenimine, is also stabilized in the complex $[Re(CO)_3(PR_3)_2(NH{=}O)]OTf$ and in other similar species discussed in Section 13. Trisubstituted species $[Re(CO)_3L_2L']^+$ are produced by X^- abstraction from *fac*-$[ReX(CO)_3L_2]$ with the retention of *Stereochemistry*. $[Re(CO)_3L_3]^+$ (L = MeCN, NH_3, OH_2) are readily produced by arene displacement from $[Re(\eta^6\text{-}C_6H_5Me)(CO)_3]^+$, but they are now best prepared

by the aqueous route described in Section 15. Rhenium carbonyl cations with higher degrees of substitution are uncommon, but $[Re(CO)_2(dppe)_2]^+$ can be made from $ReX(CO)_5$ under forcing conditions, or more mildly from $ReCl(N_2)(dppe)_2$.

2.4 Chemistry of the Re Carbonyl Derivatives $[ReX_x(CO)_yL_z]_n$

Complexes within this general class comprise a wide variety of uninegative (X) ligands and neutral two-electron donors and constitute the largest family of organorhenium complexes.[2]

2.4.1 The Re Carbonyl Halides $[ReX_x(CO)_y]_n$

The entry into this class of Re complexes is the family $ReX(CO)_5$ (**14**) (X = Cl, Br, I), prepared by oxidative addition of X_2 to (**1**) in hydrocarbons (equation 5).

$$\underset{(\mathbf{1})}{Re_2(CO)_{10}} + X_2 \longrightarrow 2\ \underset{(\mathbf{14})}{ReX(CO)_5} \qquad (5)$$

The fluorides $ReF(CO)_5$ and $[Re(CO)_5F{\cdot}MF_5]$ (M = Re, I, As, Ta) have been reported and the crystal structure of $[Re(CO)_5F{\cdot}ReF_5]$, prepared from (**1**) and ReF_6 or XeF_2 in HF, is consistent with a bridge between $Re(CO)_5$ and ReF_6 radicals.

A number of other $[ReX_x(CO)_y]_n$ derivatives have been made for X = Cl, Br, I, and their schematic structures are represented in Figure 1.

Decarbonylation of (**14**), either thermally in boiling hexane (X = Cl, Br) or photochemically (X = I), gives the halide-bridged dimers $[ReX(CO)_4]_2$ (**15**) that catalyze Friedel–Crafts alkylation and acylation, as well as benzyl ester deprotection.[26]

Most of the other products (**16**–**22**), can be made directly from (**14**) and alkylammonium or phosphonium salts, R_4EX (E = N, P), under appropriate thermal and stoichiometric conditions. Mixed-halide derivatives have also been made. The preparation of the derivatives of the $[ReX(CO)_3]$ fragment, (**19**), (**20**), (**21**), and the tetrahedrane (**22**), require higher temperatures.

Nucleophilic addition of LiR or H^-, from $Li[BEt_3H]$, to (**14**) occurs at the *cis*-CO to give acyl or formyl anions $[Re\{C(O)R\}X(CO)_4]^-$, which may be protonated or alkylated to give the corresponding Fischer carbenes $[Re\{C(OR')R\}X(CO)_4]$. In contrast to the dinuclear formyls $[Re_2(CO)_9(CHO)]^-$, these are not stabilized by $SnBu_3H$ because rapid X^- loss produces $Re(CO)_4(CHO)$, which decomposes to $ReH(CO)_5$ or oxidatively adds the Sn–H bond.[3] Remarkably, double nucleophilic alkylation is possible without X^- replacement, and upon protonation bis(hydroxy)carbene complexes, for example, *fac*-$[ReX\{C(OH)Me\}_2(CO)_3]$ are obtained.[27]

Re carbonyl halides in higher oxidation states are rare. The paramagnetic *cis*-$[ReX_4(CO)_2]^-$ (X = Cl, Br) results from oxidative addition of X_2 to (**15**) or $[Re(CO)_3Br_3]^{2-}$. In

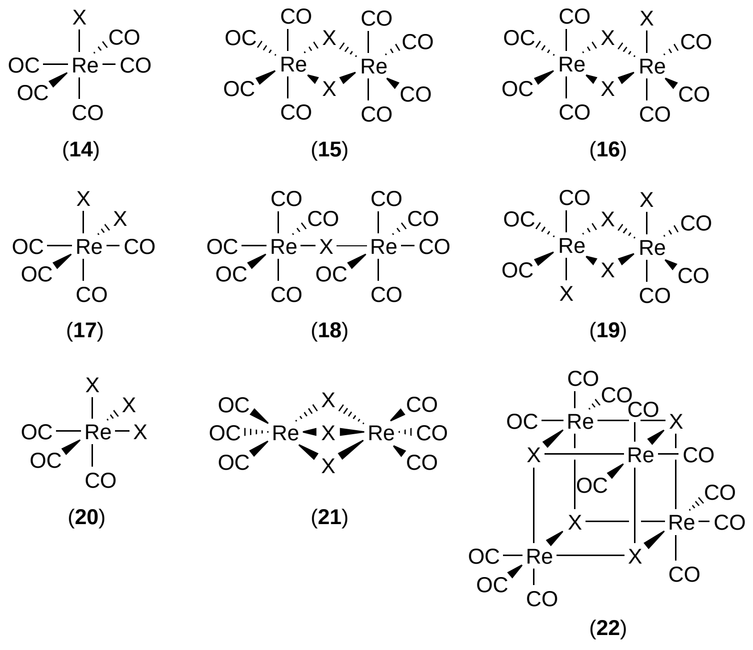


Figure 1 Schematic structures of $[Re^IX_n(CO)_m]^{x-}$ complexes; charges omitted

contrast, many oxidative additions of these types are known for the more electron-rich $[ReX(CO)_nL_{5-n}]$ analogs.

2.4.2 The Halide Derivatives $[ReX_x(CO)_nL_{5-n}]$

The Re^I complexes $[ReX(CO)_nL_{5-n}]$ are generally prepared by straightforward CO substitution on (**14**), by ligand addition to the dimer (**15**), or by X_2 addition to $Re_2(CO)_8L_2$.

A wide variety of ligands form $[ReX(CO)_4L]$ complexes ($L = PR_3$, AsR_3, SR_2, SeR_2, OPR_3, H_2O, THF, N-heterocycles, MeCN, MeNC) and $[ReX(CO)_3L_2]$ complexes ($L = PR_3$, $P(OR)_3$, N-heterocycles, MeCN, MeNC; L_2 = bipy, TMEDA, diimine). Carbonyl substitution in $ReX(CO)_5$ is ca. 60 times slower than in $MnX(CO)_5$ analogs. This is in agreement with a dissociative mechanism with cis labilization increasing in the order $I < Br < Cl$ as revealed by kinetic experiments with ^{13}CO.

The second substitution proceeds by a similar dissociative mechanism, producing *fac*-$[ReX(CO)_3L_2]$ which isomerizes to *mer,trans*-$[ReX(CO)_3L_2]$ at higher temperatures. A cis-labilizing effect in the order $L = py > PPh_3 > P(OPh)_3 \sim CO$ is responsible for the difficult preparation of $ReX(py)(CO)_4$ and other N-heterocycle analogs. The decarbonylation product of (**14**) in THF, $[Re_2(\mu\text{-}X)_2(CO)_6(THF)_2]$, provides an alternative mild route to *fac*-$[ReX(CO)_3L_2]$ ($L = PR_3$, NR_3, N-heterocycles), as does the dissolution of the tetramer (**22**) in donor solvents, for example, py. Wrighton's discovery of the luminescence of $ReCl(CO)_3(phen)$ in solution at rt produced an extraordinary impact on inorganic photochemistry and in the development of the studies on *fac*-$[ReX(CO)_3L_2]$ complexes (*see* ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds***). The literature spans several hundred articles on this topic studied from the photophysical, spectroscopic, and spectroelectrochemical aspects to very recent applications in molecular devices and solid-state materials as liquid crystals,[28] and photoresponsive materials.[29,30] A few references help highlighting the approaches used.[31–33]

An overwhelming number of different complexes bearing the $[Re(CO)_3]^+$ fragment as $ReX(CO)_3L_2$ or $[Re(CO)_3L_2L']^+$ have been studied and can by no means be covered here. Some of them can be found in reviews and most can be retrieved under Re^I and luminescence keywords.[34–36]

The largest families stem from substituted py, bipy, phen, and DAB but virtually any kind of O, N, S or P donor can be used. Both the nature of the ligands and their substituents as well as the nature of X (halide, alkoxide, alkyl, alkynyl) have been used as handles for tuning the photophysical properties of the excited state and emission of these complexes.

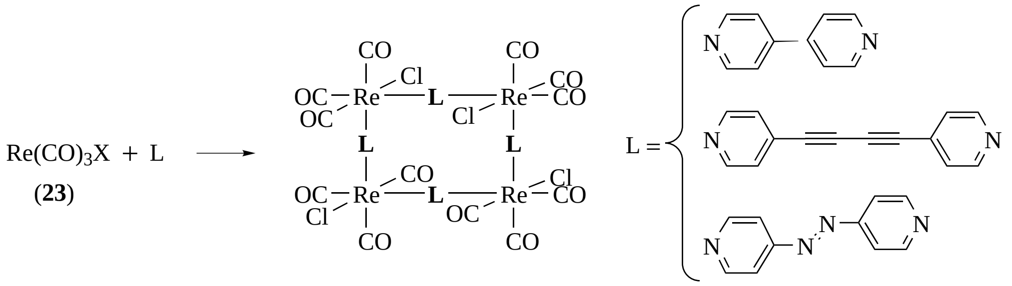
With regard to their excited state properties, $[Re(CO)_3X(N\text{–}N)]$ (N–N = diimine) complexes are organometallic analogues of $[Ru(bipy)_3]^{2+}$ and other octahedral d^6 low-spin metal complexes of Os, Rh, and Ir. They display long-wavelength MLCT ($Re' \rightarrow$ diimine) absorptions in their electronic spectra. These bands exhibit solvatochromism tunable by the energy level of the diimine π^* orbitals. In analogy to $[Ru(bipy)_3]^{2+}$, many (not all) of these rhenium complexes show an emission that originates from the lowest-energy MLCT triplet. This phosphorescence which appears in solution at rt can be quenched by electron and energy transfer. The MLCT excited states of both $[Ru(bipy)_3]^{2+}$ and $Re(bipy)(CO)_3Cl$ are inert to ligand substitution. Therefore, they are not inherently reactive but strongly emissive and susceptible to electron or energy transfer. $Re(bipy)(CO)_3Cl$ catalyzes the photoreduction of CO_2 to CO in the presence of an amine–electron donor, and this process is highly favored at high pressure.[37]

The poliynyl complexes $[Re(CO)_3(bipy)\{C{=}C\text{–}(C{=}C)_nR\}]$ are highly luminescent at rt with an uncommon blue shift in energy emission upon extension of the carbon chain.[38]

Supramolecular systems based on $Re(CO)_3X$ (**23**) and other fragments, generally called metallo-cyclophanes or molecular squares, are recent.[39]

The self-assembly of these squares (Scheme 7) from $Re(CO)_3X$ is highly efficient and seems thermodynamically controlled (*see* ***Self-assembled Inorganic Architectures***).[40]

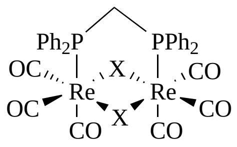
These supramolecular assemblies are being intensely studied with regard to host–guest behavior,[41] molecular, biologic[42] and ion sensors,[43,44] nanoporosity, and photo-switching.[45]



Scheme 7

Association of another light sensitive system with the $[Re(CO)_3(N–N)]^+$ chromophore leads to photoswitchable systems[46] or photoinduced electron transfer.[47]

Another class of halogen-bridged dimers is derived from reaction of (**14**) with bidentate ligands that bridge the two metal centers in the final product, as (**24**).



(**24**)

Trisubstitution from (**14**) with excess PR_3, $P(OPh)_3$, or tripodal phosphines gives the *mer*,*cis*-$[ReBr(CO)_2L_3]$, but further direct substitution from (**14**) or (**15**) requires bidentate phosphines (*trans*-$[ReX(CO)(dppe)_2]$) and forcing conditions. Alternatively, $[ReX(CO)L_4]$ ($L = PMe_2Ph$, diars) complexes are made via carbonylation reactions, for example, from *mer*-$[ReCl_3(PMe_2Ph)_3]$ to give *trans*-$[ReCl(CO)\{(PMe_2Ph)_3\}_4]$. The unprecedented MeECN (E = S, Se) sulfur bound ligands are obtained by methylation of the neutral $[Re(CO)_2(triphos)(ECN)]$ complexes at the E atom.[48]

Only a few Re^{II} octahedral, paramagnetic 17-electron complexes $[ReX_2(CO)_nL_{5-n}]$ are known, for example, all-*trans*-$[ReCl_2(CO)_2(PEt_3)_2]$, $[ReX(CO)(dppe)_2]^+$, and a few isocyanide analogs (see Section 14). The first compound is prepared by carbonylation of $Re_2X_4(PR_3)_4$ and the second by oxidation of the parent Re^I species. Electrochemical studies have shown these compounds to be strong oxidants and yet stable in solution.[49]

The Re^{III} complexes, generally prepared by X_2 oxidative addition to the parent Re^I species (equation 6), are normally seven coordinate and diamagnetic with a capped octahedron structure, but six-coordinate, 16-electron derivatives have been found, especially with isocyanide ligands.[50] (*see* ***Structure & Property Maps for Inorganic Solids***).

$$ReBr(CO)_3(PPhMe_2)_2 + Br_2 \longrightarrow ReBr_3(CO)_2(PPhMe_2)_2 \quad (6)$$

2.4.3 *The Complexes $[ReX_x(CO)_y]_n$ (X = Pseudohalide, Uninegative Group 15 and 16 Ligands)*

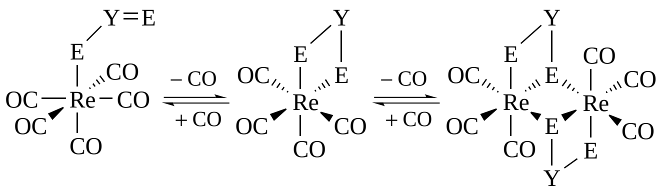
The fundamental examples of this class of complexes, for example, cyanides, nitrates, thiocyanate, and the isocyanato derivatives are well known, and with the exception of the interesting, strong labilizing effect of the latter, which leads to fast decarbonylation to $[Re_2(\mu\text{-}NCO)_2(CO)_8]$, they do not have a special chemistry and are sometimes difficult to prepare. In any case, these difficulties have been removed by the use of $Re(CO)_5FBF_3$, which readily reacts with these types of anionic ligands to form the corresponding Re complexes.[21] A few structural analogs of (**14**) and (**15**), $Re(ER_2)(CO)_5$, $[Re_2(\mu\text{-}ER_2)_2(CO)_8]$, are known (E = P, As). These may be prepared, among other variations, by reaction of $HRe(CO)_5$ with E_2R_4 (e.g. $As_2(CF_3)_4$), $[Re(CO)_5]^-$ with XPR_2, or (**14**) with phosphide anions (e.g. $KPPh_2$).[2]

The coordination chemistry of the derivatives of the group 16 ligands, $[Re(AR)_x(CO)_y]_n$ (A = O, S, Se, Te) resembles that of the halides and group 15 anions, ER_2^-, namely the structural types (**14**), (**15**), and (**22**). No monomeric alkoxide $Re(CO)_5(OR)$ has been isolated, but $Re(CO)_5(OSi{\equiv}anchored\ on\ SiO_2)$,[51] $Re(CO)_5(OReO_3)$, and $Re(CO)_5(OTf)$ are stable compounds. The tetrahedrane (**22**, X = OH) is made by photolysis of (**1**) in H_2O and is active in *Alkene Metathesis*.[52] Reaction of OH^- with (**19**, X = Br) leads to $[Re_3(CO)_9(OH)_4]^-$, which corresponds to the removal of $[Re(CO)_3]^+$ from one corner of (**22**, X = OH). Reaction of the latter tetrahedrane with OH^- quantitatively forms (**20**, X = OH), an important compound in biomedical applications.[53]

$[Re_3(CO)_9(OH)_4]^-$ has been used as a tripodal ligand toward metal ions and fragments, for example, Mn^{II}, Cu^{II}, and $[PtMe_3]^+$. Basic alcoholysis of $[ReH_9]^{2-}$ gives triply bridged alkoxides $[Re_2(\mu\text{-}OR)_3(CO)_6]^-$with (**21**). A recent review on the chemistry of late transition metal alkoxides reports a series of $Re(OR)L_2(CO)_3$ ($L = PR_3$) complexes. They do not decompose by β-H elimination and react like anions producing $ReClL_2(CO)_3$ from acyl chlorides and $Re(EAr)L_2(CO)_3$ from HEAr (E = O, S, NH).

They insert CE_2 (E = O, S) but do not exchange OR groups between them. $Re(OR)(CO)_3(dppe)$ in benzene solution reversibly absorbs atmospheric CO_2.

Complexes of thiolates, selenates, and tellurates (AR) can be made either by reaction of their Na salts with (**14**) or by reaction of $ReH(CO)_5$ with the HAR to give either $Re(AR)(CO)_5$ or dimers with (**15**). The latter complexes, $[Re_2(\mu\text{-}AR)_2(CO)_8]$, are favored for R = alkyl, and the former for R = CF_3 or C_6F_5. Upon further heating, the tetrahedranes $[Re(AR)(CO)_3]_4$ are formed. Reaction of $[Re_2(\mu\text{-}AR)_2(CO)_8]$ with phosphines may lead to CO substitution, bridge cleavage, or both, depending on the reaction conditions. Potentially bidentate monoanionic ligands of the general formula $[E_2Y]^-$ (E = O, S, Se; Y = CR, COR, CNR_2, PR_2, AsR_2) form complexes with (**25–27**). Few complexes of type (**25**) have been directly prepared from (**14**), because its reaction with the anions $[E_2Y]^-$gives preferentially (**26**) and (**27**) as a result of the labilization effect of this type of ligand.



(**25**) (**26**) (**27**)

Carbonylation of (**26**) or (**27**) needs very high pressure, but the addition of PPh_3 is very easy and $Re(O_2CR)(CO)_3(PPh_3)$ is formed from $[Re(O_2CR)(CO)_3]_2$ at rt. Also favored in the PR_3 family of complexes, $ReX(CO)_3(PR_3)_2$, are the insertions of CE_2 into Re–H and Re–C bonds, yielding formates, carboxylates, and their S analogs, that is, $Re(E_2CR)(CO)(PR_3)_2$ (E = O, S; R = H, alkyls, phenyl) with (**27**). R_2PO_2, β-diketone derivatives, and other mixed O,S donors, for example, $HSCH_2CO_2Et$ also give complexes of related coordination types.[2] Derivatives in higher oxidation states are rare, but $Re(SR)_3(CO)_2$ is obtained by carbonylation of the parent MeCN derivative.

3 CHEMISTRY OF Re HYDRIDES

3.1 The Re Polyhydrides: $[ReH_9]^{2-}$ and $[ReH_xL_y]^{2-}$

Owing to their importance in many organometallic processes, *Polyhydrides* (*see* ***Hydride Complexes of the Transition Metals***) that are not strictly organometallic compounds justify being mentioned.[54] $[ReH_9]^{2-}$ prepared by reduction of $NaReO_4$ with Na in EtOH has a tricapped trigonal prism structure. It reacts with ER_3 (E = P, As) to give $[ReH_8(ER_3)]^-$, with CO to give $[Re_2(\mu\text{-}H)_3(CO)_6]^-$, and under basic conditions to give $[Re_2(\mu\text{-}OR)_3(CO)_6]^-$ With dppe, under N_2 atmosphere, the very useful precursor $[ReH(N_2)(dppe)_2]$ is obtained. Another central compound in this area is $ReH_7(PPh_3)_2$ (**28**) made from $ReOCl_3(PPh_3)_2$ and $LiAlH_4$.[55]

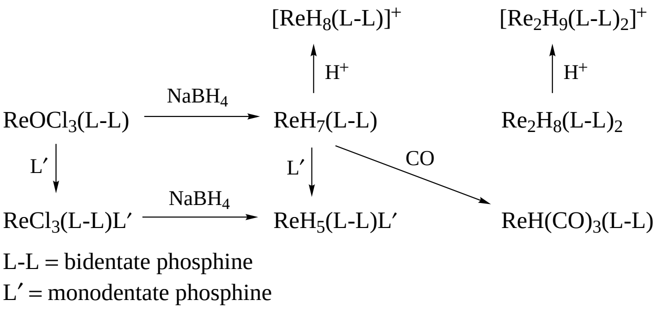
The main characteristic of the reactivity of $ReH_7(PR_3)_2$ and other polyhydride*s* is their ability to lose H_2 upon thermal, photochemical, or oxidative (electrophilic) activation. The resulting free coordination positions may then be occupied by two-electron donors, forming substitution products (equations 7 and 8) like $ReH_5(PR_3)_3$, $ReH_5(PR_3)_2L$, $ReH_3L(PR_3)_3$, and $ReHL_3(PR_3)_2$ (L is usually PR_3 or CO). Analogues with tripodal and bidentate phosphines also exist. $ReH_7(PR_3)_2$ can be protonated at low temperature to $[ReH_8(PR_3)_2]^+$, better formulated as the tautomer $[ReH_{8-x}(H_2)_x(PR_3)_2]^+$. These transformations are summarized in Scheme 8.

$$ReH_7(PR_3)_2 \xrightarrow{L} ReH_5(PR_3)_2L + H_2 \qquad (7)$$

$$ReH_7(PR_3)_2 \xrightarrow[NCMe]{HBF_4} [ReH(NCMe)_4(PR_3)_2]BF_4 + 3H_2 \qquad (8)$$

Cp and poly(pyrazolyl)borates also stabilize polyhydrides, for example, $ReCpH_4(PR_3)$ and $ReH_4\{\kappa^3\text{-}HB(OR)(3,5\text{-}Me_2pz)_2\}(PPh_3)$.[56] Nitrosyl hydrides, $ReH_x(NO)_yL_z$, are mentioned in Section 13.

Several polyhydrides dimerize producing dinuclear and a few higher nuclearity species like $[Re_2H_7(PR_3)_4L]^+$, $[Re_2H_6(PR_3)_5]$, and $[Re_2(\mu\text{-}H_4)H_4(PPh_3)_4]$ (**29**), the dimerization product of (**28**). The 'agno-hydrides' (**29**) and the



Scheme 8

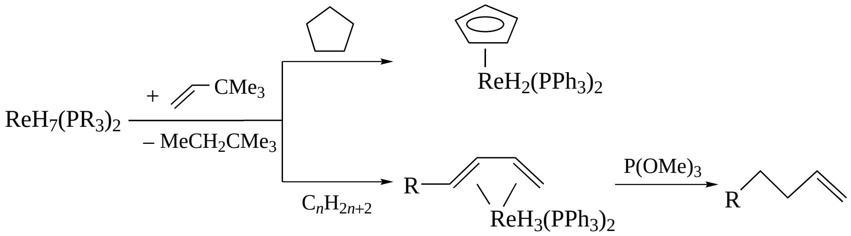
pentahydrides are not very reactive, unless activated by *Electrophiles* such as H^+, or Ph_3C^+. In this way, $ReH_5(PPh_3)_3$ produces a number of substituted $[ReH_x(PPh_3)_2L_y]^{n+}$ derivatives (L = RCN, RNC). Similarly, paramagnetic, for example, $[Re_2H_7]^+$, and diamagnetic H bridged cores are prepared from (**29**).

NMR spectroscopy and neutron diffraction studies established the tautomeric formulation of many polyhydrides as dihydrogen (η^2-H_2 or H_2) complexes or *Nonclassical hydrides*. Examples are inter alia $ReH_5(H_2)\{P(o\text{-}tol)_3\}_2$, $[ReH_2(H_2)(PPh_3)_3]$, and $ReCl(H_2)(PMe_2Ph)_4$.[57] (**28**), but not $ReH_7(AsPh_3)$, may be considered borderline since it has one H–H stretched interaction and has been represented as $ReH_5(H\cdots H)(PPh_3)_2$. Electronic and steric factors seem to influence the extension of the H–H interactions and the balance between both tautomeric formulations that can be found in equilibrium in some cases like $[ReH_4(CO)\{(PMe_2Ph)_3\}_3]^+$. The borderline H_2 complex $[Re(\eta^2\text{-}H_2)\{N(C_2H_4NC_6F_5)_3\}]$ undergoes H/D exchange via a less usual oxidative addition process.[58]

Similarly, reaction of (**28**) with 2-hydroxypyridine or similar pyridine derivatives (HA) leads straight to $ReH(A)_2(PPh_3)_2$. With bulkier anions, for example, 2-mercaptoquinoline (mq), the intermediate $ReH_4(mq)(PPh_3)_2$ can be isolated.

Alkenes and dienes react smoothly with $ReH_7(PR_3)_2$ and a number of $ReH_3(\eta^4\text{-diene})(PPh_3)_2$ and $ReH_3(\eta^2\text{-alkene})_2(PPh_3)_2$ *Alkene Complexes* have been characterized. In the case of C_5H_6, a fast equilibrium between $ReH_3(\eta^4\text{-}C_5H_6)(PPh_3)_2$ and $ReH_2(\eta^3\text{-}C_5H_7)(PPh_3)_2$ is established. Addition of excess L produces $ReH(PPh_3)_2L_3$ or $ReH(PMe_3)_5$ (**30**) and cyclopentene. In agreement with this facile H migration from metal to ring, $ReCpH_2(PPh_3)_2$ undergoes substitution by PMe_3, under photolysis, via $ReH_2(\eta^3\text{-}C_5H_7)(PPh_3)$ as an intermediate.[59]

In spite of their high formal oxidation states, the polyhydrides behave as low-oxidation species because of the low charge on the metal, which is close to the charge found in the free metal. From the organometallic point of view, the most remarkable consequence of this reactivity is found in the reactions of polyhydrides with alkanes leading to alkane dehydrogenation, Alkane Activation or C–H Bond



Scheme 9

Activation, with the formation of alkenes or dienes and H_2. For thermodynamic reasons, H_2 removal is effected by concomitant hydrogenation of t-butylethylene, as shown in Scheme 9, or by a flow gas.

$[ReH_5(triphos)]$ is active for cyclooctene dehydrogenation but $[ReH_5(PPh_3)_3]$ is not.

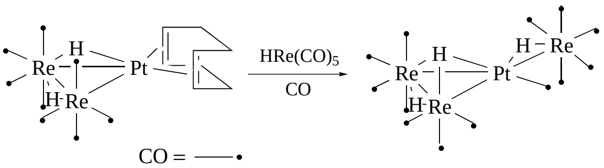
A remarkable property of the Re–H bonds in polyhydrides is their ability to establish a new kind of hydrogen bond, M–H$\cdots$HX (X = O, N, C), called protonic-hydridic or dihydrogen bonds. Initially found in intramolecular systems, they can also be formed intermolecularly as established by neutron diffraction of the adduct $ReH_5(PPh_3)_2\cdot C_8H_6$ NH$\cdot C_6H_6$ formed in the cocrystallization of the hydride with indole in benzene.[60,61]

These bonds seem to play a crucial role in catalytic reactions involving M–H and X–H bonds.[55]

Several Re polyhydrides form heterobimetallic complexes with other transition and main-group metal fragments. Bimetallic complexes with a (μ-H_3) bridging system are common, although those having (μ-H_4), like (**29**), are rare due to geometric reasons. A clear-cut example is the formation of $[(PPh_3)_2H_3Re(\mu\text{-}H_3)M(CO)_3]^-$ from $[ReH_6(PPh_3)_2]^-$ and $L_3M(CO)_3$ (M = Cr, Mo, W). In many cases, M–M′ bonds are formed as discussed in Section 14.2.

3.2 The Re Carbonyl Hydrides, Clusters, and Related Complexes

The complexes in this section encompass a rich variety of structural types, from the simplest mononuclear $ReH(CO)_5$ (**31**) and its substituted analogs to high nuclearity clusters, for example, $[Re_8C(CO)_{24}]^{2-}$. Complex (**31**) was first prepared in 1961 by acidification of $[Re(CO)_5]^-$ generated from $Re_2(CO)_{10}$ and Na/Hg, but it may be prepared by H_2 reaction with $Re_2(CO)_{10}$ or H^- substitution on $ReX(CO)_5$. Complex (**31**) is rather inert in high purity and in the absence of light, but the presence of light induces ligand substitution by a radical chain mechanism and, therefore, derivatives such as $ReH(PPh_3)_2L_3$ or (**30**) are best prepared by alternative routes.[62] CO_2, CS_2, and fluorinated alkenes and alkynes insert into the Re–H bond. In NCMe solution, (**31**) has a pK_a value of 21.1 (14.1 for $MnH(CO)_5$) but reacts with thiols and carboxylic acids to give thiolates and carboxylates (see Section 2.4.3). The more *Electron-Rich Compound* (**30**) also cleaves C–H bonds.[62] (**31**) has been found to behave as a 'ligand', for example, in the reaction depicted in equation (9). This mode of coordination enhances the acidity of its H atom that can be removed by py.[63]



(9)

Labile H_2 complexes $[Re(\eta^2\text{-}H_2)(PR_3)_2L_3]^+$ (L = CO, CN-t-Bu) formed upon protonation of $ReH(PR_3)_2L_3$ are stabilized by large noncoordinating anions $[BAr_4]^-$ in comparison to $[BF_4]^-$. Similar W complexes have been widely investigated (*see* ***Tungsten: Organometallic Chemistry***).[64]

Reaction of $[Re(CO)_n(PMe_3)_{5-n}H]$ with $BH_3\cdot THF$ gives the borohydride complexes $[Re(CO)_n(PMe_3)_{5-n}(\eta^2\text{-}BH_4)]$ (n = 1, 2).[65]

The first two preparative methods given above for (**31**) also produce tri- and tetranuclear clusters, a characteristic of all the reactions of (**1**) in protic basic media, including its own electrochemical reduction. Dinuclear species are depicted in Scheme 1, but under normal conditions more complex mixtures result from nucleophilic attack of BH_4^- and OH^- on (**1**), and these reactions are strongly dependent on reaction conditions. As an example of the complexity of the equilibria involved, the structurally characterized mononuclear dihydride $[ReH_2(CO)_4]^-$ protonates to $[Re_3H_3(CO)_{12}]$. The systematic exploration of these synthetic routes, together with hydrogenation of (**1**), led to the characterization of a large number of Re carbonyl hydride clusters $[Re_xH_y(CO)_z]^n$ (R = 3, 4; n = 0, 1, 2). This rich chemistry is summarized in Figure 2 and includes the geometry of the Re frameworks, the electron counts at Re, and specific examples. No parallel chemistry exists for Mn, as a result of weaker M–M bonds, but many similar compounds exist or might be expected for Tc. No CO *Bridging Ligands*, common in other metal clusters, are present due to the long Re–Re distance. In the clusters, the H atoms bridge the Re–Re bonds. Their absence in a given bond is reflected in a shorter Re–Re distance. The conjugate bases may be very basic. CO can be replaced by other ligands, for example, py, PPh_3, Hpz, and NCMe in several of the compounds in Figure 2.

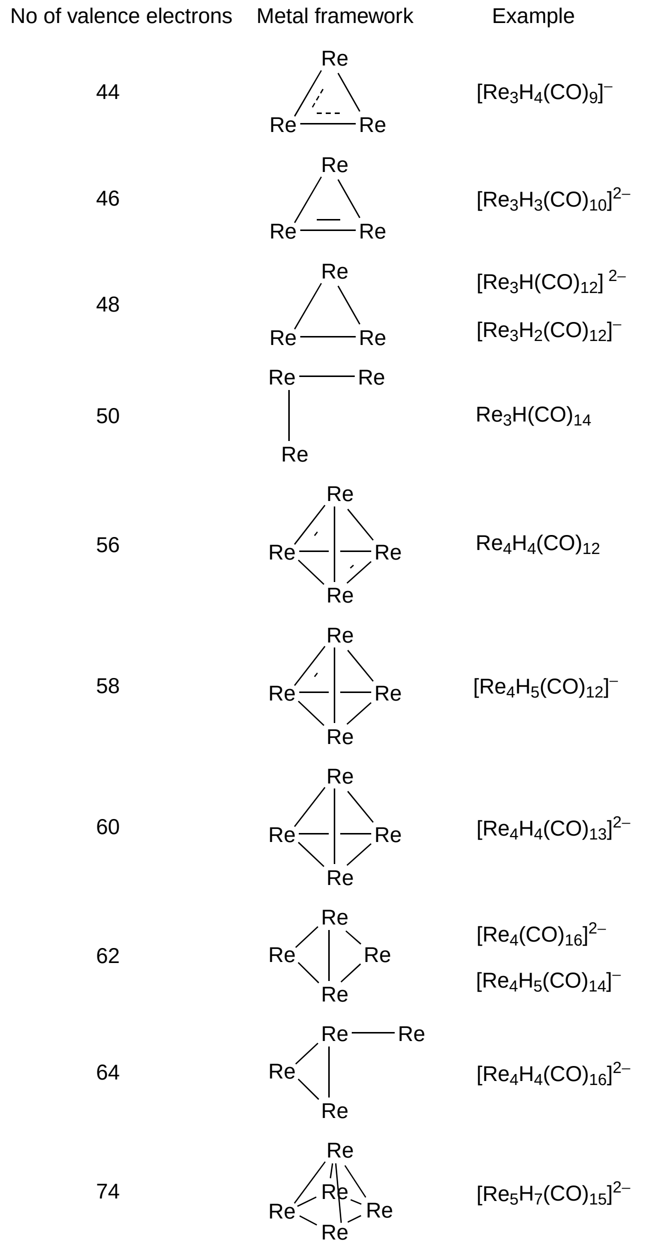


Figure 2 Schematic metal framework of rhenium carbonyl hydride clusters, electron counts, and selected examples

At the sites of Re unsaturation, ligands can be added. $Re_4H_4(CO)_{12}$ adds NCMe to give $Re_4H_4(CO)_{12}(NCMe)_4$, a 64 v.e. cluster. However, this is unstable and fragments to give $[Re_3H_4(CO)_9(NCMe)]^-$. Equation (10) describes the similar fragmentation with DMF leading to a super-unsaturated anion cluster with 44 v.e. (**32**) that readily adds CO, py, NCMe, Hpz, and PPh_3 to give $[Re_3H_4(CO)_9L]^-$.

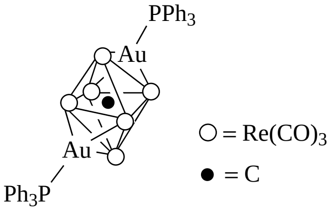
This fragmentation is also found with Cl^- and other weak donors. The cluster with L = Hpz presents an intramolecular dihydrogen bond between one N–H bond and a Re–H–Re bridge atom (see Section 3.1).[66]

$$Re_4H_4(CO)_{12} \xrightarrow{\text{DMF}} \underset{(\mathbf{32})}{[Re_3H_4(CO)_9]^-} + [Re(CO)_3(DMF)_3]^+ \quad (10)$$

The structure of the super-unsaturated cluster (**32**) is similar to that of $[Re_3H_4(\mu\text{-}H)_3(CO)_9(\mu_3\text{-}CH_3)]^-$ where the methyl group bridges simultaneously the three Re atoms.

D'Alfonso and coworkers have studied the chemistry of $[Re_2(\mu\text{-}H)_2(CO)_8]$ (**33**) exploring its 'ethylene-like' character. Indeed, $ReH(CO)_4$ is isolobal with singlet CH_2 making (**33**) an analogue to C_2H_4. Addition of nucleophiles X^- ($X = Re(CO)_5$, Cl) initially forms an L-shaped cluster (**34**) that initiates oligomerization of (**33**) to linear oligomers bearing XRe_n ($n = 4, 6, 8$) chains isolobal with the respective linear hydrocarbons (Scheme 10). Cyclic analogues of $(CH_2)_n$ have also been prepared with the general formula $[ReH(CO)_4]_n$ ($n = 3, 4, 5, 6$). The Re_5 member has an amplitude of ring puckering similar to that of cyclopentene itself and the Re_6 member presents a typical cyclohexene chair conformation in the solid state.[67]

Heteroatoms (transition metals, main-group elements, and carbon) can be incorporated into the clusters (*see Metal Carbonyl Clusters*). For instance, carbides may be introduced in the clusters on pyrolytic reduction of (**1**) with Na, with CO_2 production. High nuclearities become favored, for example, $[Re_5HC(CO)_{16}]^{2-}$. High-temperature reactions of (**1**) with other elements, for example, In or heating of its substituted derivatives, for example, $Re_2(CO)_8(PPh_3)_2$ provide a route to a wealth of clusters containing heteroatoms, as exemplified in Figure 3. $[Re_8C(CO)_{24}]^{2-}$ can be considered as a homobicapped derivative of $[Re_6C(CO)_{18}]^{4-}$ with two faces of the central Re_6 octahedron capped by $[Re(CO)_3]^+$. Similarly, $[Re_6C(CO)_{18}(Au(PPh_3)_2)]^{2-}$ (**35**) has two $[Au(PPh_3)]^+$ capping fragments. The C atom occupies the center of the octahedron coordinating six Re atoms.



(**35**)

Decapping one face of $[Re_8C(CO)_{24}]^{2-}$ originates $[Re_7C(CO)_{21}]^{3-}$. This anion is isolobal with Cp and originates a wide range of heterobicapped derivatives represented in (**36**).[68]

The Ir atom can exchange positions with one Re atom of the central octahedral core.

A comprehensive review provides information on syntheses, reactivity, and NMR and a list of all structurally

characterized $[Re_xH_yX_z(CO)_p]^{n-}$ clusters up to mid-1988 (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***).[52]

4 CHEMISTRY OF Re (η^1-HYDROCARBYL) COMPLEXES

4.1 Re Carbonyl Alkyls, Aryls, Acyls, and Related Complexes

The title complexes are generally prepared by reaction of $[Re(CO)_5]^-$ (**13**) with organic halides (Scheme 11), affording a variety of alkyl, vinyl, acyl, aryl, and perfluoroalkyl and perfluoroacyl complexes.

The very strong nucleophile (**13**) is able to replace Cl^- from chlorofluoro hydrocarbons or F^- directly from perfluoroalkenes and activated alkynes, and is only second to $[FeCp(CO)_2]^-$ in the reactivity order of aromatic nucleophilic substitution on homo- and heterofluoroaromatics.

The interesting dimers $(CO)_5ReC(O)C(O)Re(CO)_5$ and $(CO)_5ReC{\equiv}CRe(CO)_5$ have been prepared, the former from (**13**) and oxalyl chloride and the latter by reaction of $[Re(CO)_5FBF_3]$ with HC≡CTMS and a base. $(CO)_5ReC{\equiv}CRe(CO)_5$ behaves as a common substituted acetylene in its coordination to M^+ ions (M = Cu, Ag, Au).[69]

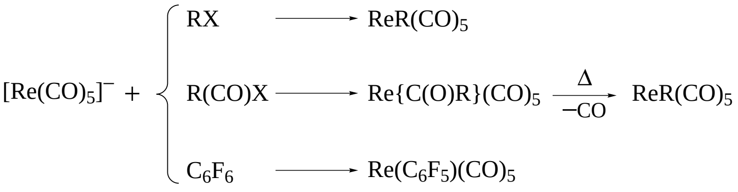
The reverse route, that is, addition of R^- to either the cations $[Re(CO)_nL_{5-n}]^+$ or to $ReX(CO)_nL_{5-n}$, is of very limited value due to preferential nucleophilic addition of LiR to coordinated CO. Although not a general reaction, the decarbonylation shown in Scheme 11 has been used to prepare several alkyl and aryl derivatives including the hydrocarbon-bridged $[Re(CO)_5(\mu\text{-}C_xH_y)Re(CO)_5]$ that can also be made by reaction of (**13**) with $X(C_xH_y)X$ (X = Cl, OTf).[70]

Insertion of alkynes and perfluoroalkenes into the Re–H bond of (**31**) allows the preparation of β-hydrogen-substituted vinyl and fluoroalkyl derivatives, $Re\{C(CF_3){=}CH(CF_3)\}(CO)_5$ and $Re(CF_2CHF_2)(CO)_5$.

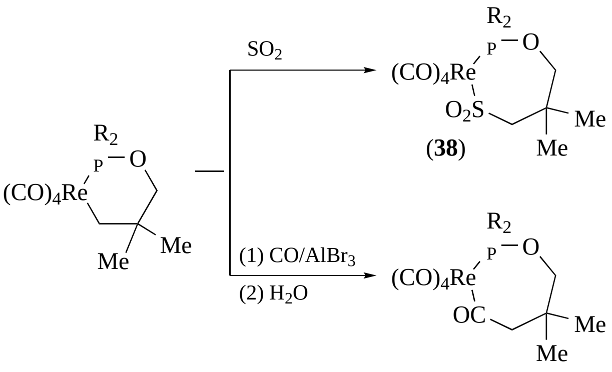
CO does not insert into $ReMe(CO)_5$ (**37**) before decomposition is observed (200 °C), whereas analogous formation of $Mn\{C(O)Me\}(CO)_5$ is facile at ca. 50 °C.[71]

The insertions in Scheme 12 combine two important driving forces for this reaction, namely the formation of a metallocycle and Lewis acid catalysis. Exceptional in this respect are the anions *cis*-$[Re\{C(O)R\}R(CO)_4]^-$ that readily form $[Re\{C(O)R\}\{C(O)R\}L(CO)_4]^-$ on addition of PR_3.[2]

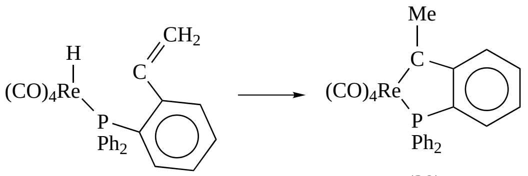
More electrophilic substrates, such as CO_2, CS_2, fluoroalkenes, and fluoroalkynes, insert into the Re–Me bond of (**37**) but not so easily as into Re–H bonds. Electrophilic SO_2 insertion is facile, and gives O-bonded sulfinates $[Re\{OS(O)R\}(CO)_5]$, which rearrange to more stable S-bonded $[Re\{S(O)_2R\}(CO)_5]$, as in (**38**). Protonation of $MR(CO)_5$ (M = Mn, Re) with HSO_3Rf and an electrophilic attack with $[Ph_3C][BF_4]$ give $M(OSO_2Rf)(CO)_5$ and $[Re(CO)_5FBF_3]$, both excellent precursors of $[M(CO)_5]^+$ derivatives.[21] Formyl derivatives are mentioned in Sections 2.1.4, 2.3, and 8.1.2.



Scheme 11

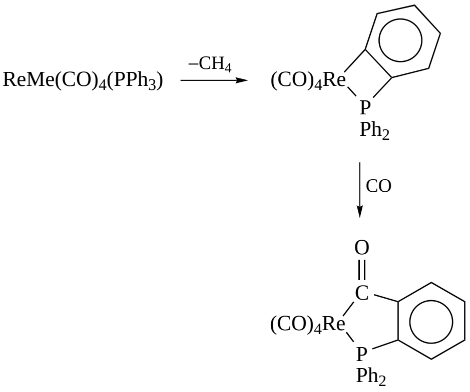


Scheme 12



(12)

(39)



(13)

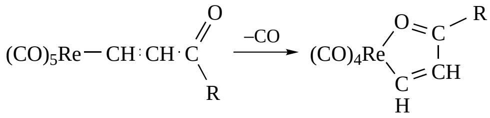
(40)

Not unexpectedly, cationic complexes like $[Re(CO)_4(dppe)]^+$ react readily with $NaBH_4$ to give the formyl $[Re\{C(O)H\}(CO)_3(dppe)]^+$ that decarbonylates in solution to $[ReH(CO)_3(dppe)]$.

The acyl derivatives $[Re\{C(O)R\}(CO)_5]$ undergo nucleophilic addition of LiR to the *cis*-CO ligands, producing metalla-β-diketones. These may be protonated, complexed to other metal fragments or ions, and functionalized to imines by *Schiff-Base* condensation with amines (Scheme 13). A second attack forms *fac*-$[Re\{C(O)Me\}_3(CO)_3]Li_2$. Many such analogs of classical β-diketonates have been used as ligands for ML_n fragments and applied in imaging and biomedical uses with radiolabeled Re (see Section 15).[72]

The selected examples in equations (11–13) represent ways of generating *Metallacycles*, although other less predictable routes have been observed.[2,3]

The stabilization of the metallacycle is the driving force for some of the cyclizations shown. Analogous intermolecular reactions do not take place in the absence of a ring-closure process, namely the substitution in equation (11), the insertions forming (**39**) and (**40**), and the *Orthometalation* in equation (13).[73]

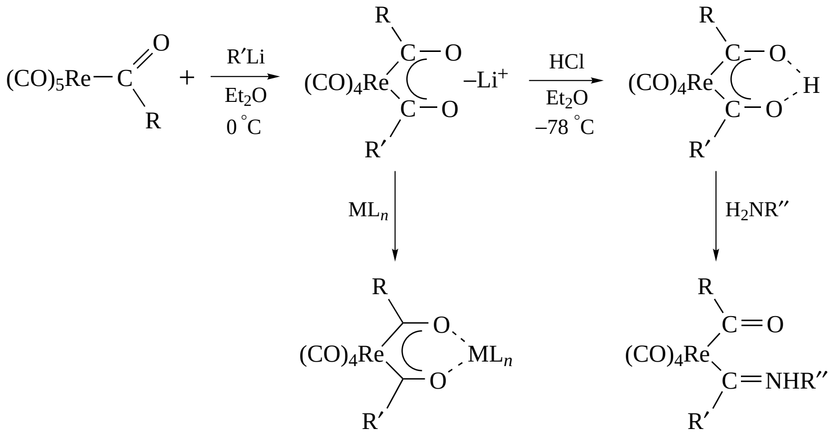


(11)

4.2 Homoleptic Re Alkyls and Aryls

Some early transition metals form homoleptic MMe_x complexes (*see Homoleptic Compound*), where x equals the highest oxidation state of the metal, for example, $TaMe_5$ and WMe_6. In the case of Re, probably as the result of a very unstable seven coordination, no corresponding d^0 Re alkyl has yet been observed. Instead, the deep-green, paramagnetic, explosive at rt, d^1 complex $ReMe_6$ (**41**), from alkylation of $Re(O)Me_4$ with $AlMe_3$ stands alone as a neutral homoleptic Re alkyl complex. It has a slightly distorted trigonal prismatic structure, which is intriguingly closer to D_{3h} symmetry than that of WMe_6. Complex (**41**) (or $ReOCl_4$) adds LiMe to give the square antiprismatic, paramagnetic dianion $[ReMe_8]^{2-}$ (**42**) with an almost perfect S_8 symmetry axis. (**42**) regenerates (**41**) on hydrolysis.[74]

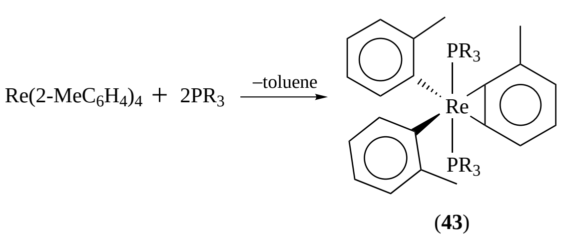
A pronounced tendency toward the formation of Re–Re bonds in the lower oxidation states affords a number of di- and trinuclear Re alkyls, many of which have a structure analogous to the corresponding halides. Treatment of Re_3Cl_9 with MeMgCl in the presence of phosphine gives $Re_3(\mu\text{-}Me)_3(Me)_6(PR_3)_2$ with three bridging Me groups in the Re_3Me_3 plane and six other out-of-plane Me ligands.



Scheme 13

Treatment of $ReCl_4(THF)_2$ with Grignard reagents gives volatile complexes $[Re_3R_{12}]$ (R = Me, CH_2TMS, $CH_2{}^tBu$) and in one case the dinitrogen complex $(ReR_4)_2N_2$ and a bridging-carbyne derivative, $Re_2(\mu\text{-}CTMS)_2(CH_2TMS)_4$. Indeed, alkyl ligands may undergo α-H abstraction to produce carbenes (alkylidenes) and carbynes (alkylidynes). In this respect, Schrock's complex $Re(\equiv CCMe_3)(=CHCMe_3)(CH_2CMe_3)_2$ is most remarkable since it contains simultaneously alkyl, alkylidene, and alkylidyne as sole ligands.[75]

Early attempts to prepare Re aryls using phosphine-stabilized Re halides, oxo halides, and nitrides yielded a number of adducts, of which $[ReAr_3(PR_3)_2]$ was shown to have a TBP coordination with apical PPh_3 ligands and almost coplanar equatorial phenyl rings. Improvements were only possible using bulkier aryls, a general strategy that has produced excellent results in the stabilization of reactive, coordinatively unsaturated species. This allowed the synthesis of the homoleptic d^3 Re aryl complex $Re(2\text{-}MeC_6H_4)_4$. It is monomeric with a slightly flattened tetrahedral structure similar to its Os^{IV} analog. The importance of the ring bulk is reflected in the fact that the above mentioned Re^{IV} alkyl, $[Re_3(CH_2TMS)_{12}]$, is trimeric even in the gaseous state. Upon reaction with basic small phosphines, for example, PMe_3, the air-stable benzyne complex (**43**) is formed (equation 14).[3]



(14)

(**43**)

Complex (**43**) and its corresponding cation $[Re(\eta^2\text{-}2\text{-}MeC_6H_3)(2\text{-}MeC_6H_4)_2(PMe_2R)_2]^+$ have similar structures indicating a benzyne coordination of the rhenacyclopropene type as depicted.

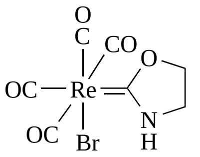
4.3 Re Alkyl and Aryl Halides and Related Complexes

Reaction of Re_3Cl_9 with RMgX forms complexes $Re_3Cl_3R_6$ (**44**) (R = Me, CH_2TMS, CH_2CMe_3, CH_2Ph) with a structure based on an equilateral Re_3 triangle and three in-plane bridging Cl atoms, as determined for R = CH_2TMS. Addition of CO, H_2O, and py to (**44**) affords $Re_3Cl_3(R_6)L_3$ (**45**), but PMe_3 induces reductive cleavage to give $Re_2Cl_2(R_2)(PMe_3)_4$ with a quadruple Re–Re bond.

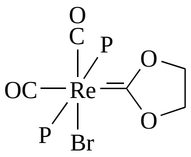
4.4 Re Carbene Complexes

The very important unsaturated carbene (CXR) or (CR_2) ligand appears in Re chemistry coordinated to different types of fragments. The classical examples, [M]{C(OR)R}, where [M] represents the fragments $Re_2(CO)_9$, $ReX(CO)_4$, and $ReCp(CO)_2$ (R = Me, Ar; R = H, Me, Et),[2] resulting from the two-step standard procedure to Fischer-type carbenes shown in Scheme 6. Fischer-type carbenes are electrophiles and are subject to nucleophilic attack, which seems to be frontier orbital rather than charge controlled (*see Frontier Orbitals*). This explains the preferential addition of nucleophiles to the LUMO located at the {C(OR)R} (or {C(X)Ph}) ligands, and not to the adjacent CO that bears the highest positive charge in the complex. In fact, other derivatives [M]{C(X)Ph} (X = NR_2, SR) may be obtained by reaction of alkoxycarbenes [M]{C(OR)R} with nucleophiles, for example, HNR_2 and HSR, with ROH elimination. Another method of preparing carbene complexes results from nucleophilic attack on carbynes $[L_nM(CR)]^+$. $ReCp(CO)_2\{C(X)Ph\}$ (X = CN, SCN, Me, H) and $[ReCp(CO)_2\{C(L)R\}]^+$ (L = PMe_3, CNMe) are prepared in this way (see also Section 4.5).

Another set of related carbenes are the five-membered cyclic aminooxy and dioxy derivatives (**46**) and (**47**) prepared from aziridines or epoxides and $ReX(CO)_5$ or $ReX(CO)_3(PPh_3)_2$.



(**46**)



(**47**)

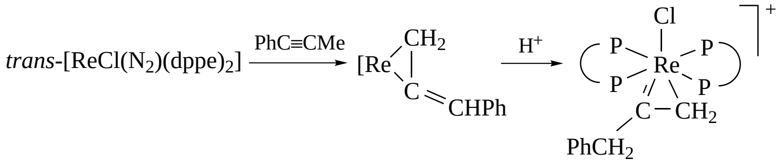
The reactions are catalyzed by X^-, and the mechanism, the results of substitution reactions, and several structures have been reported.[3] α-H abstraction from M–alkyl bonds with Ph_3C^+ generates the alkylidene or *Schrock-Type Carbene Complexes*, for example, $[ReCp(NO)(PPh_3)(CHR)]^+$. Even the simplest carbene, CH_2, is stabilized in $[ReCp^*(NO)(PPh_3)(CH_2)][BF_4]$ and air-stable $[ReCp_2(CH_2)][BPh_4]$ complexes, as discussed in Sections 8.1. Associated with the chemistry of high-oxidation states in the Re^{VII} imidoalkyls (Section 4.7), a number of alkylidenes have been prepared by intramolecular α-H abstraction reactions, for example $Re(NR)_2(CHR)(CH_2R)$ (R = t-Bu).[4] In a different approach, reaction of $[Re(O)(OR)_3(THF)_2]$ with 3,3-diphenylcyclopropene gives the oxo-vinylalkylidene $[Re(O)(=H–CH=CPh_2)(OR)_3(THF)]$ in high-yield (R = $O(CF_3)_2Me$).[76]

Vinylidene complexes [M](=C=CHR),[77] may form on rearrangement of coordinated terminal alkynes. [M] represents $ReCl(dppe)_2$, $[Re(CO)_3(PR_3)_3]^+$ $ReCp(CO)_2$, $[ReCp(NO)(PPh_3)]^+$, and $[Re\ (CO)_2(P_3)]^+$ (P_3 = tripodal P ligand; see Section 8.2). The first example of the parent vinylidene complex was reported as $[ReCp(CO)_2(=C=CH_2)]$.[78]

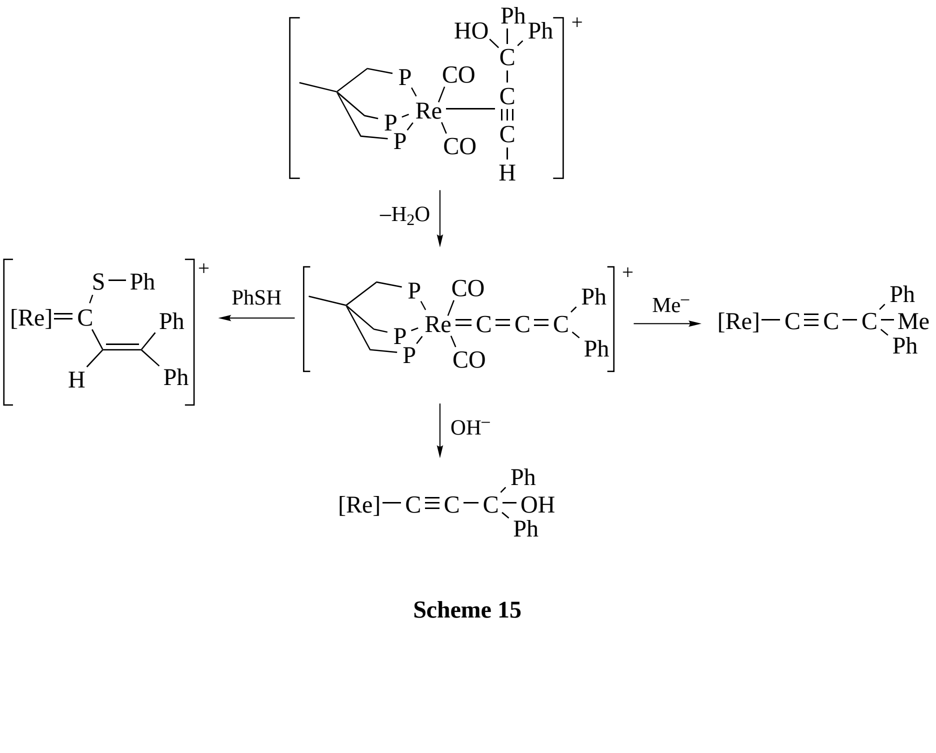
A range of vinylidene complexes $[ReX(=C=CHR)(dppe)_2]$ (X = F, Cl) has been prepared by deprotonation of the corresponding carbynes $[ReX(\equiv C\text{-}CH_2R)(dppe)_2]^+$. The mechanism of the protonation of these complexes has shown that, depending on the reaction conditions, protonation occurs either directly at the vinylidene β-carbon or at the metal, followed by migration to the referred β-carbon.[79]

The fragment $ReCl(dppe)_2$ also adds to PhC≡CMe to give the allene $[M](\eta^2\text{-}CH_2C{=}CHPh)$, which is protonated with HBF_4 to give the cationic metallacyclopropene, as shown in Scheme 14. Allenylidene $[Re(CO)_2(triphos)(=C=C=CRR')]^+$, hydroxyvinylidene, and hydroxycarbene complexes are formed from $[Re(CO)_2(triphos)]^+$ on reaction with propargyl alcohols. The allenylidene cation undergoes a nucleophilic addition of H^- and C, O, S nucleophiles at the γ-carbon according to Scheme 15. However, RSH and RNH_2 add across the Cα–Cβ bond.[80]

The chemistry of allenylidenes and related cummulylidenes with many other transition metals has been reviewed.[77]

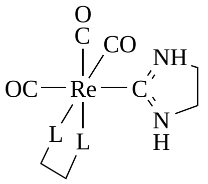


Scheme 14



Scheme 15

The aminocarbenes derived from reactions of coordinated isocyanides are treated in Section 14 and bridging alkylidenes arising from C–H activation by Re atoms are presented in Section 9. The recent boom of metal complexes derived from simple ligand substitution with the stabilized N-heterocyclic carbenes has produced only a very limited number of Re complexes like the luminescent (**48**).[81]

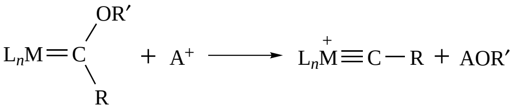


L-L = bipy, phen,

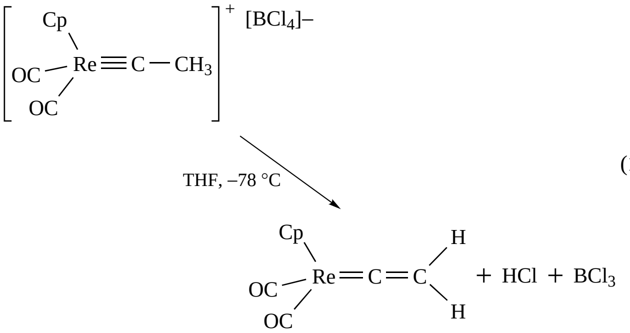
(**48**)

4.5 Re Carbyne Complexes

The oldest route to carbyne (CR) complexes involves a Lewis acid (A^+) attack on Fischer-type carbenes (equation 15). In this way, several Re carbyne derivatives under the general formula $[[Re](CR)]^{0,+}$ have been prepared. The leading examples are $[ReCp(CO)_2(CR)]^+$ (R = Ph, $SiPh_3$) because the analogous alkyl carbynes (alkylidynes) are much less stable due to facile deprotonation as elegantly shown by the spontaneous near-quantitative proton loss shown in equation (16).[78,82]



(15)



(16)

The molecular orbital analysis of the nucleophilic addition at the carbyne C atom infers the orbital control of the reaction since the C atom undergoing attack is the most negative one in the carbyne complex. [2 + 2] cycloadditions of $[ReCp(CO)_2(CPh)]^+$ with MeN=C(Ph)H, *t*-BuN=O, and ArN=NAr (Ar = aryl) but not with alkenes or alkynes, give the metallacycles. These reactions are driven by the nucleophilic attack of the lone pairs of the N atom at the electrophilic carbyne carbon atom.[83] These metallacycles are very stable and some may undergo nucleophilic attack of PMe_3 at the Cp ring as in Scheme 16.

Olefin oxides and sulfides also add to the carbyne carbon leading to ring opening and forming alkoxycarbenes and other products.[83]

The abstraction of 'O^{2-}' from the acyl group in $[Re(CO)_5(C(O)Ar)]$ with triflic anhydride leads to the carbyne $[Re(CO)_4(CAr)(OTf)][OTf]$ that opens the way to a number of other rare Re^V carbynes like $[Re(CO)_2(CAr)(OR)_2]$ (Ar = 2,4,6-$Me_3C_6H_2$).[84]

This same method was used to prepare a number of highly luminescent, similar Re^V carbynes with P and N donors.[85]

Protonation of the nucleophilic β-C of vinylidenes originated a one-pot synthesis of a range of carbyne complexes *trans*-$[ReF(dppe)_2(\equiv CCH_2R)]BF_4$ upon treating *trans*-$[ReCl(dppe)_2(N_2)]$ with HCCR, $[NH_4][BF_4]$, $[NH_4]Tl$, and light. $NH_4{}^+$ provides the protons necessary to the protonation of the vinylidene intermediates *trans*-$[ReCl(dppe)_2(=C=CHR)]$, whereas $BF_4{}^-$ provides the F^- ion that replaces Cl^-.[86]

Related aminocarbynes, $[ReX(\equiv CNRH)(dppe)_2]^+$, derived from CNR complexes are treated in Section 14.

Upon protonation of $ReH_4(mq)(PPh_3)_2$ with HPF_6, H^- is removed to form $[ReH_3(mq)(PPh_3)_2]+$ that reacts with alkynes forming hydrido-alkylidyne complexes in high-yield $[Re(\equiv CCH_2R)H_2(mq)(PPh_3)_2]^-$. The reaction involves fast and quantitative alkyne isomerization via η^2-allene intermediates.[87]

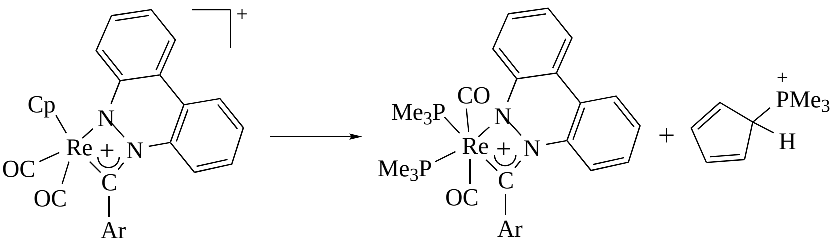
Re imidoalkyl chemistry in Section 4.7 ended up in several important carbynes, for example, $Re(CR)(CHR)L_2Cl_2$ (R = *t*-Bu; L = py) and $Re(CR)(CHR)(OR)_2$, the latter being active in alkene metathesis.[4] A remarkable preference for carbynes over carbenes is seen in complex $[Re(\equiv C\text{-}t\text{-}Bu)(=CH\text{-}t\text{-}Bu)(CH_2\text{-}t\text{-}Bu)_2]$ (**49**), which is preferred to its tautomer $Re(=CH\text{-}t\text{-}Bu)_3(CH_2\text{-}t\text{-}Bu)$ that would be an analogue to the utterly stable $[ReMeO_3]$.[75]

Protonation of (**49**) with HOTf yields $[Re(\equiv C\text{-}t\text{-}Bu)(CH_2\text{-}t\text{-}Bu)_3(OTf)]$. Addition of py leads to $[Re(\equiv C\text{-}t\text{-}Bu)(=CH\text{-}t\text{-}Bu)(CH_2\text{-}t\text{-}Bu)(OTf)(py)_2]$ (**50**) that reacts with $L_3 = Cp^-$, Tp^- or 1,4,7-trithiacyclononane to give $[Re(\equiv C\text{-}t\text{-}Bu)(=CH\text{-}t\text{-}Bu)(CH_2\text{-}t\text{-}Bu)L_3]^{0,+}$.[88]

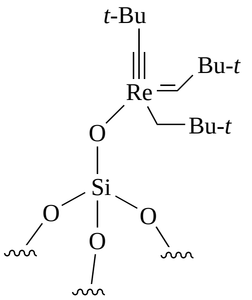
Grafting (**49**) on a silica surface led to a 'well defined', highly active, heterogeneous olefin metathesis catalyst (**51**) fully characterized by solid-state NMR spectroscopy.[89]

4.6 Re Alkyl and Aryl Oxide Complexes

Organotransition metal oxides or organo oxo complexes (*see Oxo Complex*) represent a fast expanding area for early transition metals of groups 4 to 7, due to their relationship with catalytic species formed on the surface of oxides under catalytic conditions. Furthermore, they may also supply a convenient set of volatile starting materials for application in *Metal–Organic Chemical Vapor Deposition* and related techniques of solid-state and surface chemistry. Most of



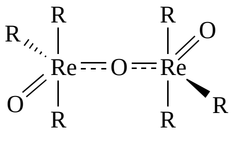
Scheme 16



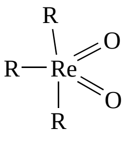
(**51**)

the fundamental work has been covered in comprehensive reviews.[4,90] Related examples are discussed in Sections 8.1.4 and 5.3.

Alkylation of $Re(O)Cl_4$ with MgRX proceeds through Re^V intermediates, $[R_4ReO]_2Mg(THF)_x$, that can be smoothly oxidized with H_2O_2 to give square-pyramidal, paramagnetic, d^1, $Re(O)R_4$ (R = Me, CH_2TMS). Simultaneously, the diamagnetic dimers (**52**) are formed in good yields. The trans conformation of the O=Re–O–Re=O unit with a linear Re–O–Re bond and partial multiple Re–O bond character is held responsible for the observed diamagnetism. They react with pyNO or Me_3NO to yield *cis*-$Re(O)_2R_3$ (**53**) quantitatively.



(**52**)

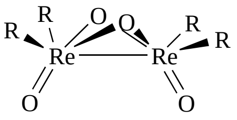


(**53**)

The dimer (**52**) splits upon addition of pyridine, establishing the equilibrium in equation (17). Addition of PPh_3 to the mixture consumes $ReO_2(CH_2TMS)_3$ but use of PMe_3 forms $OPMe_3$ and $ReO(PMe_3)(CH_2TMS)_3$ (**54**). Substituted alkynes readily replace PMe_3. However, acetylene inserts into the Re–P bond to give resonance stabilized ylides, $ReOR_3(CHCHPMe_3)$.[91] CO also inserts into a Re–C bond of (**54**) to give a rare example of a high-oxidation state acyl complex.[92]

$$Re_2O_3R_6 \underset{}{\overset{py}{\rightleftharpoons}} Re(O)R_3py + Re(O)_2R_3 \xrightarrow{PPh_3} 2Re(O)R_3py + OPPh_3 \quad (17)$$

The diamagnetic Re^{VI} dimers $Re_2O_4R_4$ (**55**) (R = Np, CH_2CMe_2Ph, CH_2TMS, Me, Et) result from the reduction of Re^{VII} species, for example $ReRO_3$, (see below). The structures may be described as dimers of the paramagnetic ReR_2O_2 fragment with a Re–Re bond. Reduction with the Li or Na amalgam gives the Re^V anions $[ReO_2Np_2]^-$, structurally characterized with several counterions, but reduction of $Re_2O_4Me_4$ with $CoCp_2$ gives a trimeric linear $Re(\mu\text{-}O)_2Re(\mu\text{-}O)_2Re$ framework.



(**55**)

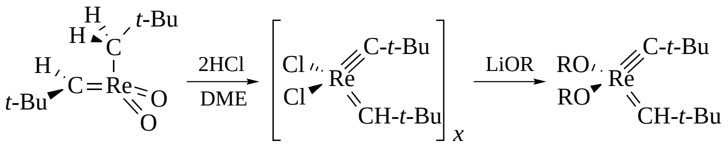
Oxidation of (**55**) with pyNO and with X_2 (X = Cl, Br) gives $[\{Re(O)_2R_2\}_2O]$ (**56**) or trigonal bipyramidal *cis*-$Re(O)_2Np_2X$ respectively. The latter may be alkylated to ReO_2Np_2R (R = Me, Np, CH_2TMS, Ph) (**57**),[93] or substituted to give *cis*-$Re(O)_2Np_2X$ (X = F, SR, OR).

The general reactions of the dioxo complexes (**53**) are oxygen abstraction by phosphines and photolytic conversion to the dimers (**55**), but in the case of (**57**; R = Np) the moderately air-stable carbene complex $Re(O)_2$(CH-*t*-Bu)Np (**58**) is formed.[93]

For (**57**; R = Ph) the same photolysis, in pyridine, gives $ReO_2(Np)(py)_3$ that reacts with acetylene to give $ReO_2Np(RC{\equiv}CR)$.[93]

In the same vein, the primary event on broad-band UV-visible photolysis of matrix-isolated $(CH_3)_4ReO$ and (**53**; R = Me) is elimination of CH_4 and formation of methylene derivatives $H_2C{=}ReO(CH_3)_2$ and $H_2C{=}Re(CH_3)O_2$, respectively.[94]

The carbynes obtained by the transformations of (**58**) described in Scheme 17 form adducts with a series of ligands,



(**58**) (**59**)

Scheme 17

and the tetrahedral alkoxides (**59**) are the first homogeneous Re carbene alkene metathesis catalysts. The carbyne seems to play a spectator role in the reaction.[4]

A number of Re aryl oxides exist in some of the same structural classes described for the Re alkyl oxides. Examples are the paramagnetic d^1 $ReOAr_4$ (Ar = mesityl, *o*-tolyl, *o*-methoxyphenyl), the anionic $[ReO(mes)_4]^-$ and $[ReO_2(mes)_2]^-$. Paramagnetic $ReO_2(Ar)_2$ (Ar = mesityl, xylyl) do not have alkyl counterparts because of their avoided dimerization, but Mo and Os analogues are known.

So far, the trioxides $ReRO_3$ are the most important class of hydrocarbyl oxides of Re. A range of hydrocarbyl complexes $ReRO_3$ (**60**) has been prepared by reaction of Re_2O_7 with ZnR_2 or $SnR(n\text{-Bu})_3$, including primary β-H-containing chains, for example, R = Et, Pr (no β-H elimination is observed (*see β-Elimination*)), aryls, cyclopropyl, vinyl, alkynyl, η^1-allyl, and η^1-indenyl. On the whole, the ReO_3 fragment can be considered as a general hydrocarbon substituent with an electronegativity close to that of $[PPh_3]^+$ or $[SMe_2]^+$. The chemistry of $ReR(O)_3$ complexes is very extensive and has been thoroughly reviewed.[90]

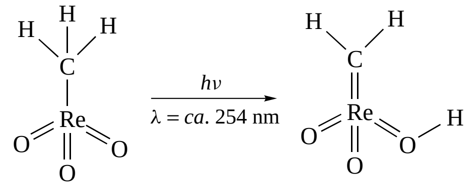
$ReMe(O)_3$ (**61**) is the most prominent member of this family. Initially prepared from Re_2O_7 and $SnMe_4$, (equation 18), it can be now obtained from cheaper ReO_4^- salts.[95]

$$Re_2O_7 + SnMe_4 \xrightarrow[\text{reflux}]{\text{THF}} ReMe(O)_3 + Re(O)_3OSnMe_3 \qquad (18)$$

The colorless, air-stable, volatile (**61**), usually abbreviated as MTO, has an outstanding thermal stability (dec > 300 °C) and is freely soluble in virtually any solvent from water to pentane. It is converted to ReO_4^- in basic aqueous solution.[96] In water at 70 °C, it forms an electrical conducting polymer of formula $[H_{0.5}\{Re(CH_3)_{0.92}O_3\}]\infty$. Photolysis homolyzes the Me–Re bond.[35] However, the primary reaction brought about by irradiation into the UV absorption near 260 nm in a solid Ar matrix involves tautomerization of MTO to the methylidene hydroxo derivative $H_2C{=}Re(O)_2OH$ (**62**).[97]

Chemical (thermal) trapping of this tautomer has been achieved by the combined reaction of py and $SnMe_2Cl_2$ to give $[\{(C_5H_5N\text{-}CH_2\text{-}Re(O)\text{-}O)\}_2SnMe_2Cl_2][ReO_4]_2$.[98]

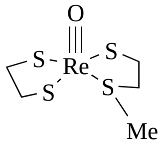
This kind of intramolecular abstraction of αH by an oxo group has also been reported when the complexes ReTpO(R)OTf (R = Me, Et, *n*-Bu) are rapidly oxidized at ambient temperatures by pyO or DMSO to give $ReTpO_3$ and the corresponding aldehyde, RHCO.[99]



(**61**) (**62**)

MTO readily forms adducts with one or two N-donor ligands having trigonal bipyramidal (O ligands equatorial) or fac-octahedral structures respectively.[100]

A series of Re^V oxo complexes of general formula $Re(O)MeX_2(bipy)$ (X = alkyl, aryl, Cl, Br, OR) have been prepared either from $ReMeO_3(bipy)$.[101] MTO condenses with diols forming the diolates $[ReO_2Me(O,O)py]$. Reactions with arylthiols produce $Re(O)Me(SAr)_4$. However, when 1,2-ethanedithiol is used, the complex (**63**) is obtained by rearrangement of the intermediate $ReMe(O)(S_2C_2H_4)_2$. This represents the only example of Me transfer from a metal to a thiol ligand other than that of methylcobalamine and Co^{II} complexes related to vitamin B12.[102]



(**63**)

The related reaction with $1,2\text{-}C_6H_4(SH)(CH_2SH)$ ($mtpH_2$) forms $\{ReMe(O)(mtp)\}_2$ and disulfide. The dimer is split by L donors to, for example, $ReMe(O)(mtp)(PR_3)$ (**64**). This monomer is a catalyst for the oxygen-atom transfer reactions mimetic of those catalyzed by the biological Mo and W oxygen transfererases containing MO_2 fragments (equation 19).

$$XO + Y \longrightarrow YO + X \qquad (19)$$

$$XO = pyO,\ t\text{-BuOOH},\ Me_2SO;\ Y = PPh_3$$

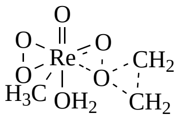
The postulated key intermediate $ReMe(O)_2(mtp)(XO)$ has been modeled from more stable 1,2-hydroxothiolate

analogues.[103] (**64**) also catalyzes R_2S and thiophene oxidation to sulfoxides and sulfones with t-BuOOH.[104]

Oxygen abstraction from MTO with PPh_3 or H_3PO_2 forms the elusive $ReMeO_2$ that can be trapped with several ligands to give the Re^V derivatives, for example, $ReMeO_2(PPh_3)_2 \cdot ReMeO_3$ and $ReMe(O)_2(\eta^2\text{-RC}{\equiv}\text{CR})$.[105] The latter are efficient catalysts for the olefination of aldehydes.[106]

MTO is an astonishingly versatile catalyst particularly in oxidation and oxygen-transfer reactions. This varied research initiated by Herrmann and extensively developed by Espenson has been comprehensively reviewed up to 1999 but keeps growing.[107]

The first breakthrough was the identification of its end reaction product with H_2O_2, $ReMe(O_2)_2O$ (**65**) which, in spite of being explosive, was structurally characterized by gas-phase electron diffraction and as a solid adduct with H_2O or HMPA by X-ray diffraction.[108] Isolated (**65**) is active in olefin epoxidation. Reaction of MTO with H_2O_2 (1 equivalent) produces a monoperoxo species $ReMe(O_2)O_2$, but it was never isolated and exists in equilibrium with MTO and (**65**). In MTO-catalyzed alkene epoxidation with H_2O_2, both peroxo species may be active depending on the reaction conditions and concentration of H_2O_2 used. However, (**65**) seems to be active in a larger number of other oxidation reactions. Alkene epoxidation ensues at $-30\,^{\circ}C$ and can reach high turnover values. Even C_{60} can be converted to its epoxide. Experiments and calculations suggest that the oxygen transfer occurs through transition state (**66**).



(**66**)

Epoxide opening and diol formation are suppressed by added Lewis bases, for example, py. Aromatic N-bases also lead to accelerated reactions with high selectivity allowing for oxidation of functionalized olefins in a now largely used protocol in organic synthesis. The complexes $ReMe(O)_3 \cdot L_2$ (L_2 = bidentate N-donor) are also highly selective epoxidation catalysts.[100]

However, chiral amines only lead to modest enantiomeric excesses because of rapid decomplexation equilibria in solution.[109]

The MTO/H_2O_2 system is a general oxidizing system as can be seen from the variety of reactions in Table 1.

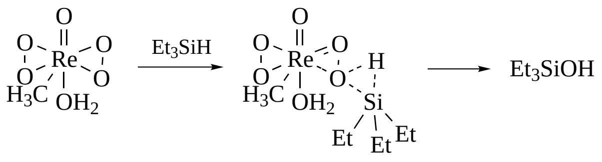
For catalytic purposes, MTO has also been supported on zeolites, niobia and polymers a useful means of preparing quinones in high yields (*see* ***Supported Organotransition Metal Compounds***).[110] Other useful variations use the urea-H_2O_2 adduct as an oxidant in water-free reactions or ionic liquids as solvents.[111]

Table 1 Oxidation products of the MTO/H_2O_2 system

Substrate	Product
Alkene, Dienes, 1,4-PBD, Allyl alcohols	Epoxide
5-Hydroxyalkenes	Tetrahydrofurans
RCH_2OH	Aldehyde or carboxylic acid[a]
R_2CHOH	Ketone
Furans	Enediones
2-hydroxymethylfurans	Pyranones
Silyl enol ethers	α-hydroxyketones
Internal alkynes	α-diketones and carboxylic acids
Terminal alkynes	α-ketoacids and carboxylic acids
Cyclic β-diketones	dicarboxylic acids
Ketene acetals	α-hydroxyesters
R_2S and thiophene	R_2SO or R_2SO_2[a]
RSSR	RS(O)SR and $RS(O)_2SR$[a]
Thioketones	$R_2C{=}S{=}O$
$XC_6H_4\ NH_2$ (X = H, Me, Cy, OMe, Cl)	XC_6H_4NO
p-$XC_6H_4NMe_2$	p-$XC_6H_4N(O)Me_2$
R_2NH	R_2HNO
RNH_2	RNO_2
$(RCH_2)_2NOH$	$RCH_2N(O){=}CHR$
$RHC{=}N\text{-}NMe_2$	RCN
$R_2C{=}N\text{-}NMe_2$	R_2CO
R_3E (E = P, As, Sb)	R_3EO
Ph_2CO	$Ph_2CH(OH)$
R_3SiH	$R_3SiOH + (R_3Si)_2O$
Naphthalenes, Phenanthrene, Anthracene	Corresponding quinones, for example Vitamin K
$(Me)_xC_6H_{6-x}$ (x = 2, 3, 4)	p-benzoquinones
p-$(RO)C_6H_4COH$	p-$(RO)C_6H_4OH$
Cl^-, Br^-	ClOH, BrOH
Cycloketones	Cyclolactones (Bayer-Villiger and Dakins)
$ReCp^*(CO)_3$	$ReCp^*O_3$

[a]Depending on specific reaction conditions or procedures.

Instead of O addition to the substrate, the reaction with silanes R_3SiH results in a clean and net insertion of O into a Si–H bond to give R_3SiOH via the computed transition state (**67**).[112]



(**65**) (**67**)

Besides oxidation reactions, MTO supported on Al_2O_3/SiO_2, niobia, or zeolites also catalyzes the metathesis of functionalized alkenes, 1,2 transposition of allylic alcohols, addition of epoxides to ketones, alkoxylation of epoxides, dehydration and amination of alcohols, and

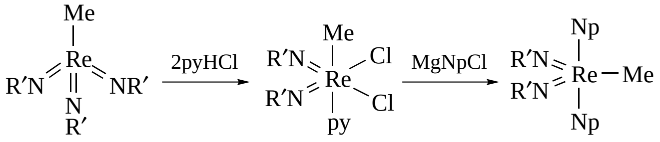
Diels–Alder additions in water.[113] It also catalyzes aldehyde olefination with $N_2C(CO_2Et)_2$ and PPh_3 as oxygen sink. Its catalyzed decomposition of $N_2C(CO_2Et)_2$ leads to carbene transfer reactions allowing for the formation of epoxides from aldehydes and ketones, aziridines from imines and cyclopropanation.

4.7 Re Alkyl and Aryl Imido Complexes

The isoelectronic oxo and imido ligands (NR) expectedly build isostructural types of complexes whose chemistry is largely parallel and has been jointly reviewed.[4,90] However, a significant advantage of the imido over the oxo ligand is the possibility it offers of tuning the reactivity of the metal center by adequate manipulation of the electronic and steric properties of the R substituent. Further stabilization is attained by the stronger π-donor character of these ligands, which renders the metal less electrophilic. Steric protection favors monomeric reactive species. These factors are abundantly expressed in the alkene metathesis catalysts derived from imido complexes of Mo and W (*see* ***Molybdenum: Organometallic Chemistry*** and ***Tungsten: Organometallic Chemistry***). Most of the organometallic Re imido complexes known are Re^{VII} species of the two main types: $ReR_3(NR)_2$ (**68**) and $ReR(NR)_3$ (**69**) and derive from the work of Schrock or Herrmann. The preparation of complexes (**68**) was first achieved by alkylation of $Re(N\text{-}t\text{-}Bu)_2Cl_3$ or its aryl congener $Re(NAr)_2(py)Cl_3$ with the appropriate MR_n reagent (MR_n = $AlMe_3$, $PhCH_2MgCl$, $Zn(CH_2TMS)_2$).

A TBP structure isostructural with (**53**) has been assigned to these complexes with the N-t-Bu groups on the equatorial plane. Mixed halo alkyl derivatives $Re(NR')_2Np_2Cl$ and $Re(NR')_2NpCl_2$ may be prepared with rigorous control of the stoichiometry of the alkylating agent, although a better preparation of some of these complexes is shown in Scheme 18.[4]

Alkylation of $Re(NR)_2Cl_3$ with $ZnNp_2$ gives directly $Re(NR)_2(CH\text{-}t\text{-}Bu)Np$ (**70**) (R = t-Bu, Ar) isostructural with (**58**). Controlled hydrolysis of $Re(NAr)_2(CH\text{-}t\text{-}Bu)Np$ (Ar = DIPP) gives an alternative preparation for (**58**), and a complex containing simultaneously M=O, M=N, and M=C double bonds, $Re(O)(NAr)(CH\text{-}t\text{-}Bu)Np$, is also isolated by this process.



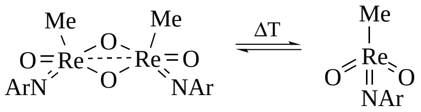
(**69**) (**71**)

Scheme 18

The other main type of d^0 imido alkyl complexes are the red–purple derivatives (**69**). A number of examples have been prepared with different alkyls (R = Me, Et, Np, 1-C_3H_5, C≡CPh; R′ = t-Bu, DIPP) and aryls (R = 2-MeC_6H_4, 2,6-$Me_2C_6H_3$, 2,4,6-$Me_3C_6H_2$), by alkylation of $Re(NR')_3(OTMS)$ with either LiR or MgRX. These alkylations occur smoothly, in contrast to the similar reactions with $Re(O)_3(OTMS)$ where the same reagents lead to reduction, thus reflecting the increased electronic density at the metal in the $Re(NR')_3R$ complexes. Alkylation of $[Re(NR')_3]^-$ also produces $Re(NR')_3R$ and protonation produces the hydride $Re(NR')_3H$ (**71**) that does not have an oxo counterpart. The hydride (**71**) adds π-acceptor ligands L, like acetylenes, to produce $Re(NR')_2(NR'H)L$.[114]

The alternative conversion of $ReRO_3$ into $Re(NR)_3R$ with R′NCO is limited to the methyl case due to the lesser stability of the other alkyl and aryl Re trioxides.[4]

As a result of the high electron density around the Re in $Re(NR')_3R$ complexes, the NR′ groups are extremely sensitive to hydrolysis and protonation. This type of reaction occurs with HCl, catechol, or pyHCl and opens a new route into $Re(NR')_2R_xX_{3-x}$ complexes and from these into the mixed alkyls $Re(NR')_2R_xR''_{3-x}$ as exemplified in Scheme 18.

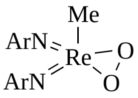


(**72**)

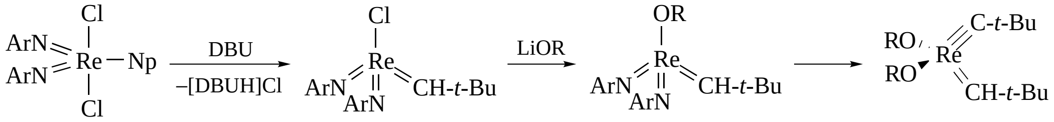
Mixed oxo–imido complexes $ReMeO_n(NR)_{3-n}$ exchange NR and O. $ReMeO_2(NAr)$ (**72**) is a dimer in the solid state and the monomer/dimer equilibrium in solution is temperature dependent.[115]

The complex $ReMe(NAd)_3$ exchanges NAd for O with aldehydes, not ketones, to form $ReMeO_3$ and RCH=NAd. It also exchanges NAd for NR′ with imines RCH=N′ (imine metathesis).[116]

$ReMe(NAr)_2O$ reacts rapidly with $P(OMe)_3$ to form $OP(OMe)_3$ and $ReMe(NAr)_2\{P(OMe)_3\}_2$ (**73**). More basic phosphines react very slowly but replace $P(OMe)_3$ in (**73**). Interestingly, (**73**) under O_2 rapidly forms $ReMe(NAr)_2O$ and $OP(OR)_3$. This catalytic reaction is proposed to take place via the peroxo complex (**74**) that unveils the activation of molecular O_2 by a $ReMe(NAr)_2$ fragment. A parallel activation of O_2 with MTO is, however, less efficient.[117]



(**74**)



(**75**)

Scheme 19

Reduction of $Re(NAr)_2Cl_3(py)$ or $Re(NAr)Cl_3(Py)_2$ in the presence of acetylenes leads to $Re(NAr)_2(\eta^2\text{-}C_2R_2)Cl$ or $Re(NAr)(\eta^2\text{-}C_2R_2)_2Cl$ respectively. These can be further reduced to the anions $[Re(NAr)_2(\eta^2\text{-}C_2R_2)]^-$ and $[Re(NAr)(\eta^2\text{-}C_2R_2)_2]^-$, which are stronger nucleophiles than $[Re(N(Ar)_3)]^-$. Therefore, they undergo easy protonation and alkylation with alkyl halides to produce $Re(NAr)_2((\eta^2\text{-}C_2R_2)R'$ (R′ = H, CH_2R') or $Re(NAr)(\eta^2\text{-}C_2R_2)_2R'$ (R′ = H, CH_2R') with similar properties to the analogue oxo complexes (Section 5.3).[114]

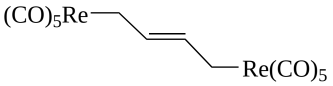
The complex $Re(NAr)_2NpCl_2$ (Ar = DIPP) undergoes dehydrohalogenation with the strong base DBU, and the resulting halide can be further transformed into the alkoxide derivatives (**75**) with LiOR, for example, (R = $CH(CF_3)_2$, $CMe(CF_3)_2$) (Scheme 19). Contrary to earlier expectations, neither (**75**) nor its analogs, $Re(NAr)_2(CH\text{-}t\text{-}Bu)X$ (X = Cl, OR) and (**58**), are active for alkene metathesis or even polymerization of the very reactive norbornene.

5 CHEMISTRY OF Re (η^2-HYDROCARBON) COMPLEXES

5.1 Complexes with Alkenes

In comparison with late transition metals of groups 8 to 10, Re does not have an extensive chemistry with alkenes. Most of the complexes involving the fragments $Re(CO)_4$, $[Re(CO)_5]^+$, $ReCp(CO)_2$, $[ReCp(NO)(PPh_3)]^+$, *trans*-$[ReX(dppe)_2]^+$, $[Re\{N(C_2H_4NC_6F_5)_3\}]$,[58] and $ReH_x(PPh_3)_2$ are now known. An example of the oxidative addition of alkenes to (**1**) under photolytic conditions is the formation of the labile dimers (**8**). Reaction of $Re(CO)_5FBF_3$ with alkenes gives a variety of cations $[Re(CO)_5(\eta^2\text{-alkene})]^+$ and dications $[\{Re(CO)_5\}_2(\mu\text{-diene})]^{2+}$ in the cases of nonconjugated dienes, for example COD, which bridge the two Re atoms.[21]

Alkenes undergo nucleophilic addition when coordinated to cationic fragments, for example, $[Re(CO)_5]^+$ or $[ReCp(NO)(PPh_3)]^+$, and electrophilic abstractions when coordinated to the more electron-rich $ReCp(CO)_2$ fragment. One example is the formation of (**76**) from $[Re(CO)_5(\eta^2\text{-}C_4H_6)]^+$ and $[Re(CO)_5]^-$, but many others are known including the synthesis of α-aminoacids with organometallic side chains.[118]



(**76**)

Section 8.1 contains examples pertaining to the $[ReCp(NO)(PPh_3)]^+$ fragment.

As already mentioned, $ReH_x(PR_3)_2$ (x = 5, 7) adds to and transforms alkenes and dienes. In this way, the complexes $ReH_3(\eta^2\text{-}C_2H_4)(PR_3)_3$ and $ReH_5(\eta^2\text{-}C_2H_4)(PR_3)_2$ are obtained from $ReH_7(PR_3)_2$ and C_2H_4 using $Pt(PR_3)_2$ as hydrogen abstractor. The allene *trans*-$[ReCl(\eta^2\text{-}H_2C{=}C{=}CHPh)(dppe)_2]$ is depicted in Scheme 14. Deprotonation of the allene ligand in $[ReCp(NO)(CO)(\eta^2\text{-}H_2C{=}C{=}CH_2)]^+$ leads to the neutral η^1-allenyl complex $[ReCp(NO)(CO)(\eta^1\text{-}HC{=}C{=}CH_2)]$.[119] Other alkene complexes of this metal fragment are treated in Section 8.1.2.

5.2 Complexes with η^2-aromatics

The coordination of aromatic molecules to certain strong metal π-bases leads to $(\eta^2\text{-aromatic})ML_n$ complexes (aromatic = arenes and aromatic heterocycles). This kind of η^2 coordination can activate the aromatic molecules toward an electrophilic attack since d → π back-donation into a π^*-orbital of the aromatic ligand disrupts its aromaticity. This dearomatization provides important synthetic pathways for the functionalization of aromatic compounds that are complementary to activation toward nucleophilic addition induced by their η^6-coordination to π-acid fragments (see Section 9). Induction of η^2-aromatic coordination by electron-rich metal fragments has its paramount example in $[Os(NH_3)_5]^{2+}$ (**77**), which provides the most stable η^2-aromatic complexes and the most useful functionalization reactions. However, this fragment suffers from several limitations that hamper its wider use, the most serious ones being its lack of chirality, the acidity of the ammonia ligands, and the reduced solubility due to its high positive charge. The development of Re^I surrogates to (**77**) attempted circumventing these handicaps.[120]

Indeed, Re^I complexes provide the best fragments for η^2-aromatic coordination after (**77**), although many are too labile to be of use (Figure 4).

The TpRe(CO)(L) fragment coordinates η^2-aromatics more strongly. While $\{TpRe(CO)_2\}$ binds naphthalene, furan, and N-methylpyrrole in a labile η^2 fashion,

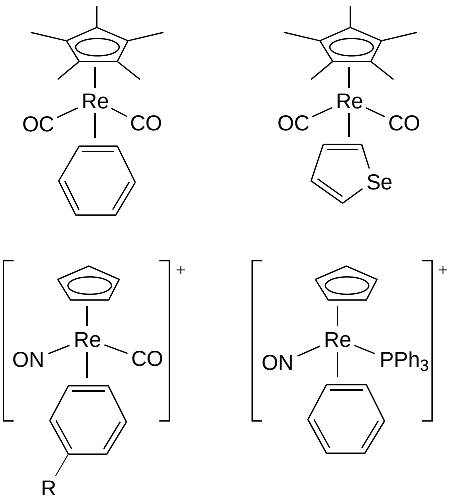


Figure 4 Some Re complexes with η^2-bonded aromatics

{TpRe(CO)(PMe_3)} produces a variety of stable η^2 complexes of the type TpRe(CO)(PMe_3)(η-L) (L = cyclohexene, cyclopentene, naphthalene, phenanthrene, thiophene, 2-methylthiophene, furan, or acetone).[121] They are obtained by reduction of the Re^{II} complex TpRe(CO)(PMe_3)(OTf) with Na/Hg in the presence of the unsaturated ligand.[122]

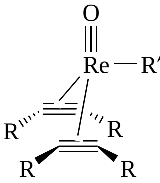
The {TpRe(CO)(PMe_3)} fragment is isoelectronic with $[CpRe(NO)(PPh_3)]^+$ and yet considerably more electron rich. This stronger π basic character is reflected in its capacity to bind naphthalene, diasterospecifically, in a η^2-coordination mode, to prefer η^2-thiophene over η^1-thiophene coordination and form stable π complexes with acetone rather than the more common σ-bonded species in, for example, $[CpRe(NO)(PPh_3)(acetone)]^+$.

The complex Re(Tp)(CO)(MeIm)(η^2-C_6H_6) is indeed able to effect dearomatization of the benzene ring allowing its uncoordinated 'diene' system to participate in Diels–Alder and other cycloadditions and, therefore, produce a synthetically useful protocol for benzene functionalization.[123]

5.3 Complexes with Alkynes

The chemistry of this class of complex parallels that of alkenes but, being more reactive and stronger donors, alkynes have a richer chemistry. The C–H addition of terminal alkynes to (**1**) forming bridging $Re_2(\mu\text{-H})(\mu\text{-C}{\equiv}CR)(CO)_8$ dimers and the formation of vinylidenes on electron-rich fragments have already been mentioned (see Section 4.4 and the cyclization shown in equation 4). Internal alkynes RC≡CR bind in typical η^2 fashion to $ReCp(CO)_2$, $[ReCp(NO)(PPh_3)]^+$, and $[Re(CO)_4]^+$ fragments. The reactivity of the $ReCp'(CO)_2(\eta^2$-alkynes) has been explored in great detail and depth by the group of Casey and has produced a variety of very delicate structural rearrangements supported by the $ReCp'(CO)_2$ fragment.[124] For the rearrangement of putative $ReCl(dppe)_2(\eta^2\text{-MeC}{\equiv}CPh)$ to η^2-allene and H^- abstraction from coordinated 2-butyne, see Sections 5.1 and 6, respectively. The insertion of fluoroalkynes into Re–H and Re–C bonds, and related insertions involving $ReCp_2H$, are found in Sections 4.1 and 8.1.

A remarkable family of oxo alkyne complexes has been developed from $Re(O)I(\eta^2\text{-RC}{\equiv}CR)_2$ (**78**) (R = Me, Et). These complexes have an unusual electronic structure where the alkyne ligands do not rotate. Reaction of (**78**) with ZnR'_2 gives air-stable $Re(O)R'(\eta^2\text{-RC}{\equiv}CR)_2$ (R′ = Me, Et, *i*-Pr, η^1-C_3H_5) complexes (**79**), which are reversibly protonated at the O atom to give $[Re(OH)R'(\eta^2\text{-RC}{\equiv}CR)_2]^+$ and even further to liberate H_2O.[125]



(**79**)

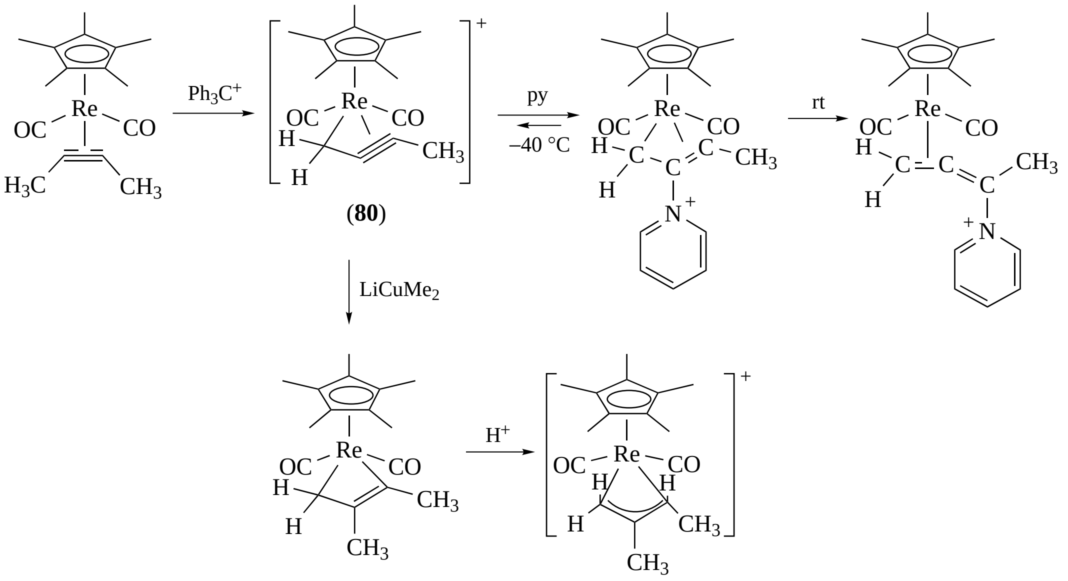
A rare oxo hydride, $Re(O)H(\eta^2\text{-RC}{\equiv}CR)_2$, and unsupported Re–Re bonded dimers $[Re(O)(\eta^2\text{-RC}{\equiv}CR)_2]_2$ reported in a series of papers by Mayer have been carefully compared in terms of structural and bonding properties.[126]

The oxo-hydride $Re(O)H(\eta^2\text{-RC}{\equiv}CR)_2$, is formed from $Re(OH)(\eta^2\text{-RC}{\equiv}CR)_3$, by intramolecular H migration from the hydroxo group to the metal followed by acetylene dissociation. Alkyl migrations from $Re(OR)(\eta^2\text{-RC}{\equiv}CR)_3$ to give (**79**) do not take place.[127] Analogous $ReX(\eta^2\text{-RC}{\equiv}CR)_3$ complexes have been made for X = Cl, OTf, NH_2, SH.

Related examples are the $ReMe(O)_2(\eta^2\text{-RC}{\equiv}CR)$ derivatives obtained from (**68**) where alkyne rotation is only observed at ca. 100 °C and isomers exist at room temperature. Other alkyne complexes of high-oxidation state halides are essentially limited to $ReCl_4(C_2Ph_2){\cdot}OPCl_3$,[128] and derivatives of the ReCp* fragment mentioned in Sections 8.1.4 and 8.1.5.

6 CHEMISTRY OF Re (η^3-HYDROCARBYL) COMPLEXES

Homoleptic mononuclear Re-allyl complexes are not known. The closest is the triply bonded dimer $Re_2(\eta^3\text{-}C_3H_5)_4$ (see Section 12). In the absence of an autonomous chemistry, the allyl ligand appears associated with other fragments. Several $Re(\eta^3\text{-}C_3H_4R)(CO)_4$ compounds are conveniently prepared from $ReBr(CO)_5$ and $SnMe_3$allyl or by reaction of $[Re(CO)_4]^-$ with $[Pd(\eta^3\text{-}C_3H_4R)Cl]_2$. Protonation releases propene and forms the strong electrophilic solvent-stabilized $[Re(CO)_4]^+$ fragment that adds a wide range of ligands.[129]



Scheme 20

$Re(\eta^3\text{-}C_3H_5)(CO)_4$ adds PPh_3, py, CNR, and NCR ligands to give $Re(\eta^3\text{-}C_3H_5)(CO)_3L$. Bidentate phosphines, bipy, and phen induce a $\eta^3 \rightarrow \eta^1$ shift forming $Re(\eta^1\text{-}C_3H_5)(CO)_3L_2$.[129]

The π-benzylic derivative $Re(\eta^3\text{-}CPh_3)(CO)_4$ is made from $[Re(CO)_5]^-$ and $[Ph_3C]^+$ and loses CO to give $Re(\eta^5\text{-}C_5H_5C{=}CPh_2)(CO)_3$. Addition of bulky PCy_3 leads to the radical $Re(CO)_3(PCy_3)_2$ but smaller phosphines lead to isolable $Re(\eta^1\text{-}C_5H_5C{=}CPh_2)(CO)_3L_2$.

Allylic complexes are intermediates in the reaction of $ReH_x(PR_3)_2$ and in the photolysis of (**1**) with dienes.[12] The photolysis of $ReH_7(PR_3)_2$ with propene gives $ReH(\eta^3\text{-}C_3H_5)_2(PPh_3)_2$, and the complex $[ReH_4(\eta^3\text{-}2\text{-}i\text{-}PrC_3H_4)(dppe)]$ is isolated from the reaction of $ReH_7(dppe)$ with 2,3-dimethylbutadiene.

In a general method of preparation of allylic complexes, reaction of $ReCp(CO)_2(THF)$ with dienes or allylic alcohol followed by protonation with HBF_4 produces allylic cations $[ReCp(\eta^3\text{-}C_3R_nH_{5-n})(CO)_2]^+$. H^- abstraction from $ReCp(CO)(\eta^2\text{-}C_3H_6)$ with $[Ph_3C]^+$ forms $[ReCp(CO)_2(\eta^3\text{-}C_3H_5)]^+$. Nucleophiles like H^-, $MeCO_2^-$, RS^-, MeO^-, Me_2HC^-, Ph^-, N_3^-, H_2N^-, and PMe_3 add at the terminal C atom of the allyl ligand in this cation, as predicted by the Davies–Green–Mingos Rules.[130] However, H^-, LiPh, and Grignard reagents react with $[ReCpCl(CO)(\eta^3\text{-}C_3H_5)]$ to give $[ReCpR(CO)(\eta^3\text{-}C_3H_5)]$. Reaction of the hydride derivative with electrophiles (HX, NO^+, $MeOC_6H_4N_2^+$) forms propene complexes, for example, $[ReCp(NO)(CO)(\eta^2\text{-}C_3H_6)]^+$ and $[ReCpHX(CO)(\eta^2\text{-}C_3H_6)]$.[131]

The recently reviewed chemistry of the η^3-allenyl and propargyl ligands has significant contributions from Re complexes.[132,133] η^3-propargyl derivatives of the $ReCp^*(CO)_2$ fragment (**80**) have been prepared either by H^- abstraction from alkyne complexes $ReCp^*(CO)_2(RC{\equiv}CR')$ or by protonation of the propargyl alcohol complexes $ReCp^*(CO)_2(RC{\equiv}CCHR'OH)$, (Scheme 20). Some fascinating structural rearrangements of these complexes have been examined in detail by Casey.[134]

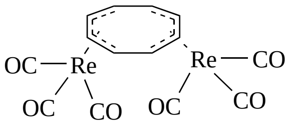
These η^3-propargyl rhenium complexes undergo kinetic addition of nucleophiles at the central C atom to produce rhenacyclobutenes. The nucleophiles range from PR_3 to malonate, acetylides, pyridines, and water. The derivatives of the addition of pyridines, however, are unstable and undergo further rearrangements to allene or acetylene complexes.[135] Protonation of the metallacyclobutenes produces η^3-allyl complexes.

Electrophilic addition to the alkyne ligand in $ReCp'(CO)_2(\eta^2\text{-}RC{\equiv}CR)$ complexes leads to 1-metallacyclopropene cations similar to (**80**). These undergo a number of structural rearrangements eventually ending up in $ReCp'(CO)_2(\eta^3\text{-allyl})$ complexes.[124]

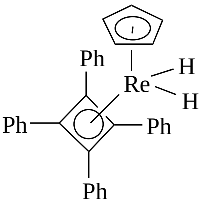
7 CHEMISTRY OF Re (η^4-HYDROCARBON) COMPLEXES

Like the alkenes, dienes have a very limited chemistry with Re. Photolytic reactions of (**1**) in the presence of dienes give complex mixtures of products, with η^3-allyl and bridging alkenyl structures, in a similar manner to the alkene dimers (**8**).[12] Reaction of $ReBr(CO)_3(THF)_2$ with the cyclooctateraene dianion $[C_8H_8]^{2-}$ produces a dimer $(CO)_3Re(\mu\text{-}C_8H_8)Re(CO)_3$ (**81**). Each Re atom is η^4 coordinated to 'one half' of the fluxional tetraene ligand.[136]

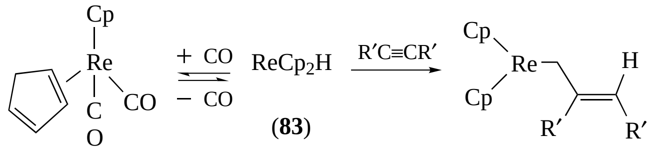
While the fragment $[Re(CO)_5]^+$ reacts with $MeC{\equiv}CMe$ to give the complex in equation (4), the fragment



(**81**)



(**82**)



Scheme 21

$[Re(CO)_4]^+$ adds two MeC≡CMe ligands that undergo further cyclization to the cyclobutadiene complex $[Re(\eta^4\text{-}C_4Me_4)(CO)_4]^+$.[137] When heated at 80 °C, the complex $ReCpBr_2\{\eta^2\text{-}(4e)PhC{\equiv}CPh\}$ (with a 4e donor alkyne ligand) rearranges to the cyclobutadiene derivative $ReCp(\eta^4\text{-}C_4Ph_4)Br_2$. This can be transformed into the dihydride $ReCp(\eta^4\text{-}C_4Ph_4)H_2$ (**82**) that adds CF_3CO_2H, opening the cyclobutadiene ring to give $ReCp(\eta^4\text{-}1,3\text{-}C_4Ph_4H_2)H(O_2CCF_3)$.[138]

Reaction of $ReH_7(PR_3)_2$ or $ReH_5(PR_3)_2$ with dienes gives the fluxional $ReH_3(\eta^4\text{-diene})(PR_3)_2$ (diene = COD, C_4H_6, C_5H_6, C_6H_8).[54] Hydride migration to the ring is reversible, and the complexes are in equilibrium with $ReH_2(\eta^3\text{-allyl})(PR_3)_2$ or $ReH_2(\eta^5\text{-dienyl})(PR_3)_2$ species. Such complexes are intermediates in the C–H activation process of alkane dehydrogenation.[73] Some related chemistry arising from Re atom chemistry in benzene/diene mixtures is presented in Section 9.

8 CHEMISTRY OF Re (η^5-HYDROCARBYL) COMPLEXES

8.1 Bis(η^5-cyclopentadienyl)Re Complexes

The parent compound in this family, the rhenocene hydride $ReCp_2H$ (**83**) is a milestone in organometallic chemistry, since it was the first isolated carbonyl-free hydride and the first hydride to be characterized by ^1H NMR in 1958. However, it has a more limited chemistry compared to the other groups 4, 5, and 6 bent metallocenes (*see Metallocene Complexes*).[2,4]

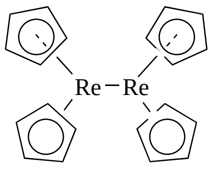
Complex (**83**) is as basic as an organic amine and reversibly protonates in aqueous medium to give $[ReCp_2H_2]^+$, one of the earliest examples of metal complex basicity. Accordingly, (**83**) readily forms adducts with inorganic Lewis acids giving polynuclear complexes (Section 14). Reaction with C_3H_5Br and CCl_4 give $[ReCp_2(\eta^2\text{-}C_3H_6)]Br$ and $ReCp_2Cl$ respectively. Oxidation with halogens gives the d^2 cations $[ReCp_2X_2]^+$ (X = Cl, Br, I), but SbF_5 yields the Re^{VII} species $[ReCp_2X_2][SbF_6]_3$. Reactions with CO and alkynes are represented in Scheme 21.

CO addition probably involves a ring slippage toward η^1-Cp, followed by intramolecular reductive elimination; its reverse was established in low-temperature matrix studies. The alkyne insertion is kinetically controlled and leads to stereospecific trans insertion, as shown. Use of HC≡CR further established regioselectivity for β insertion. Deprotonation of (**83**) with LiBu, with or without the help of a chelating N base, affords the anion $[ReCp_2]^-$ (**84**) from which $ReCp_2R$ (R = Me, Et, Pr, $\eta^1\text{-}C_3H_5$) is easily obtained. Further reaction with MeI gives $[ReCp_2Me_2]^+$, which yields the diene derivative $ReCpMe_2(\eta^4\text{-}C_5MeH_5)$ on reaction with LiMe, a typical nucleophilic addition to a coordinated diene in a cationic complex. The rhenocene cation $[ReCp_2]^+$ is easily stabilized as an adduct with NCMe, CN-*t*-Bu, or HC≡CPh. Photolysis of $[ReCp_2(NCMe)]^+$ in the presence of C_6H_6 or thiophene leads to C–H activation forming the cations $[ReCp_2H(R)]^+$ (R = Ph, 2-C_4H_3S) in much the same way as described for the isoelectronic fragment WCp_2 (*see* ***Tungsten: Organometallic Chemistry***).[139]

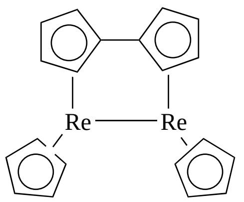
Hydride abstraction from $[ReCp_2Me]$ with $[Ph_3C][BArF]$ quantitatively produces the air-stable methylene complex $[ReCp_2(CH_2)][BArF]$. This is another example of the ability of MCp_2 fragments to stabilize highly reactive molecular fragments. However, in the present case the outstanding stability of the compound depends on the size of the anion being high for $[BArF]^-$ and $[BPh_4]^-$ and marginal for $[BF_4]^-$ and $[PF_6]^-$. A tight association between the cation and the $[BArF]^-$ anion is proposed to operate preventing a bimolecular coupling of two $[ReCp_2(CH_2)]^+$ species that generate $[ReCp_2(C_2H_4)]^+$ and a solvent-stabilized cation $[ReCp_2(S)]^+$.[140]

The electrophilic methylene ligand undergoes nucleophilic additions with PPh_3, py, and CN-*t*-Bu. It reacts with O and S donors to give $[ReCp_2(\eta^2\text{-}H_2CE)]^+$ (E = O, S) and with N_2CHTMS to form the olefin complex $[ReCp_2(\eta^2\text{-}H_2C{=}CHTMS)]^+$.

Mild oxidation of (**84**) gives the Re–Re bonded dimer of rhenocene (**85**), which further reacts upon warming to form other dimers, such as the fulvalene derivative (**86**).



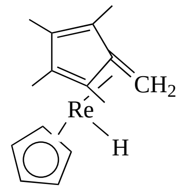
(**85**)



(**86**)

A similar chemistry is observed for MCp_2 (M = Mo, W), reflecting the instability of these metallocene complexes toward dimerization and C–H activation. Indeed, $ReCp_2$ can only be isolated in low-temperature CO and N_2 matrices by in situ UV irradiation of (**83**). Dimerization is prevented by use of Cp*, thus enabling the isolation and full structural and spectroscopic characterization of $ReCp^*_2$ formed upon UV irradiation of $ReCp^*_2H$ (**87**). The rings are parallel and eclipsed. The hydride (**87**) is prepared by MVS techniques from Cp*H and Re atoms in 10–15% yield.

The chemistry of (**87**) resembles that of (**83**), allowing isolation of the analogs $[ReCp^*_2H_2]^+$, $[ReCp^*_2]K$, $ReCp^*_2Cl$, and $ReCp^*_2Me$. C–H activation of the ring methyls, also common in other early transition metal MCp^*_2 metallocenes, arises upon irradiation of $ReCp^*_2Cl$ or oxidation of $ReCp^*_2$, for example, (**88**).[141]



(**88**)

8.1.1 *Chemistry of ReCp(CO)$_3$*

$ReCp(CO)_3$ (**89**), first prepared in 1968, and its analog $ReCp^*(CO)_3$ (**90**) represent, together with $Re_2(CO)_{10}$ and $Re(CO)_5X$, the most important entries into rhenium organometallic chemistry. Some ring-substituted congeners, for example, $C_5Me_nH_{5-n}$, indenyl, and fluorenyl, are also known, and the synthetic methods outlined in equations (20) and (21) are general and have good yields in most cases.[2]

$$ReBr(CO)_5 + NaCp \text{ or } SnCpRe_3 \xrightarrow{\Delta} ReCp(CO)_3 \quad (20)$$

$$Re_2(CO)_{10} + C_5Me_5H \xrightarrow{\Delta} ReCp^*(CO)_3 \quad (21)$$

The pentahapto coordination is attained from the first formed and isolable $Re(\eta^1\text{-}Cp)(CO)_5$. Added CO quantitatively reverses the reaction in the case of $Re(\eta^5\text{-}fluorenyl)(CO)_3$. Not unexpectedly, *fac*-$[Re(\eta^1\text{-}Cp)(CO)_3L_2]$ is obtained from $[ReXCO)_3L_2]$ and Cp^- (L_2 = bidentate phosphines). Surprising, however, is irradiation of $Re(\eta^1\text{-}Cp)(CO)_5$, which only produces radicals by cleavage of the C–Re σ bond.

A variety of alternative methods for preparing $ReCp'(CO)_3$ where Cp′ means a Cp ring substituted with bioactive molecules or with functions that enable binding of biomolecules, has been developed for biomedical applications (see Section 15).

Transformations of (**89**) may take place at the metal, the ring, or the coordinated carbonyls, engendering a variety of other monocyclopentadienylrhenium complexes, discussed in the following subsections.

Substitution Reactions. Thermal substitution is difficult to achieve both with (**89**) and the isoelectronic Mn analog. Thermal reaction of (**89**) with PMe_3 only yields $ReCp(CO)_2PMe_3$ under severe conditions. However, in refluxing hexane, the octahedral adduct *fac*-$Re(\eta^1\text{-}Cp)(CO)_3(PMe_3)_2$ is isolated. The intermediate $Re(\eta^3\text{-}Cp)(CO)_3PMe_3$ is unobserved but is kinetically required. Accordingly, the indenyl derivative $Re(\eta^5\text{-}Ind)(CO)_3$, which favors the $\eta^5 \rightarrow \eta^3$ ring slippage over the Cp, reacts much faster with PMe_3 but, again, only the final $Re(\eta^1\text{-}Ind)(CO)_3(L)_2$ is isolated. ReCp(CO)(NO)Me (see below) has a similar behavior.

Dissociatively photoinduced substitution is facile and extremely useful. Low-temperature photolysis in CO and N_2 matrices has identified the loss of one CO ligand as the primary step. Photolysis of (**89**) in hexane gives a good yield of the dimer $Re_2Cp_2(CO)_5$ with one bridging CO ligand by association of $ReCp(CO)_2$ with $ReCp(CO)_3$, whereas in benzene, structurally characterized $ReCp(CO)_2(\eta^2\text{-}C_6H_6)$ is first isolated but the reaction can be taken to completion producing $ReCp(\eta^6\text{-}C_6H_6)$. Photolysis of $ReCp^*(CO)_2(N_2)$ in 1,4-$C_6H_4F_2$ gives both the C–H activation product $ReCp^*(H)(C_6H_3F_2)(CO)_2$ and the coordinated arene $ReCp^*(CO)_2(\eta^2\text{-}C_6H_4F_2)$ in 5:9 ratio.[142]

The strong tendency of the $Cp'Re(CO)_2$ fragment to bind alkenes and η^2-arenes was mentioned in Section 5.2.

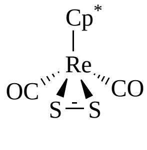
Ultrafast spectroscopy studies determined the oxidative addition of the Si–H bond to the unsaturated $ReCp(CO)_2$ fragment to be much faster (4.4 ps) than that of the C–H bond (230 ns).[143]

The photolytic generation of $ReCp^*(CO)_2$ in alkanes at low temperature forms the complexes $ReCp^*(CO)_2$(alkane). At rt the cyclopentane derivative, $ReCp^*(CO)_2(C_5H_{10})$, is the longest-lived alkane complex observed to date (t = 125 ms).[144] B–H bonds also coordinate unbroken as in $ReCp^*(CO)_2(\eta^2\text{-}HBpin)$.[145]

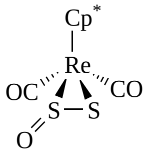
From a preparative point of view, the most useful substitution is achieved photochemically in THF ($\lambda <$ 300 nm) to give $ReCp(CO)_2(THF)$ (**91**) or $ReCp^*(CO)_2(THF)$ (**92**). Replacement of labile THF leads to a variety of substitution products of general formula $ReCp(CO)_2(L)$ with two-electron donors, for example, PR_3, $AsPh_3$, $P(OR)_3$, py, N_2, RC≡CR, SR_2, and is responsible for the wide scope of the chemistry of the fragment $ReCp(CO)_2$.[3]

The simplicity of this preparative method, coupled with the versatile coordination ability of the $ReCp(CO)_2$ and $ReCp^*(CO)_2$ fragments, provides a good model for the studies on coordinative activation of less usual ligands and molecules, many of which do not have an autonomous existence as free molecular entities. One example is the formation of $ReCp(CO)_2(CE)$ (E = S, Se), together with $EPPh_3$, on reaction of (**89**) with CE_2 and PPh_3. Reaction of (**89**) with elemental sulfur (S_8) gives a mixture of several structurally characterized

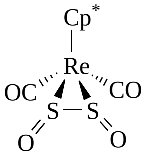
S-bridged dimers and the monomeric complex $ReCp(CO)_2(S_2)$ (**93**). Stepwise oxidation of (**95**) with MCPBA produces many unusual complexes, for example, $ReCp^*(CO)_2(SSO)$ (**94**) and $ReCp^*(CO)_2(OSSO)$ (**95**).[3]



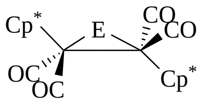
(**93**)



(**94**)



(**95**)



(**96**)

The series $[ReCp^*(CO)_2]_2(\mu\text{-E})$ (**96**) (E = O, S, Se, Te) and related complexes have also been prepared from the elements or from EH_2 and (**92**). Slow decomposition of solid (**92**) in a glovebox produces the dimer $Cp^*Re(CO)_2{=}Re(CO)_2Cp^*$ (see Section 11). Reaction of (**91**) with PhC≡CH gives the vinylidene $ReCp(CO)_2({=}C{=}CHPh)$, but the structure of the coordinated PhC≡CPh in $ReCp(CO)_2(\eta^2\text{-PhC≡CPh})$, in spite of being bent, has an almost unperturbed C≡C bond with a rather short length. In contrast, the azobenzene derivative $ReCp(CO)_2(\eta^2\text{-PhN=NPh})$ has an almost pure single N–N bond and is best described as a metallacyclic structure. The extensive research on the coordination of unsaturated N–N bonds to the fragment $[Re] = ReCp(CO)_2$ as related to N_2 reduction involving species sketched in Scheme 22 has been reviewed.[25]

The electron-rich $ReCp^*(PMe_3)_2(N_2)$ is protonated at the metal and not at N_2 in spite of its low ν (NN) vibration frequency. The aryldiazenido cations $[ReCp^*(CO)_2(N_2Ar)]^+$ undergo nucleophilic addition of R^- and H^- to give analogs of ligated N_2H, N_2H_2, and N_2H_3. Their somewhat unpredictable reaction with nucleophiles, for example, halides, CN^-, SCN^-, PPh_3, and $NaBH_4$, to yield the dinitrogen complex $ReCp'(CO)_2(N_2)$ actually proceeds by one-electron reduction ensuing a radical process.[146]

Electrophilic Attack and Oxidative Additions. Complex (**89**) cannot be protonated, but rapid H/D exchange of the ring protons is observed in CF_3CO_2D. The more electron-rich complex $ReCp(CO)_2PPh_3$, however, reacts in both ways giving faster H/D exchange and protonating at the metal to yield the isomers *cis*- and *trans*-$[ReHCp(CO)_2PPh_3]^+$, where the equilibrium favors the latter. Adducts with other Lewis acids, for example, $SnCl_4$ are known.[2]

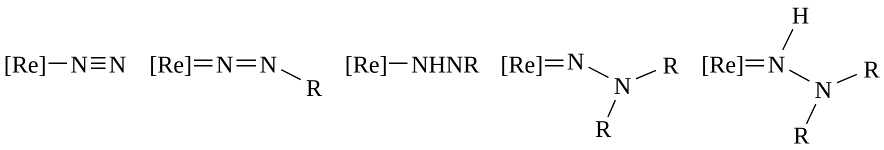
Two other electrophiles give important reactions with (**89**) and (**90**) in terms of the vast chemistry of the resulting products: NO^+ and X_2. The former gives electrophilic substitution, yielding the cation $[ReCp(CO)_2(NO)]^+$ (**97**), while the latter gives $ReCpX_2(CO)_2$ (**98**; X = Br, I) with a four-legged piano stool structure. The diagonal (trans) and lateral (cis) isomers can be separated chromatographically. In boiling toluene solution, *lat*-(**98**) isomerizes to *diag*-(**98**) (X = Br). Heating in the solid state reverts *diag*-(**98**) back to *lat*-(**98**). This first example of a reversible phase-dependent isomerization reaction of one organometallic complex was further studied for other $ReCp(CO)LX_2$ (L = CO, $P(OMe)_3$) complexes adsorbed on a silica gel surface under visible light irradiation and found to be dependent on the nature of both X and L and the interaction with the surface hydroxyl groups.[147]

Internal alkynes displace both CO ligands to give $ReCpBr_2(\eta^2\text{-(4e)RC≡ CR})$.

The complexes $[ReCp^*(CO)_2X(NCMe)][BF_4]$, prepared from the parent dihalides and $AgBF_4$, react with $Et_3N{\cdot}3HF$ to produce the fulvene complex $[Re(\eta^6\text{-}C_5Me_5CH_2)X(CO)_2]$ (see Section 9).[148]

$ReCp(CO)_2(H)(MR_3)$ and $ReCp(CO)_2H_2$ are the products of photoinduced oxidative addition of (**89**) to H–MR_3 bonds (M = Si, Ge, Sn) (see Section 8.1.5). Photochemical activation of (**89**) or (**90**) in the presence of B_2pin_2 gave *cis* and *trans*-$ReCp'(CO)_2(Bpin)_2$, that is, oxidative addition to the B–B bond. Most remarkable, however, is the fact that further irradiation of this compound or of a mixture of (**90**) and B_2pin_2 in pentane led to regiospecific terminal C–H activation of the pentane with formation of $C_5H_{11}Bpin$ and HBpin. The mechanism of this elegant C–H activation process does not seem to take place via C–H activation on intermediate $ReCp'(CO)_2$.[149]

Photolysis of $ReCp^*(CO)_3$ in C_6F_6 does not lead to the $\eta^2\text{-}C_6F_6$ complex. Instead, both C–H and C–F activation take place leading inter alia to the fulvene complex $Re(\eta^6\text{-}C_6Me_5CH_2)(CO)_2(C_6F_5)$ and HF elimination (see Section 9).[150]



Scheme 22

The intramolecularly chelated Re($C_5H_4CH_2CH_2NHMe$)($CO)_2$, being more electron rich than (**89**) undergoes facile oxidative additions of a variety of RX halocarbons to give [Re($C_5H_4CH_2CH_2NHMe$)R$(CO)_2$]X. They show a rich chemistry including CO insertion into Re–N bonds and CO activation.[151]

ReCp$(PMe_3)_3$ is only accessible on reduction of *mer*-[$ReCl_3(PMe_3)_3$] with Na/Hg in the presence of C_5H_6. Photolysis expels one PMe_3 ligand and the orthometalation product [ReCpH(2-CH_2PMe_2)(PMe_3)] is formed. This extremely reactive species oxidatively adds to a series of hydrocarbons RH, including CH_4, to generate ReCp(H)(R)$(PMe_3)_2$. The reactivity order observed for the C–H activation is Ar > cyclopropyl ∼ vinyl > Me > primary alkyl > secondary alkyl. This type of C–H activation is also found in low-valent MCp (M = Rh, Ir) complexes.

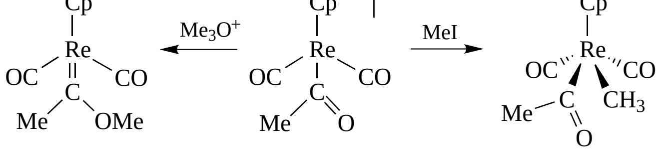
Reactions with Bases. Reaction of (**89**) with lithium alkyls may deprotonate the Cp ring, generating metallates Re(η^5-C_5H_4Li)$(CO)_3$. Reaction of these species with electrophiles such as XY (X_2, XC(O)R, $SiXR_3$, $(H_2CO)_n$) forms ring-substituted derivatives, for example, Re(η^5-C_5H_4Y)$(CO)_3$ with pendant organic functions that are useful for biomedical applications, for example, Re(η^5-$C_5H_4CH_2OH$)$(CO)_3$.[152]

Disubstituted derivatives, Re(η^5-$C_5H_3Y_2$)$(CO)_3$ can also be obtained by this method.

Nucleophilic Addition at the CO. The formation of the metal acyl [ReCp$(CO)_2${C(O)Me}]$^-$ (**99**) is a classic example of acylmetallate formation. The site of electrophilic alkylation of (**99**) is dependent on the hardness of the electrophile used. In fact, its reaction with the oxonium $[Me_3O]^+$gives the expected Fischer carbene [ReCp$(CO)_2${C(OMe)Me}], but the softer electrophile MeI attacks the Re, forming [ReCpMe$(CO)_2${C(O)Me}] (**100**) (Scheme 23).

Oxidative Decarbonylation. First observed by adventitious air oxidation of (**92**), ReCp*O_3 (**101**) was later synthesized from (**90**) with H_2O_2 (30%) in a two-phase water/benzene system with 80–85% yields.[90]

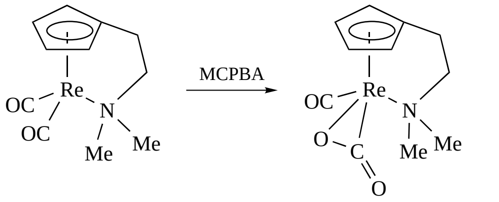
The detailed mechanism of this reaction is not known, but intermediates like (**96**) (E = O) and the dinuclear complex (**102**) have been characterized. This reaction is not general



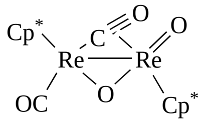
(**99**) (**100**)

Scheme 23

and cannot be used for the preparation of ReCpO_3 from (**89**). In this context, is it worth mentioning the unusual result of the oxidation reaction in equation (22).[153] The chemistry of (**101**) is presented in Section 8.1.4.



(22)



(**102**)

8.1.2 Chemistry of [ReCp(CO)$_2$NO]$^+$, [ReCp(NO)(PPh$_3$)]$^+$, and Derivatives

The cation, [ReCp$(CO)_2$NO]$^+$ (**103**), with excess I$^-$ undergoes ring slippage with Cp loss to [Re(NO)-$(CO)_2I_3$]$^-$. Hydrides, however, add to the CO, producing inter alia, the formyls ReCp(NO)(CO){C(O)H} (**104**) and [ReCp(NO){C(O)H}$_2$]. Double H$^-$ attack at the same CO ligand, that is, at the formyl in (**104**), gives ReCp(NO)(CO)CH_2OH, the first identified hydroxymethyl complex. This ligand represents an intermediate step in the reduction of coordinated CO to methyl. Reaction of (**104**) with BH_3 completes reduction to give ReCp(NO)(CO)Me. Hydroxide addition to [ReCp*$(CO)_2$NO]$^+$ gives [ReCp*(NO)(CO){C(O)OH}], which originated a range of binuclear complexes [ReCp*(NO)(CO)(μ-CO_2) ML_n] with a CO_2 bridge between the metals.[154]

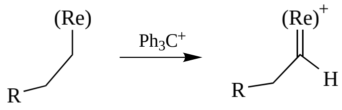
Equation (23) describes a parallel behavior for [ReCp(NO)-(CO)(PPh_3)]$^+$, where the stable formyl [ReCp(NO)(PPh_3)(CHO)] has a rather short Re–C bond.

$$[\mathrm{ReCp(NO)(CO)(PPh_3)}]^+ \xrightarrow{\mathrm{H^-}} [\mathrm{ReCp(NO)(PPh_3)\{C(O)H\}}] \quad (23)$$

Complex (**105**) is a pivotal compound in the development of a vast amount of chemistry of the fragment [ReCp(NO)(PPh_3)]$^+$, hereafter abbreviated as (Re)$^+$ for simplicity, which was recently reviewed.[155] Scheme 24 summarizes the fundamental set of reactions used to generate derivatives of this fragment.

The methylidene complex [ReCp*(NO)(PPh_3)CH_2]$^+$ is stable above 100 °C. Not surprisingly, (**106**) is less stable and decomposes to [(Re)(η^2-C_2H_4)]$^+$ and [(Re)(solvent)]$^+$ via a rate-determining dimerization process. It can, however, be trapped by a variety of nucleophiles to give both

neutral and cationic derivatives (**107**). The alkyl complexes (Re)−CH_2CH_2R, obtained from (**106**) and $LiCH_2R$, generate new alkylidene species via predominant, but uncommon, H^- abstraction at C_α (equation 24). The C_β disubstituted (Re)-CH_2CHR_2 analogs undergo the normal β-H^- abstraction to give cationic alkene complexes $[(Re)(\eta^2\text{-}C_2R_2H_2)]^+$.

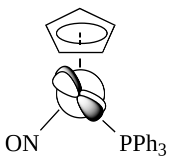


(24)

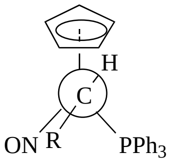
Evidence points to initial electron transfer between (Re)-CH_2R and Ph_3C^+ followed by H transfer to Ph_3C. For further chemistry of these alkylidene complexes, see Section 8.1.3.

The facile low-temperature protonation of (**105**) in chlorinated solvents provides an easy entry into the chemistry of the complexes $[(Re)\text{−}L]^+$ (**110**) *via* (**108**) and the alkyl halide intermediates (**109**) or its ClC_6H_5 analogue. Other alkyl halides, including $I(CH_2)M(CO)_5$ (M = Mn, Re), form similar adducts that undergo stereochemically controlled C–X bond cleavage in highly accelerated S_N2 reactions with inversion at C.[156]

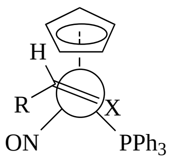
The complexes (**110**) span a wide variety of donors L making the fragment $(Re)^+$ highly suited to study activation of coordinated ligands. More importantly, the 16-electron, pyramidal, Lewis acidic and π-basic $(Re)^+$ fragment has a remarkable stereochemical rigidity. The optically pure parent complex (**105**) can be easily prepared and all the transformations in Scheme 24 proceed with enantiomeric excesses >98%. Therefore, the $(Re)^+$ fragment behaves as a stereogenic center templating stereoselective binding and reactions of its coordinated ligands. The preferred geometry of the (Re)L complexes is dictated by the interaction of ligand p or π orbitals with the high-lying HOMO (**111**) of the fragment and by minimization of the steric interferences of the R substituents with Cp and PPh_3 as depicted in (**112**) to (**115**).



(**111**)

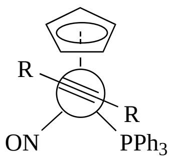


(**112**)



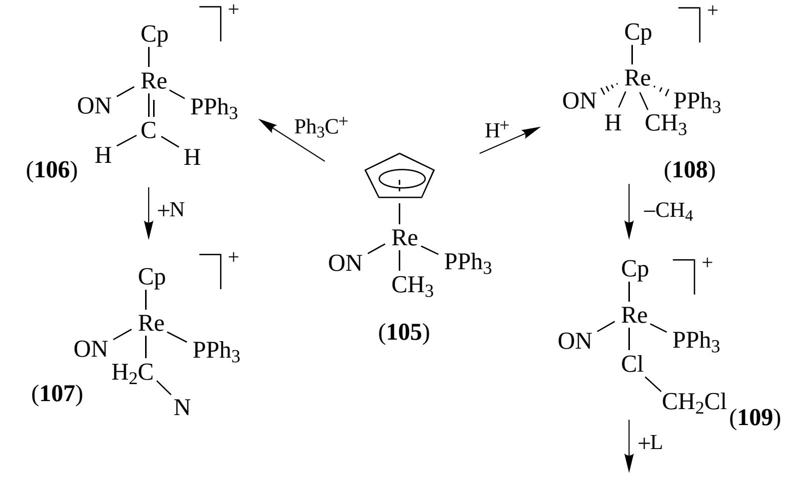
X = O, CH_2

(**113**)



(**114**)

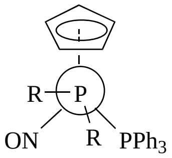
Because of the different degree of steric congestion in the interstices between the NO, Cp, and PPh_3 ligands (NO/PPh_3 most congested > Cp/PPh_3 > NO/Cp least congested), the chiral $(Re)^+$ fragment is able to discriminate between both faces of prochiral alkenes and aldehydes with high kinetic and thermodynamic selectivities. For example, the thermodynamic



$N = R^-, CN^-, RS^-, PR_3, R_2S$ $[(Re)\text{-}L]^+$ (**110**)

L = NCR, CO, $C_2H_2R_2$, C_2R_2, HRCO, R_2CO, PHR_2, $HN{=}CR_2$, $H_2C{=}CR_2$, OR_2, SR_2, OSR_2, NHR_2, RCO_2R', pyrrolyl, OR, NR_2, PR_2, CCH

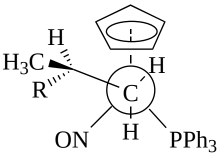
Scheme 24



(**115**)

selectivity in monosubstituted alkenes and aliphatic aldehydes favors the diastereomer with the substituent in the least hindered interstice shown in (**113**) in a ca. 99:1 ratio. Ketones tend to bind in a σ fashion and show modest binding selectivities. This deep and extensive chiral recognition study methodically carried out mainly by Gladysz and collaborators with the (Re)$^+$ fragment over two decades has been revised by the author.[157]

This enantioselectivity translates into the outcome of the products resulting from nucleophilic addition to the [(Re)-(η^2-alkene)]$^+$ and [(Re)(η^2-aldehyde)]$^+$ cations. For example, addition of $LiCuMe_2$ to the alkene diastereomer in (**113**) results in (**116**) in >95:5 ratio.



(**116**)

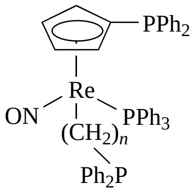
Chiral alkoxides are also obtained from the analogous aldehydes albeit with lower selectivity. Methyl ketones are selectively attacked on the face, unblocked by the bulky PPh_3. The obtained ee values match or exceed the ones found with other classic enantioselective reductants.

Other selected reactions of (Re)$^+$ derivatives include: the deprotonation of S-bound DMSO, $S(CH_2R)_2$ (R = sp^2 or sp^3 C) complexes at the Cα atom that are followed by stereospecific rearrangements; the deprotonation/reprotonation of [(Re)-(η^2-CH_2=CHR)]$^+$ to give [(Re)(=$CHCH_2R$)]$^+$; deprotonation of amine and phosphine derivatives [(Re)(EHR_2)]$^+$ to the amides and phosphides [(Re)(ER_2)]; epimerization of secondary alcohols catalyzed by [(Re)-(OMe)]; unprecedented transformation of N-bound pyrrolyl to C-bound pyrrolyl species.[155]

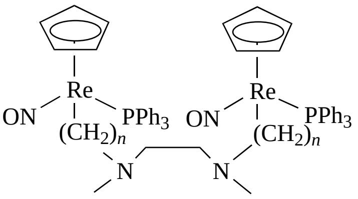
The configurationally robust [CpRe(NO)(PPh_3)X] complexes, easily obtained in an enantiomerically pure form (except for X = OR, NR_2), were used as building blocks for new chiral ligands with spectator chiral-at-metal fragments. Both chiral diphosphine (**117**) and diamine ligands (**118**) have been prepared and successfully tested in catalysis.[158]

The complexes (Re*)(C≡C)$_n$H) (n = 1, 2) have been used to produce binuclear species (Re*)(C≡C)$_n$(Re*) (**119**) bridged by linear sp carbon chains with lengths up to C_{20}.

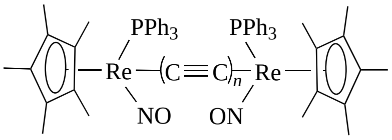
With the increase in the value of n, the properties of the complexes approach those of a one-dimensional sp carbon



(**117**)



(**118**)



(**119**)

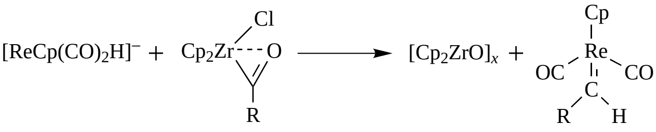
allotrope. Both metal centers can be oxidized separately but the differences in the potentials almost fade out for C20 carbon chains. The monocations exhibit delocalized mixed valence and the dications exhibit cumulenic ground states, for example, $^+$Re=C=C=C=C=Re$^+$.[159]

Some polynuclear complexes of general formula (Re*)C$_n$M′L$_m$ have been made.[155]

Deprotonation reactions of (Re)X derivatives have been clarified in terms of a general, initial kinetically controlled formation of Re(η^5-C_5H_4Li)(NO)(PPh_3)X. Fast migration of X to the ring occurs for X = C(O)R or SiR_3, leaving a metal-centered anion [Re(η^5-C_5H_4X)(NO)(PPh_3)]Li. No migration occurs for X = Me. For X = H, migration occurs above – 32 °C cleanly generating the synthetically useful anion [ReCp(NO)(PPh_3)]$^-$.[160]

8.1.3 *Chemistry of [ReCp(CO)$_2$(carbene)] and [ReCp(NO)(PPh$_3$) (carbene)]$^+$ Complexes*

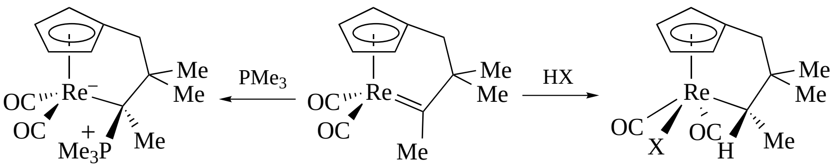
The alkoxycarbenes ReCp(CO)$_2${C(OR′)R} have been known since 1968, but the first alkylidene analogs, ReCp(CO)$_2$(CHR) (**117**) (R = Me, $CH_2CH_2CMe_3$), were recently prepared by the unobvious, but effective, route shown in equation (25).



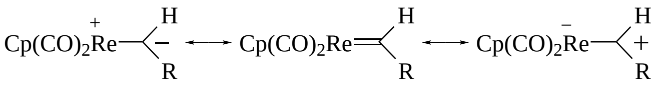
(**117**)

(25)

Complexes of type (**120**) are examples of an amphiphilic alkylidene, that is, the CHR ligand undergoes both electrophilic addition, typical of Schrock-type carbenes, and nucleophilic addition, typical of Fischer-type carbenes, as exemplified in Scheme 25.[161]



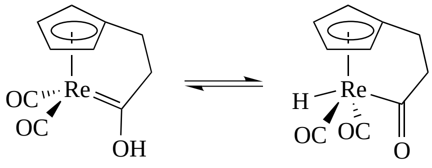
Scheme 25



(**121**) (**120**) (**122**)

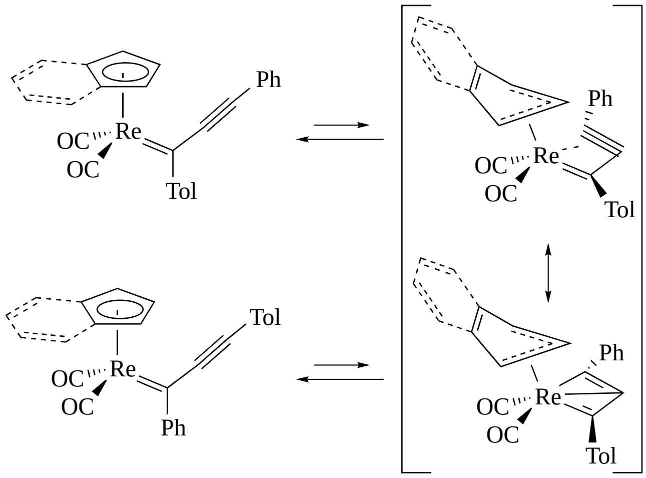
This rare feature is understood as the result of high polarizability of the Re=C bond, between the extreme contributors (**121**) and (**122**).

The same studies also revealed the first example of the interconversion of a hydroxycarbene (**123**) and its isomeric metal acyl hydride (**124**).[162]



(**123**) (**124**)

The chemistry of the synthetically useful class of alkynylcarbene complexes represented in this context by the general formula $[ReCp'(CO)_2\{=C(Tol)C\equiv C(p\text{-}XC_6H_4)\}]$ (Cp′ = Cp, Cp*, Ind; X = H, NMe_2, CF_3, SO_2CF_3) undergoes an unprecedented kind of [1,3] metal shift under thermolysis at 120 °C to $[ReCp'(CO)_2\{=C(p\text{-}XC_6H_4)C\equiv C(Tol)\}]$

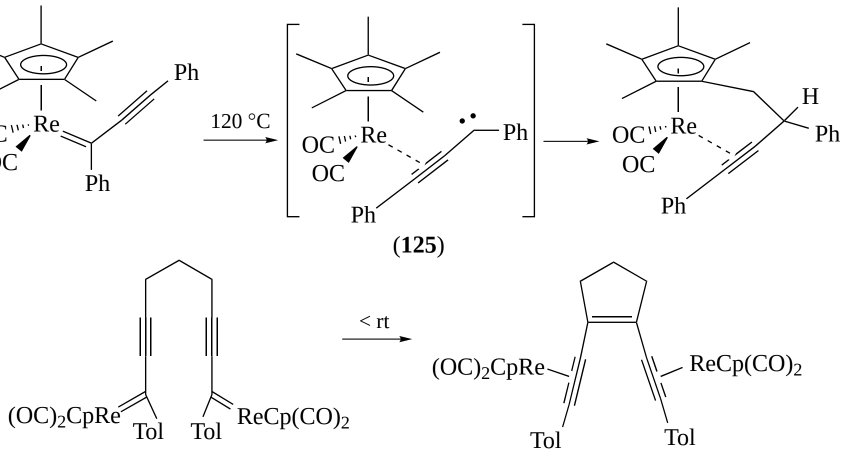


Scheme 26

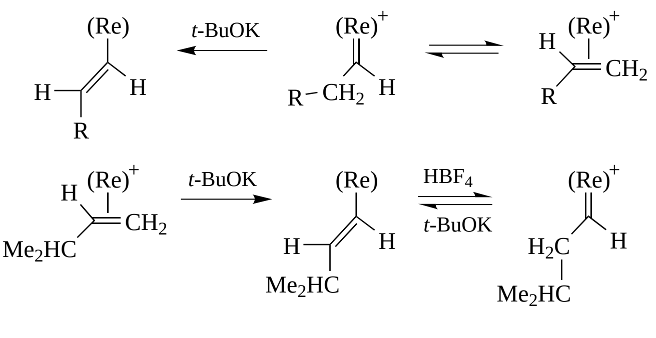
(Scheme 26), which is accelerated by electron-withdrawing substituents X and even more by ring slippage.[163]

However, the main product of this thermolysis results from a highly reactive carbene intermediate (**125**). This kind of species is responsible for a variety of intra and intermolecular reactions of alkynylcarbenes like those depicted in Scheme 27.[164]

Alkylidenes $[ReCp(NO)(PPh_3)(CHR)]^+$ and $[(Re)CHR]^+$ are readily formed via α-H^- abstraction from the corresponding



Scheme 27



Scheme 28

alkyls. Some interconversions between alkylidene, vinyl, and alkene complexes on the (Re) fragment are summarized in Scheme 28. Vinylidene derivatives, $[(Re)(=C=CRMe)]^+$, are obtained by alkylation of the β-C of acetylides (Re)-C≡CR with $MeSO_3F$ and undergo nucleophilic addition of PMe_3 at the α-C.

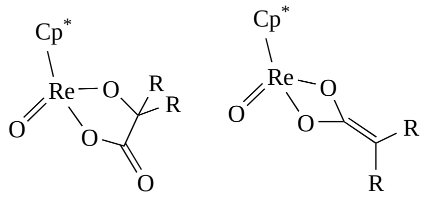
Another type of carbenes, the vinylcyclopropenes play an important role in the transformations of alkynes coordinated to the $ReCp'(CO)_2$ fragment as mentioned in Section 5.3.

*8.1.4 Chemistry of ReCp*O$_3$ and Related Derivatives*

The title complex (**126**) is greatly responsible for the recent expansion of high-oxidation state organometallic chemistry of Re and the neighboring metals, as seen in Section 4.2.[90] $ReCpO_3$ has to be prepared by alkylation of $ReO_3(O_2CCF_3)$ with $SnBu_3Cp$ as the normal $ReRO_3$ complexes. The O atoms in (**126**) are more electron rich than those in $ReMeO_3$ as determined from a wealth of spectroscopic (^{17}O NMR and IR) and structural data. The crystal structure of $Re(\eta^5\text{-}C_5Me_4Et)$ reveals rather long Re–C bonds to the symmetrically bound ring when compared to $ReCp(CO)_3$ complexes. Nevertheless, its chemistry is dominated by reductive processes, with the Cp* ligand being lost in only a few cases.[90]

In the strict absence of O_2, the reaction of (**126**) with PPh_3 gives the Re^V dimer $[Re_2Cp^*_2(O)_2(\mu\text{-}O)_2]$ (**127**).

In the presence of alkynes and PPh_3, no $ReCp^*O_2(\eta^2\text{-}RC{\equiv}CR)$ complex is formed, as in the $ReMeO_3$ case. Cycloaddition of ketenes to (**126**) and (**127**) gives the Re^V species (**128**) and (**129**). No glycolates are formed in similar reactions with alkenes, in contrast to Tc analogs and OsO_4, but the reverse reaction is possible. Indeed, glycolates (**130**) formed from vicinal diols and (**127**) extrude the alkene, reforming $ReCp^*O_3$ in a stepwise mechanism (Scheme 29).[165]



(**128**) (**129**)

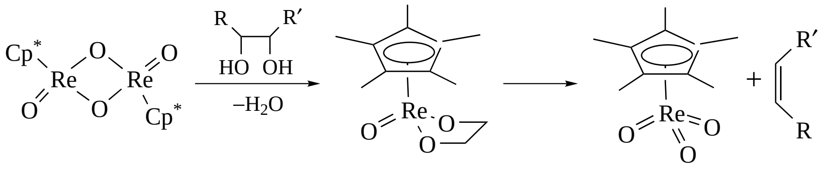
These two reactions were elegantly combined in the deoxydehydration of diols and polyols to alkenes and allylic alcohols catalyzed by $ReCp^*O_3/PPh_3$, which provides a useful means of reducing oxygen-rich organics like carbohydrates.[166]

The system $ReCp^*O_3/PPh_3$ is not efficient in catalytic deoxygenation of epoxides but its analogue $ReTpO_3$ is and shows stereoselectivity.[167]

$ReCp^*OCl_2$ (**131**) and other oxo halides (X = F, Cl, Br, I) have been prepared by reaction of HX or pyHI with (**127**). (**131**) can be alkylated with Grignard reagents to give the dialkyls $ReCp^*OR_2$ (**132**) (R = Me, Ph, CH_2Ph, Np). The crystal structures of complexes (**131**) and (**132**) reveal a remarkable asymmetrical coordination of the Cp* ligand attributed to a trans effect of the strong π-donor oxo ligand. A similar distortion of the Cp* ring, almost η^3-Cp*, is found in the imido complex $ReCp^*(N\text{-}t\text{-}Bu)Cl_2$. The metallacycle (**133**), and the structural analogs $ReCp^*O(CO_3)$ and $ReCp^*O(SO_4)$, readily available from (**131**) easily eliminate $Me_2C{=}CH_2$, CO_2, and SO_2 (reversibly in the latter case), respectively. Deoxygenation of (**131**) with PMe_3 yields $ReCp^*Cl_2(PMe_3)_2$. $ReCp^*Cl_4$ is prepared by the deoxygenation/halogenation in equation (26).

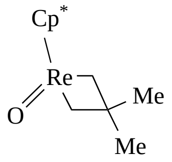
$$ReCp^*O_3 \xrightarrow[Me_3SiX]{PPh_3} ReCp^*X_4 \qquad (26)$$

Use of $TiCpCl_3$ provides both functions simultaneously and reaction with (**132**) gives $ReCp^*R_2Cl_2$. However, in the case of $ReCp^*ONp_2$, this reaction produces the paramagnetic carbyne $ReCp^*Cl_2(C\text{-}t\text{-}Bu)$, which is reversibly oxidizable chemically.[3]



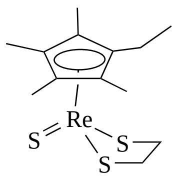
(**127**) (**130**) (**126**)

Scheme 29



(**133**)

The first complex in this system to present the terminal Re=S bond (**134**) has been very recently reported in spite of the number of complexes of ReCp* with polysulfide rings (S3, S4) and thiolates previously known.[168]



(**134**)

8.1.5 *Chemistry of ReCpX$_x$L$_y$ Complexes (X = Halides, Hydrocarbyls, and Hydrides)*

Complexes such as ReCp(CO)$_2$Br$_2$ (**135**) and ReCp(CO)$_2$-H$_2$ are mentioned in Section 8.1.1. The latter is available from the former upon reaction with Ph$_3$SnH. ReCp(CO)$_2$Me$_2$ may be prepared by the reaction sequence in Scheme 30, whereas the analogues ReCp*(CO)$_2$R$_2$ can be prepared from R$_2$CuLi and ReCp*(CO)$_2$Br$_2$.

The nucleophilicity of [ReCp(CO)$_2$H]$^-$ is exemplified in equation (25). ReCp(CO)$_2$MeX and the anion [ReCp(CO)$_2$X]$^-$ are mentioned in earlier literature as the result of alkylation reactions on (**135**) with LiR and MgRX. These are, however, not straightforward substitutions, since ring metalation and metal–halogen exchange take place under these circumstances. The study of ReCp*(CO)$_2$Br$_2$ presents a thorough summary of the preceding chemistry in this field and shows that metal–halogen exchange with LiR or RMgX, to give isolable [ReCp*(CO)$_2$Br]$^-$, is quantitative at −78 °C.[169]

Related ReCp(PR$_3$)$_2$H$_2$, ReCp(PR$_3$)$_2$(H)R, and ReCp-(CO)$_2$R{C(O)R} have already been referred to above.

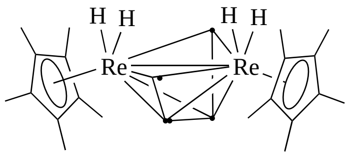
All the other half-sandwich complexes in this section derive from the chemistry of ReCp*O$_3$ and ReCp*Cl$_4$ (**136**).[90] Complex (**136**) forms an octahedral adduct ReCp*Cl$_4$(PMe$_3$), but excess phosphine reduces it to ReCp*Cl$_2$(PMe$_3$)$_2$. Hydrolysis and aminolysis form ReCp*OCl$_2$and ReCp*(NR)Cl$_2$ respectively. Stepwise reductive dehalogenation with Al/HgCl$_2$ affords the bridged halide dimers [Re$_2$Cp$^*_2$Cl$_4$(μ-Cl)$_2$] (Re–Re bond) and [ReCp*Cl(μ-Cl)]$_2$ (Re=Re bond).[4]

$$\mathrm{ReCp(CO)_2H_2} \xrightarrow{\mathrm{KOH}} \mathrm{[ReCp(CO)_2]^-} \xrightarrow{\mathrm{MeI}} \mathrm{ReCp(CO)_2Me_2}$$

Scheme 30

In the presence of dienes or alkynes, identical reduction of (**136**) yields ReCp*Cl$_2$(diene) and ReCp*Cl$_2$(RC≡CR). The latter has an interesting chemistry which includes inter alia hydrolysis to form ReCp*(O)(RC≡CR), alkylation to give ReCp*Me$_2$(RC≡CR), and a series of H$^+$-catalyzed coupling reactions with alkenes to form ReCp*Cl$_2$(diene) and ReCp*Cl(dienyl).[4]

The bromides ReCp*Br$_4$ and [ReCp*Br$_2$]$_2$, the iodide [ReCp*I$_3$]$_2$, and several substitution products of (**136**), for example, ReCp*(3,4-S$_2$C$_6$H$_3$Me)$_2$ and ReCp*(O)S$_4$, are also known. Monomethylation of (**136**) to form ReCp*MeCl$_3$ occurs with SnMe$_4$, whereas ReCp*Me$_4$ is obtained with MeMgCl. The complete family of mixed halo alkyls ReCp*Cl$_x$Me$_{4-x}$ has been prepared in several steps from ReCp*Me$_2$Cl$_2$. The reactions of ReCp*Me$_3$(OTf) with N$_2$H$_4$ and NHR$_2$ (R = H, Me) have been studied. The coordinated NH proton of [ReCp*Me$_3$(η^2-N$_2$H$_4$)]$^+$ and [ReCp*Me$_3$(NHR$_2$)$_2$]$^+$ can be removed with base to give imido complexes. Reduction of the hydrazine cation liberates ammonia.[4] The air-stable ReCp*H$_6$ (**137**) is prepared from (**136**) by reaction of LiAlH$_4$ and methanolysis. Its thermal decomposition (>192 °C) gives the air-stable and structurally characterized dimer [Re$_2$Cp$^*_2$H$_4$(μ-H)$_2$]. Photolysis of ReCp*H$_6$ in the presence of PPh$_3$ gives ReCp*H$_2$(PPh$_3$)$_2$. Besides (**137**), the reaction of ReCp*Cl$_4$ with LiBH$_4$ gives the cluster (ReCp*H$_2$)$_2$B$_4$H$_4$ (**138**). Reaction of this with BH$_3$·THF allows the synthesis of the Re(Cp*)$_2$B$_n$H$_n$ (n = 7–10), a fascinating family of borane clusters that has many analogues with other transition metals.[170]



• = BH

(**138**)

8.2 Miscellaneous Re (η^5-Pentadienyl) and Cyclopentadienyl Analog Complexes

A few Re complexes containing other η^5-dienyl ligands or analogs thereof have been reported. The open dienyl Re(η^5-C$_5$H$_7$)(CO)$_3$ undergoes a haptotropic shift to form Re(η^1-C$_5$H$_7$)(CO)$_3$(L)$_2$ on reaction with phosphines, a typical behavior for these complexes. Similar shifts are responsible for the formation of Re(η^5-C$_6$H$_5$CPh$_2$)(CO)$_3$ from its benzylic Re(η^3-C$_6$H$_5$CPh$_2$)(CO)$_4$ precursor and for the transient appearance of Re(η^5-C$_7$H$_7$)(CO)$_3$ in the photochemistry of Re(η^1-C$_7$H$_7$)(CO)$_5$ (see Section 10). The indenyl derivatives Re(η^5-C$_9$R$_7$)(CO)$_3$ are known (R = H, Me).

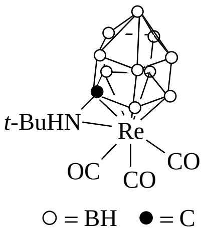
Photochemical removal of CO from Re(η^5-Ind)(CO)$_3$ in the presence of indene gives Re(η^5-Ind)(CO)$_2$(η^2-C$_9$H$_8$). This reacts with Ph$_3$C$^+$ to give [Re(η^5-Ind)(η^3-C$_9$H$_7$)(CO)$_2$]$^+$, isoelectronic with the bent indenyl complexes [M(η^5-Cp′)(η^3-Ind)(CO)$_2$] (M = Mo, W; Cp′ = Ind, Cp) (*see* ***Molybdenum: Organometallic Chemistry*** and ***Tungsten: Organometallic Chemistry***).[171]

[Re(η^5-Ind)Re(NO)(PPh$_3$)(X)]$^+$ complexes display several reactions similar to their Cp or Cp* analogues. Unexpected is the facile ring slippage caused by acetone and NCMe, which forms the adduct [Re(η^1-Ind)Re(NO)(CO)$_2$(OCMe$_2$)$_2$]$^+$ although it parallels related indenyl slippage in [M(η^5-Ind)(CO)$_2$L$_2$]$^+$, also favored by O and N π-donor ligands. A new insight into the indenyl ring slippage in the rather unreactive alkene and alkyne adducts of the fragment [Re(η^5-Ind)(CO)$_2$] led to the discovery of the alkyne assistance to CO-promoted indenyl slippage and ultimately to the new CO-catalyzed PPh$_3$ substitution in Re(η^5-Ind)(CO)$_2$(η^2-alkyne) to give Re(η^5-Ind)(CO)$_2$(PPh$_3$).[172]

A variety of η^5-hydrofullerene complexes having the Re(CO)fragment coordinated to a η^5-Cp like C$_{60}$ derivative has been disclosed. These compounds are made by Re$_2$(CO)$_{10}$-assisted hydrogenation of the fullerenes.[173]

Pyrrole reacts with ReH$_7$(PPh$_3$)$_2$ in the manner described for C$_5$H$_6$ or C$_5$H$_{10}$ to form Re(η-C$_4$H$_4$N)H$_2$(PPh$_3$)$_2$. Simple transformation to Re(η-C$_4$H$_4$N)HI(PPh$_3$)$_2$ activates the C-2 and C-5 positions for nucleophilic attack, resulting in a new stepwise preparation of mono- and difunctionalized pyrroles after ring decomplexation. Some η^5-dienyl complexes result from nucleophilic additions at coordinated arenes and rearrangements on Re^0 complexes as described in Section 9. Other classical formal analogs of cyclopentadienyl include the hydrido-tris-pyrazolylborate derivatives ReTp(CO)$_3$, and [Re(tacn)(CO)$_3$]$^+$, as described in Section 14, all of which are prepared from the ligands and ReX(CO)$_5$. The powerful π-basic fragment [ReTp(CO)(PMe$_3$)] was mentioned in Section 5.2. Phosphine derivatives of general formula [Re(P3)(CO)$_2$X] (P3 = tripodal HC(CCH$_2$PPh$_3$)$_3$ (triphos) or the macrocycle 12[ane]P3R3 (R = Et, *i*-Bu)) have been prepared from Re(CO)$_3$(PPh$_3$)$_2$Cl,[174] and by reduction of Re{12[ane]P3R3}Cl$_3$,[175] respectively. These [Re(P3)(CO)$_2$X] (X = Cl, H, OTf) complexes produce a variety of [Re(P3)(CO)$_2$L]$^+$derivatives with small molecules L = H$_2$, N$_2$, NCR. They originate vinylidenes [Re(P3)(CO)$_2$(C=C=HR)]$^+$ from terminal alkynes, and allenylidenes [Re(P3)(CO)$_2$(C=C=CRR′)]$^+$, carbenes, and vinylidenes from propargyl alcohols HC≡CRR′(OH).[176]

Another family of cyclopentadienyl analogs are the carborane derivatives the first of which, [Re(CO)$_3$(η^5-7,8-C$_2$B$_9$H$_{11}$)(CO)$_3$]$^-$, was reported in 1965. A few derivatives, [Re(η^5-7,8-R$_2$-7,8-C$_2$B$_9$H$_9$)(CO)$_3$]$^-$, [Re(NO)L$_2$(η^5-7,8-C$_2$B$_9$H$_{11}$)], and [Re(NO)(CO)(CR(OMe)(η^5-7,8-C$_2$B$_9$H$_{11}$}] are known.[177] The complex (**139**) presents intramolecular coordination of the pendant amine group and



(**139**)

displays reactivity toward alkynes unprecedented in metallacarbaborane chemistry.[178]

The novel monocarbon analogue dianion [Re(CO)$_3$(η^5-7-CB$_{10}$H$_{11}$)]$^{2-}$ was prepared with different organic cations and its chemistry generated a number of molecules with Re–M bonds (M = Pd, Pt, Rh, Ir).[179]

9 CHEMISTRY OF Re (η^6-HYDROCARBON) COMPLEXES

The bis-arene complexes [Re(η^6-C$_6$R$_6$)$_2$]$^+$ (R$_6$ = H$_6$, Me$_6$, 1,2,3-H$_3$Me$_3$) (**140**), prepared by the general Fischer–Hafner reaction (equation 27), were first reported in 1957, and the recognition of their sandwich structure similar to that of *Ferrocene*, gave decisive impetus to the then novel field of organotransition metal chemistry.[2]

$$3ReCl_5 + 4Al + 6Arene \xrightarrow[130\,^\circ C]{AlCl_3} 3[Re(\eta\text{-arene})_2][AlCl_4] + AlCl_3 \quad (27)$$

These light yellow, air- and water-stable cations can be isolated with a variety of counterions, for example, PF$_6^-$ and BPh$_4^-$ but, probably due to the very low yields, the chemistry of the complexes has been relatively unexplored.[2] Reduction by Na in liquid NH$_3$ or H$^-$ addition to (**140**) (R = H, Me) gives [Re(η^6-C$_6$R$_6$) (η^5-C$_6$R$_6$H-6-exo)]. A very unstable, paramagnetic complex, [Re(η^6-C$_6$Me$_6$)$_2$], has been isolated and identified by electron spin resonance (ESR) upon reduction of (**135**) (R = Me) with Li.

Also, the first reported yields of the cations [Re(η^6-C$_6$R$_6$)(CO)$_3$]$^+$ (**141**) were disappointingly low, especially in comparison to the higher yields obtained for the isoelectronic Mn^I analogs. These low yields are a result of very fast product hydrolysis to [Re(H$_2$O)$_3$(CO)$_3$]$^+$. Improved high-yield preparations of a series of ring-substituted (**141**) complexes on the basis of avoiding oxygenated solvents, namely H$_2$O and THF (equation 28) are now available.

$$(CO)_5ReBr + AlBr_3 \xrightarrow[120\,^\circ C]{Arene} [Re(\eta\text{-arene})(CO)_3][AlBr_4] \quad (28)$$

The hydrolytic and solvolytic stability increases with the number of Me substituents. The penta- and hexamethyl derivatives can be treated in water.

The chemistry of complexes (**141**) is dominated by their electrophilicity. The products of nucleophilic attack depend on the nature of the nucleophile, which either reacts at the metal, to give substitution, or at the ring, to give additions, as summarized in Scheme 31.

Facile arene displacement is favored by hard donor solvents (L), particularly oxygenated ones like acetone, THF, and water. Reaction with MeCN shows second-order kinetics with activation parameters consistent with a S_N2 mechanism where the MeCN adds directly to the metal. This reaction is 104 times faster for Re than for the Mn analog, due to the larger size of Re, thus explaining why preparations employing hydrolytic work-up work well for Mn but not for Re.

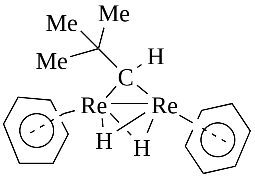
Softer nucleophiles N, for example, H^- or PBu_3, add directly (reversibly in the latter case) to the exo face of the arene to give the [Re(η^5-C_6R_6N-6-exo)$(CO)_3$] (**142**) complexes without any participation of the metal center. Attempted extension to Re complexes of the well-established methodology for double functionalization of arenes earlier developed for the Mn^I analogs on the basis of $[Mn(\eta^5\text{-dienyl})(CO)_2(NO)]^+$ (*see* ***Manganese: Organometallic Chemistry***) is thwarted by the limitations found in the preparation of the cations $[Re(\eta^5\text{-dienyl})(CO)_2(NO)]^+$.

Closely related to these arene carbonyl complexes are the cycloheptatriene derivatives, which, however, are prepared by insertion of C_7H_8 into a Re–C bond followed by H abstraction, with Ph_3C^+, as shown in Scheme 32.

Irradiation of ReCp*$(CO)_3$ in the presence of C_8H_8 produces ReCp*(η^6-C_8H_8).[136]

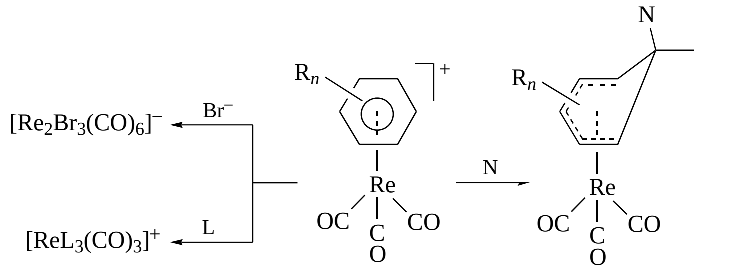
Re arene complexes also result from application of the MVS technique to the extremely refractory Re metal (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***). Cocondensation of pure benzene with Re atoms yields no tractable product, confirming the instability of $[Re(\eta^6\text{-}C_6H_6)_2]$. However, cocondensation of Re with a mixture of C_6H_6 and PMe_3 yields the Re–Re bonded dimer $[Re(\eta^6\text{-}C_6H_6)(PMe_3)_2]_2$ (**143**) in 30% yield. This complex can be protonated to give the dihydride $[\{Re(\eta^6\text{-}C_6H_6)H(PMe_3)_2\}_2]^{2+}$. Reduction of (**143**) with K followed by treatment with MeI gives $[Re(\eta^6\text{-}C_6H_6)(PMe_3)_2I]$ (**144**). $[Re(\eta^6\text{-}C_6H_6)(PMe_3)_2H]$ (**145**) is prepared by reaction of (**144**) with $LiAlH_4$, but its Mn analog results directly from the cocondensation of the metal with C_6H_6/PMe_3.[3] Underlining the parallel between the C–H activation of the $ReH_x(PR_3)_2$ polyhydrides and low-valent metal chemistry, cocondensation of Re atoms with cyclopentane and cyclohexane mixtures in the presence of PMe_3 gives $ReCpH_2(PMe_3)_2$ and (**145**), respectively.

When alkylarenes are cocondensed with Re atoms, C–H activation of the aliphatic side chains occurs and a variety of novel arene derivatives of Re with μ-arylidene and hydride bridges, $[Re_2(\eta^6\text{-arene})_2(\mu\text{-CHAr})(\mu\text{-H})_2]$, are formed, for example, products containing *o*-xylyl ligands. Similar reactions are observed with saturated hydrocarbons, for example, cocondensation with CMe_4 gives (**146**).



(**146**)

Cocondensation of Re with mixtures of benzene and unsaturated hydrocarbons gives a rich chemistry otherwise



(**141**) (**142**)

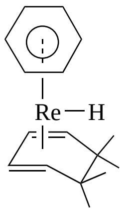
L = NCMe, Me_2CO, H_2O, NH_3 N = H^-, R^-, CN^-, PBu_3

Scheme 31

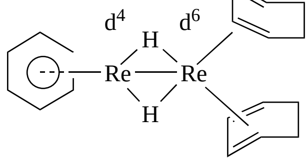
$$RePh(CO)_5 + C_7H_8 \longrightarrow Re(\eta^5\text{-}C_7H_8Ph)(CO)_3 \xrightarrow{Ph_3C^+} [Re(\eta^6\text{-}C_7H_7Ph)(CO)_3]^+$$

Scheme 32

impossible to obtain by more common synthetic methods. A few examples, resulting from the following mixtures, are given: C_6H_6/C_5H_6 gives $[Re(\eta^6-C_6H_6)Cp]$ and $ReCp_2H$; C_6H_6/indene forms $Re(\eta^5$-Ind$)(\eta^6$-IndH); C_6H_6/C_6H_8 gives $[ReH(\eta^6-C_6H_6)(\eta^4-C_8H_8)]$ (**147**) and (**148**); and C_6H_6/C_7H_8 produces $[Re(\eta^6-C_6H_6)(\eta^5-C_7H_7)]$ and $[Re(\eta^6-C_6H_6)(\eta^5-C_7H_9)]$.



(**148**)



(**149**)

$[Re(\eta^6-C_6H_6)Cp]$ is a sandwich complex and (**147**) is a bent metallocene like $ReCp_2H$. Protonation of several of the reported complexes gives new Re hydrides, and complex $[Re(\eta^6-C_6H_6)Cp]$ has a remarkable chemistry in this respect. Compound (**149**) can be considered as a Re–Re bonded mixed valency d^4-d^6 species. Double-bond hydrogenation also occurs, for example, with (**148**).

The fulvene complex $Re(\eta^6-C_5Me_4CH_2)(CO)_2(C_6F_5)$ (see Section on Electrophilic Attack and Oxidative Additions) undergoes a nucleophilic attack at the *exo*-CH_2 group to give complexes like $[Re(C_5Me_4CH_2N)(CO)_2(C_6F_5)]^z$ (N = PMe_3, z = 0; N = OMe, z = −1). $Re(\eta^6-C_5Me_4CH_2)(CO)_2X)$ (X = C_6F_5, Cl, Br, I) react with HX′ (X′ = Cl, Br, I) to give$[Re(\eta^5-C_5Me_5)(CO)_2XX']$ and with X'_2 to give $[Re(\eta^5-C_5Me_4CH_2X)(CO)_2XX']$. The later reactions are initiated by an electrophilic H^+ or X^+ attack at the metal followed by a X^- attack at the CH_2 group.[148,180]

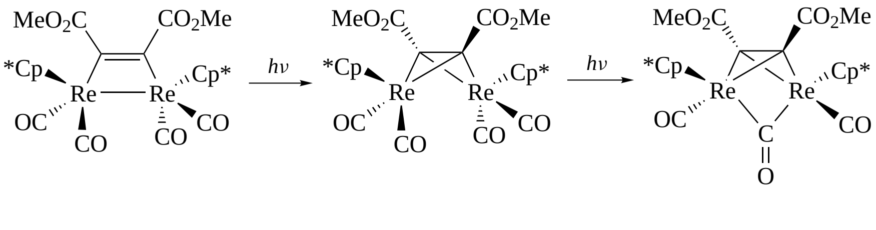
10 CHEMISTRY OF Re (η^7-HYDROCARBON) COMPLEXES

No such complex of this type has been isolated to date. In fact, attempts to photolyze the well-characterized $Re(\eta^1-C_7H_7)(CO)_5$ in order to induce haptotropic $\eta^1 \rightarrow \eta^7$ ring slippage leads to the dimer $[Re(\eta^5-C_7H_7)(CO)_2]_2$. Similarly, photolysis of (**1**) and C_7H_8 gives $Re(\eta^5-C_7H_7)(CO)_3$. However, the complex $Re(\eta^7-C_7H_7)(CO)_2$ is produced on photolysis of $Re(\eta^1-C_7H_7)(CO)_5$ in low-temperature matrices and stepwise ring slippage $\eta^1 \rightarrow \eta^3 \rightarrow \eta^5 \rightarrow \eta^7$ has been observed.[3] In the preceding section, the $(\eta^5-C_7H_7)$ derivative containing an uncoordinated double bond is mentioned.

11 CHEMISTRY OF Re–Re MULTIPLE BONDED ORGANOMETALLIC COMPLEXES

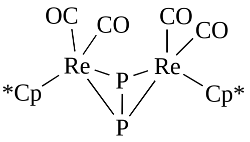
A number of organometallic complexes containing Re–Re multiple bonds, supported or not by bridging ligands, are known. Among the unsupported quadruply bonded species is the Re^{III} dianion $[Re_2Me_8]^{2-}$. This anion has an eclipsed conformation and has played an important role in the characterization of this type of multiple bond. Its reaction with excess acetic acid, forms $Re_2Me_2(\mu-O_2CMe)_2(O_2CMe)_2$. Other acetate-bridged complexes, such as $Re_2R_4(O_2CMe)_2$ (R = CH_2TMS, CH_2Ph, CH_2-*t*-Bu), are made from MgR_2 and $Re_2Cl_2(O_2CMe)_4$. A similar reaction with $Mg(2-MeOC_6H_4)_2$ gives $Re_2(2-MeOC_6H_4)_6$ with four bridging and two terminal 2-$MeOC_6H_4$ bidentate ligands. Cleavage of the triangular clusters Re_3Me_9 with excess PR_3 leads to $Re_2Me_6(PR_3)_2$. However, the analogous chloroalkyl complex (**44**) undergoes reductive cleavage under the same conditions to give the triply bonded dimers $Re_2Cl_2R_2(PMe_3)_4$. These complexes cannot be made by direct alkylation of $Re_2Cl_4(PR_3)_4$. The latter complexes, however, give triply bonded $Re_2(\eta^3-C_3H_5)_4$ (**150**) on reaction with (allyl)MgX. This contrasts with the analogues $M_2(allyl)_4$ (M = Cr, Mo), since it has an unsupported Re–Re bond without bridging allyl ligands.

$Cp^*Re(CO)_2{=}Re(CO)_2Cp^*$ (**151**) is a rare example of a formal dimer of a 16e fragment in the case of $[ReCp^*(CO)_2]$, the other one being $[Re(\equiv C\text{-}t\text{-}Bu)(O\text{-}t\text{-}Bu)_2]_2$. Two of the CO ligands are terminal and the other two are semibridging. (**151**) is thermally stable to over 100 °C but is exceedingly reactive to H_2 addition giving $[ReCp^*(CO)_2)](\mu-H)_2$ and the addition of nucleophiles giving $[ReCp^*(CO)_2](\mu-CO)[ReCp^*(CO)L]$.[181] It reacts with enynes to give bridging alkenylidenes and with acetylenes to give a series of dimetallacycles in a cascade of thermal and photochemically induced rearrangements (Scheme 33).[182]



Scheme 33

It reacts with CH_2Cl_2 to give [{ReCp*Cl}$_2$(μ-CO)$_2$] and [{ReCp*(CO)$_2$}$_2$(μ-CH$_2$)] in contrast to its parent ReCp*(CO)$_2$(THF) that gives ReCp*(CO)$_2$Cl(CH$_2$Cl). It adds the P_2 fragment (from P_4) across the Re–Re bond (**152**) and reacts with Ph_2C_2 to give ReCp*(CO)(η^4-C$_4$Ph$_4$).[183] Interestingly, irradiation of (**89**) in the presence of a borylene complex gave the transfer of this rather inaccessible fragment isoelectronic with CR_2, forming [{ReCp(CO)$_2$}$_2${μ-B=N(SiMe$_2$)}] isostructural with [{ReCp*(CO)$_2$}$_2$(μ-CH$_2$)].[184]



(**152**)

12 CHEMISTRY OF Re ISOCYANIDE COMPLEXES

The majority of Re isocyanide chemistry follows the structural patterns of the isoelectronic carbonyls and, in fact, many of them may be prepared by direct CNR substitution on parent Re carbonyl complexes. For example, Re$_2$(CO)$_{10-x}$(CNR)$_x$ (x = 1–4) and MnRe(CO)$_{10-x}$(CNR)$_x$ (x = 1–4) are prepared by PdO-catalyzed substitution. Mono- and disubstitution in ReX(CO)$_5$ and/or [ReX(CO)$_4$]$_2$ complexes, in THF, leads to ReX(CO)$_4$(CNR) and *fac*-[ReX(CO)$_3$(CNR)$_2$], with the decreasing orders of reactivities X = Cl > Br; R = aryl > alkyl. Under analogous conditions, MnX(CO)$_5$ reacts rapidly to give [Mn(CNR)$_6$]$^+$. Further substitution occurs under more forcing conditions, for example, refluxing toluene, and entails isomerization of *fac*-[ReX(CO)$_3$(CNR)$_2$] to *mer,cis*-[ReBr(CO)$_2$(CNMe)$_3$], and formation of ReBr(CO)(CNR)$_4$, ReBr(CNR)$_5$, and, in low yield, [Re(CNR)$_6$]Cl (R = *p*-tolyl). PdO-catalyzed substitution of ReX(CO)$_4$(PR$_3$) with CN-*t*-Bu leads to the mer- and fac- isomers of ReX(CO)$_3$(PR$_3$)$_2$(CN-*t*-Bu). The fac isomer is favored at higher temperatures.[185]

Alternative high-yield preparations of many other derivatives were later developed, on the basis of the cleavage of Re–Re multiple bonded complexes, a reaction normally promoted by π-acceptors such as CO, NO, and CNR. In this way, homoleptic [Re(CNR)$_6$]$^+$ (**153**) derivatives (R = alkyl, aryl) and ReX(CNAr) are obtained in excellent yields from Re$_2$(O$_2$CMe)$_4$Cl$_2$. Mixed derivatives [Re(CNR)$_4$(PR$_3$)$_2$]$^+$ (**154**) are likewise prepared from Re$_2$Cl$_4$(PR$_3$)$_4$ and are not directly available from (**153**) because of its substitutional inertness. However, in the case of Re$_2$Cl$_4$(LL)$_2$ analogs (LL = dppm or dppe) where the diphosphine ligands bridge the two metals, reaction with CNR gives the adduct Re$_2$Cl$_4$(LL)$_2$(CNR) with a bridging Cl atom. Additional CNR replaces Cl, giving [Re$_2$Cl$_3$(LL)$_2$(CNR)$_2$]$^+$, but the Re–Re bond retains its multiple character. This chemistry was later extended to CO and NCR and mixed-ligand analogs with emphasis on their structural characteristics.[186]

Alternatively, high yields of (**154**) are obtained by the reaction of the polyhydrides ReH$_7$(PR$_3$)$_2$ or ReH$_5$(PR$_3$)$_3$ with CNR. In Section 3.1, reference was made to a large number of complexes of the type [ReH$_x$(PPh$_3$)$_2$(CNR)$_y$]$^{n+}$. These compounds are prepared from polyhydrides and CNR, as illustrated in the reaction sequence of Scheme 34.

Pombeiro has shown that irradiation of ReCl(N$_2$)(dppe) in the presence of a variety of CNR ligands leads to ReCl(CNR)(dppe)$_2$, which gives [ReL(CNR)(dppe)$_2$]$^+$ (L = CO, CNR) upon treatment with Tl^+ salts in the presence of ligand, L. Electrophilic reactions of these compounds have been used as models of *Nitrogen Fixation* by low-oxidation state metal centers and will be discussed below.

As mentioned in Section 2.4.2, 17-electron, mononuclear Re^{II} complexes are rare, in contrast to the multiply bonded Re$_2$X$_4$(PR$_3$)$_4$. A few representative examples were prepared by Walton either by oxidation of the parent Re^I complexes, for example, [Re(CNAr)$_6$]$^{2+}$ from [Re(CNAr)$_6$]$^+$, or by reduction of Re^{III} species with CNR.[3]

Re^{III} isocyanide derivatives are relatively abundant either as six- or seven-coordinate species. They may be prepared, as in the case of the carbonyls, by oxidative addition to Re^I precursors, for example, ReBr$_3$(CNR)$_4$ from ReBr(CNR)$_4$(CO) and Br$_2$, by nonreductive cleavage of Re–Re bonds, by reacting [Re$_2$Cl$_8$]$_2$ or Re$_2$Cl$_6$(PR$_3$)$_2$ with CNR, giving [ReX$_2$(CNR)$_5$]$^+$ and [ReX$_2$(CNR)$_4$(PR$_3$)]$^+$, respectively, by substitution reactions, for example, from *mer*-ReX$_3$(PR$_3$)$_3$ to give [ReX$_2$(CNR)$_3$(PR$_3$)$_2$]$^+$ and by reduction of ReOCl$_2$(PPh$_3$)$_2$ with PPh$_3$ to give ReCl$_2$(CNR)(PPh$_3$)$_2$. ReCl$_3$(CNMe)$_3$ and trinuclear species Re$_3$X$_9$(CNR)$_3$ are also known.[50] In the mononuclear complexes, seven coordination achieves the 18-electron configuration and is typically a capped octahedron with a CNR ligand capping one of the faces. Upon loss of a two-electron ligand, octahedral 16-electron species are formed, of which all *trans*-[ReCl$_2$(CN-*i*-Pr)$_2$(PMePh$_2$)$_2$]$^+$ complexes were the first to be structurally characterized. This complex readily adds CO or CN-*i*-Pr to generate seven-coordinate species.[50] Re-CNR complexes in higher oxidation states, for example, [ReCl$_5$(CNMe)]$^-$ are very rare.[2]

$$\mathrm{ReH_5(PR_3)_3} \xrightarrow[\mathrm{CNMe/NCMe}]{\mathrm{C_7H_7^+}} \mathrm{ReH_4(PR_3)_3(CNMe)} \underset{\mathrm{H^+}}{\overset{\mathrm{NEt_3}}{\rightleftharpoons}} \mathrm{ReH_3(PR_3)_3(CNMe)}$$

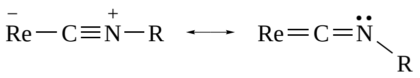
Scheme 34

In contrast with the thermal substitutional inertness, photolysis of $[Re(CNAr)_6]^+$ in the presence of X^- gives $ReX(CNAr)_5$. Like the isoelectronic CO, coordinated CNR may undergo nucleophilic addition of Y^- to give the corresponding iminoacyls $[ML_n\{C(NR)Y\}]^-$ that produce Fischer-type carbenes $[ML_n\{{=}C(NR)(YR)\}]$. The electrophilicity of the coordinated C atom in CNR is obviously enhanced in cationic complexes and when electron-withdrawing R groups are present. Competition between nucleophilic addition at CO and CNR in the same metal has been studied on the basis of electronic effects, but the steric bulk of the R group also plays a role. Addition of H_2NR to $ReBr(CO)_4(CNR)$ confirmed attack at CNPh to form the diaminocarbene complex $ReBr(CO)_4\{{=}C(NHPh)(NHR)\}$.[187]

Stressing the importance of the charge and other electronic balances, $[Re(CO)_5(CN\text{-}t\text{-}Bu)]^+$ is found to react with nucleophiles, including amines, but preferentially at a *cis*-CO ligand to give the carbamoyl derivatives *cis*-$[Re(CO)_4(CNR)\{C(O)NHR\}]$. The complex $ReBr(CO)_3(CNPh)(CNN{=}CMe_2)$ (**155**) reacts with H_2N-*i*-Pr preferentially at the N-isocyanoiminoalkane ligand to give $ReBr(CO)_3(CNPh)\{C(NH\text{-}i\text{-}Pr)(NHN{=}CMe_2)\}$, but a further attack at the CNPh ligand occurs readily to give the biscarbene $ReBr(CO)_3\{(C(NH\text{-}i\text{-}Pr)NHPh)\}\{C(NH\text{-}i\text{-}Pr)(NHN{=}CMe_2)\}$. (**155**) is obtained by the Wittig reaction of $ReBr(CO)_3(CNPh)(CNNPPh_3)$ with acetone.[188]

The $CNNPR_3$ ligand still has a rather undeveloped chemistry. The chemistry of aminocarbenes derived from isonitriles by nucleophilic addition has been reviewed.[189]

Electrophilic addition to coordinated CNR has been observed when it is ligated to very electron-rich metal centers. The structures of several of these complexes show severe bending of the C–N–R angle, between ca. 140 and 160°, and the (C≡N) stretching vibrations appear at rather low energies (ca. $1830\,cm^{-1}$) compared to normal linear CNR ligands of free CNR ($2150\,cm^{-1}$). Both effects are explained by the importance of the bonding structure (**157**) of the two bonding extremes, (**156**) and (**157**), which shows the carbene character of the Re–C bond in these complexes.



(**156**) (**157**)

More pronounced bending is systematically observed when the ligand trans to a CNR ligand is not a π-acceptor, for example, CNR being trans to Cl in $ReCl(CNMe)_3(PMePh_2)_2$ (**158**) contrasted to being trans to NCMe in $[Re(NCMe)(CNMe)_3(PMePh_2)]^+$. The structure (**157**) also points to the nucleophilic character of the N atom that may be protonated to give aminocarbynes. The first such complex was reported in 1981 by the protonation of $(ReCl(CNR)(dppe)_2)$ with HBF_4 to give *trans*-$[ReCl(CNHMe)(dppe)_2]BF_4$. Examples formally derived from the protonation of (**158**), but actually prepared by Zn reduction of $[ReCl_2(CNR)_3(PMePh_2)_2]^+$ in the presence of traces of water, have been reported as fully characterized compounds and compared with analogs of other metals, for example, Mo, W, and Fe. The simplest aminocarbyne has also been characterized in $[ReCl(\equiv CNH_2)(dppe)_2]BF_4$ as prepared from the parent CNH or CNTMS complexes.

The crystallographic data also stresses the important carbenic character of the aminocarbyne–metal bond (Re=C=NHR) inasmuch as the NHR group is planar and the C–N bond distance is appropriate for a C=N bond. The chemistry of aminocarbynes has been thoroughly reviewed.[190]

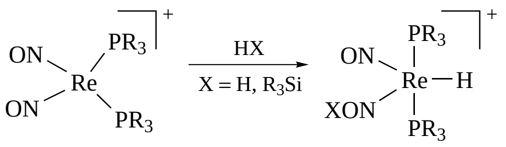
Protonation of the CNR ligand in complexes $Re\{N(CH_2CH_2S)_3\}(CNR)$ in aqueous HCl leads to the unprecedented transformation of CNR into CO producing $Re\{N(CH_2CH_2S)_3\}(CO)$ (R = *t*-Bu,CH_2COOEt). Again, the CNR ligand is strongly bent in these complexes and does not undergo nucleophilic addition at its C atom.[191]

13 CHEMISTRY OF Re NITROSYL COMPLEXES

The main role of the NO^+ ligand in organorhenium chemistry has been the replacement of CO in ML_nCO complexes to generate isoelectronic and isostructural metal nitrosyl complexes with one added unit of positive charge, for example, cationic $[ML_nNO]^+$ species. The effect of the π-acidity of NO^+ and an increased positive charge of the complex strongly activates the unsaturated ligands toward nucleophiles. The results of these effects are evident in the differences between the chemistries of $ReCp(CO)_2$ and the fragments $[ReCp(CO)(NO)]^+$ or $[ReCp(NO)(PPh_3)]^+$. In fact, while the alkenes in $[ReCp(CO)_2(\eta^2\text{-alkene})]$ undergo an electrophilic attack, in $[ReCp(NO)(PPh_3)(\eta^2\text{-alkene})]^+$ the reverse reaction, that is, nucleophilic addition, is observed. A complementary example of these ideas has been developed by Wieghardt from the systems $[Re(tacn)(CO)_3]^+$ (**159**) and $[Re(tacn)(CO)_2(NO)]^{2+}$ (**160**), which display a reactivity parallel to both isoelectronic cyclopentadienyl congeners. Complex (**159**) generates $[Re(tacn)O_3]^+$ with H_2O_2, and (**160**) reacts with $NaBH_4$ to give racemic $[Re(tacn)(CO)(NO)CH_3]^+$ (**161**), which has been resolved into its pure enantiomers.

The most useful precursors are the dimers $[ReCl_2(CO)_2(NO)]_2$, (**162**) $ReCl_2(OR)(PPh_3)_2(NO)$ (**163**), and $ReH_2(PPh_3)_3(NO)$ (**164**). Substitution or addition reactions on (**162**) give the dibromide, diiodide, and β-diketonate derivatives, $ReCl_2(CO)_2L(NO)$, $ReCl_2(CO)L_2(NO)$ complexes with a variety of two-electron ligands, L, and $ReR_2(CO)L_2(NO)$ (R = H, Me).[192]

Cationic complexes of formulae, $[Re(NO)XL_3(CO)]^+$ and $[Re(NO)L_4(CO)]^{2+}$ as well as the triflates $Re(NO)L_2(CO)(OTf)_2$ are obtained upon halide abstraction from $ReCl_2(CO)L_2(NO)$.[193]



Scheme 35

Complex (**163**) reacts with other L ligands to give $ReCl_2(PPh_3)_2L(NO)$ and with $NaBH_4$ to afford (**164**). This latter compound reacts with CO to give $Re(CO)_2(PPh_3)_2(NO)$. With strong protic acids HX, in ROH, reaction of (**164**) forms $ReH(OR)(CO)(PPh_3)(NO)$ ($X = ClO_4$) and $ReHF(CO)(PPh_3)_2(NO)$ ($X = BF_4$). The spectroscopic and chemical properties of $ReH_2(NO)(CO)(PR_3)_2$ and similar complexes has been thoroughly studied by Berke. The high-yield synthesis of $[ReBr_5(NO)][NEt_4]_2$ provided the most recent entry to the chemistry of NO containing hydrides in several oxidation states. $Re(\eta^2\text{-}H_2)Br_2(NO)(PR_3)_3$, $ReH(BH_4)(NO)(PR_3)_2$, $ReH_2(NO)(PR_3)_3$, and $ReH_4(NO)(PR_3)_2$ $[ReH_3(NO)(PR_3)_2]^-$ are interrelated by simple chemical transformations (R = *i*-Pr, Cy). Reaction of $ReH(BH_4)(NO)(PR_3)_2$ with $NOBF_4$ leads to $ReH(NO)_2(PR_3)_2$ via the isolable intermediate $ReH(NO)(NOBF_3)(PR_3)_2$ (**165**).[194]

In most of the chemistry of the NO complexes, its influence has been considered as stemming from its outstanding π-acidity and from its noninnocent behavior as either a one (bent) or three (linear) ligand. However, (**165**) clearly reveals the Lewis basicity of the O atom of the NO ligand that is also shown to engage in hydrogen bonding with Re–H bonds.[61]

Indeed, the complexes *trans*-$Re(NO)(CO)_2(PR_3)_2$ are protonated by HCl at the NO to give the nitroxyl derivatives *trans*-$ReCl(HN{=}O)(CO)_2(PR_3)_2$ that are reversibly deprotonated by N-bases. This allowed the study of the properties of coordinated nitroxyl, a most unstable molecule.[195]

NO induces a strong hydridic polarization of the Re–H bond in nitrosyl hydrides, the 'nitrosyl effect'. The conjugation of these properties enables them to perform the heterolytic cleavage of H_2 and R_3Si–H bonds as depicted in Scheme 35 as well as the insertion of Re–H bonds into polar unsaturated organic substrates.[196]

A bent NO adduct of $ReCp^*_2$ is in agreement with the expected coupling of two radicals to form a two-electron Re–NO bond.[141]

The thionitrosyl $[Re(CO)_5(NS)]^{2+}$ adds halides to give $[Re(CO)_5(NSX)]+$ (X = F, Cl, Br).[197]

14 POLYNUCLEAR Re ORGANOMETALLIC COMPLEXES

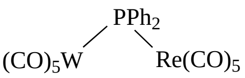
Besides the classical donor atoms, C, O, N, P, S, and the halides, Re forms organometallic complexes containing practically all other metals and *Metalloids*, a class that may be broadly classified under the heading of *Polynuclear Complexes*. The number and structural variety of these species is overwhelming and has grown dramatically, along with the development of X-ray diffraction techniques as the ultimate tool for the characterization of often totally unexpected and/or new bonding modes and structural arrangements. The progress of the Re–CO cluster chemistry (Section 3.2) is paradigmatic. Among the several existing possibilities of subclassifications within this class of compounds, the existence of direct Re–M′ bonds (M′ = main group or d or f transition element) is adopted below. This classification has, however, rather weak boundaries. In fact, some Re–M′ bonds may be only formal or simply required by the *Effective Atomic Number Rule*, and complexes that have no such bonds may readily form them by simply losing a ligand, sometimes in a facile or reversible manner. Because of the extreme variety of compounds, only a few selected examples, mainly from the more recent literature, are presented. The use of other reviews is absolutely necessary to cover this field.[2–7]

14.1 Organometallic Polynuclear Re Complexes Containing Other Metals or Metalloid M′ without Re–M′ Bonds

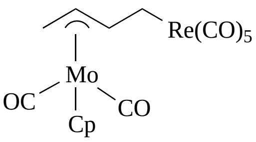
These types of complexes have the general formula L_nRe–Y–M′L'_n and at least one of the fragments is organometallic or the bridge has M–C bonds. They may be prepared in one of the following general, but not exclusive, ways: (1) a Re complex behaves as an electrophilic center for ligand substitution from an L'_mM′ complex bearing nucleophilic ligands; (2) nucleophilic addition of L_nRe to an unsaturated ligand on the M′ complex; and (3) addition of the ligands in L_nRe to L'_mM′. Examples of each type are mentioned along the preceding sections.

The complexes $Re(CO)_3(HM'(pz)_3)$ (M′ = B, Ga) represent a trivial example of the first situation. However, the use of transition metal complexes as ligands is currently receiving more detailed attention, because of the possibility of either tuning the reactivity of the Re in the resulting complex by means of the influence of M′ on the ligand or by obtaining cooperative reactivity between the two metal centers. Reaction of ferrocenyl derived ligands, for example, $Fe(\eta^5\text{-}C_5H_4PR_2)_2(FcPPh_2)$ with $[ReX(CO)_4]_2$ affords *fac*-$[Re(CO)_3Cl(FcPPh_2)_2]$. Upon ferrocene-based oxidation, the Re electronic density is lowered, as shown by the increase in the ν(CO) vibration frequencies. The use of anionic organometallic ligands is also exemplified by the formation of $[W(CO)_5(\mu\text{-}PPh_2)Re(CO)_5]^-$ (**166**) from $ReX(CO)_5$ and $[W(CO)_5(PPh_2)]^-$. A related example is the formation of $Re(CO)_5(\mu\text{-}O)Re(O)_3$ from $Re(CO)_5FBF_3$ and $ReO_4{}^-$. The second method exploits the high nucleophilicity of $[Re(CO)_5]^-$, which adds to organometallic cations with unsaturated ligands in a similar fashion to R^- or H^- as extensively studied by Beck. Examples are the formation of complex (**167**)

and analogs. The complexes formed from the ligands (**117**) and (**118**) are examples of the third method.



(**166**)



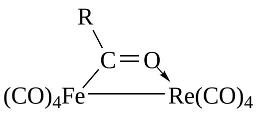
(**167**)

14.2 Organometallic Re Complexes Containing Re–M′ Bonds to Metals or Metalloid M′

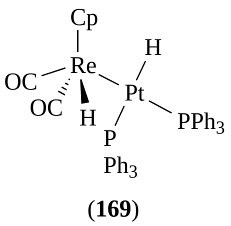
This class of compound has a very high number of representatives for two main reasons: (1) the interest in cluster chemistry and the study of the systematic pathways for their construction; and (2) the fact that many reactions initially give products without M–M′ bonds, but subsequently form M–M′ bonded species to compensate for electronic deficiencies.

The extreme complexity of boron chemistry provides a wide variety of B–Re bonds, from simple $[Re(BH_3)(CO)_5][NEt_4]$ to more complex examples as (**138**) and (**139**).[2,3] Simple acid-base addition from $ReCp_2H$ to $AlMe_3$ gives an adduct with a Re–Al bond, while with Cu^I a tetranuclear species is formed. Reaction of Ga and In metals or compounds with $Re_2(CO)_{10}$ produce high nuclearity clusters.[2,52] ReM′ (M′ = Zn, Cd, Hg), as in $[Re(CO)_5]_2M'$, are well known. With the group 14 elements, many compounds are known. Oxidative addition of R_3M'–H bonds to $ReCp(CO)_3$ under photolysis gives $ReHCp(CO)_2(M'R_3)$ (M′ = Si, Ge, Sn). A number of Ge and Sn compounds of type $Re(CO)_5(M'R_3)$ and $Re(CO)_3(\alpha\text{-diimine})(M'R_3)$ have been prepared from $[Re(CO)_3L_2]^-$ and $M'XR_3$ and their photophysics have been studied.[2] However, the most varied class of Re–M′ bonded complexes concerns the transition metals M′. According to Roberts and Geoffroy, these complexes are prepared by 17 synthetic methods divided into four main reaction categories: ligand substitution, addition, condensation, and bridge-assisted reactions.[2] This phenomenological classification does not account for mechanistic distinctions within each subcategory.

The use of carbonylate anions as nucleophiles in substitution reactions at metals has been used for a long time to prepare other Re–M′ metal-bonded derivatives, for example, $ReCo(CO)_9$ from $[Re(CO)_6]^+$ and $[Co(CO)_4]^-$ and (**168**) from $[ReBr(CO)_4]_2$ and $[Fe(CO)_4\{C(O)R\}][NMe_4]$.[198]

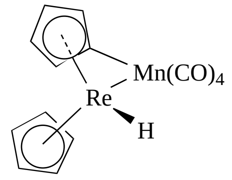


(**168**)



(**169**)

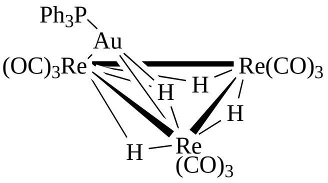
Addition of a metal fragment across a M–M or M–ligand bond is a very general and usually predictable method of preparing M–M′ bonded complexes. Among the latest Re complexes prepared by this method, (**169**) displays a rather interesting chemistry, hydrogenating alkynes to alkenes and providing the best route, so far, to $ReCp(CO)_2(\eta^2\text{-alkene})$ complexes. The mechanism of this kind of rare, effective cooperative catalysis in heterobimetallic complexes has been studied in detail.[199] The third general pathway, condensation reactions, forms a M–M bond through the elimination of a small molecule. Alkane elimination is quite useful and a classical example in Re chemistry is the formation of (**170**) from $ReCp_2H$ and $MnMe(CO)_5$ under elimination of CH_4.



(**170**)

A more straightforward elimination is observed in the reaction of $MCp_2(THF)Me$ and $ReH_7(PPh_2)_2$ (M = Y, Lu), which gives $MCp_2(THF)(\mu\text{-}H)_2ReH_4(PPh_3)_2$. In this case, there is no M–M′ bond, although a close M–Re distance is measured.[200]

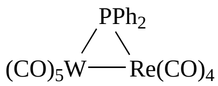
H_2 elimination is involved in the formation of $(PhMe_2P)_3(CO)ClRe(\mu\text{-}H)Au(PPh3)$ with a rare Re–Au bond.[201] Polyhydrides react with unsaturated metal fragments to originate polynuclear complexes by addition, substitution with H_2 elimination, or redox processes. H_2 elimination accompanies the reaction between (**28**) and $[IrH_2(Me_2CO)_2(PPh_3)_2]^+$ to give $[(PPh_3)_2H_3Re(\mu\text{-}H_3)IrH(PPh_3)_2]^+$. (**171**) represents the product of the addition of $[AuPPh_3]^+$ to $[Re_3H_4(CO)_9(PPh_3)]^-$.[202]



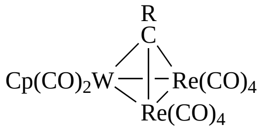
(**171**)

The central issue of the bridge-assisted mechanism is the presence of a ligand that brings the two metals together and favors the M–M′ bond formation by occupying a bridging position in the final product. The complex (**166**) is 'en route' to this mechanism and upon loss of a Re-bound CO forms a Re–W bond (**172**). Very important cases of the bridge-assisted M–M′ bond formation are the addition of $M'L_n$ fragments to $M{=}CR_2$ and $M{\equiv}CR$ fragments. This method

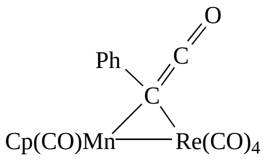
provides the rationale for the construction of clusters with many metal combinations containing bridging carbene and carbyne ligands. Addition of $Re_2(CO)_{10}$ to $WCp(CO)_2(C{\equiv}Ar)$ (**173**), commonly used for this purpose, gives (**174**). However, again depending on the lability of the metal centers involved, reaction of (**173**) with $Re_2(\mu\text{-H})(\mu\text{-CH=CHBu})(CO)_8$ gives higher nuclearity structures due to the facile loss of 1-hexene. $[ReCp(CO)_2(\equiv CAr)]^+$ has been used for the construction of related clusters. Nucleophilic addition of a wide range of metal-carbonylate anions to the alkylidyne C atom of this very sensitive and reactive cation, at low temperatures, is followed by rearrangements producing a variety of clusters with Re–M′ bonds. Carbonylates include, for example, $[M(CO)_5]^-$ (M = Mn, Re), $[Co(CO)_4]^-$, $[CpM(CO)_3]^-$ (M = Mo,W), $[CpFe(CO)_2]^-$, and some of the complexes formed are depicted in (**175–177**).



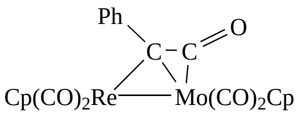
(**172**)



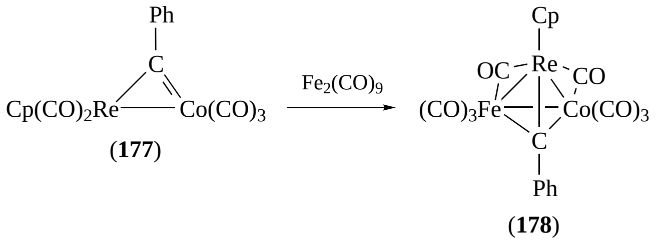
(**174**)



(**175**)



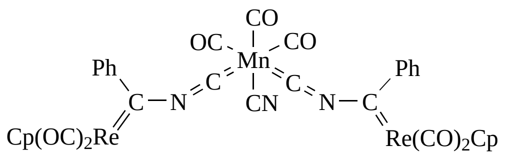
(**176**)



(**177**) (**178**)

Further reactions of these complexes lead to higher nuclearity clusters, for example, (**178**).

Reactions with carbonylate dianions, for example, $[W(CO)_5]^{2-}$, $[Fe_2(CO)_8]^{2-}$, and others, also produce a rich cluster chemistry. Ligands other than CO can be included in the carbonylate anions, for example, NO, PR_3, SR, SCN, NCO, and CN increasing the scope of cluster derivatization of these synthetic procedures as in (**179**).[203]



(**179**)

Of particular interest has been the study of Pt_xRe_y clusters due to their importance in petroleum refining where the Re seems to counteract the formation of unreactive coke, which poisons the Pt catalyst. A review covers this chemistry and structures (**180–183**) represent some examples.[204]

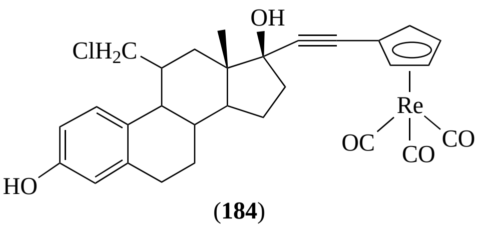
15 BIOORGANOMETALLIC CHEMISTRY OF RHENIUM

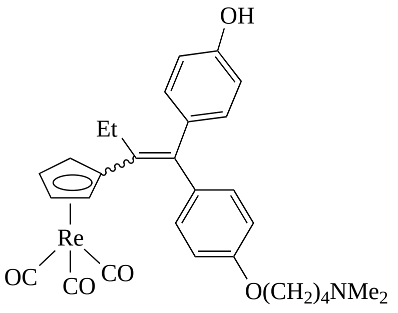
This fascinating and fast growing field, already amply reviewed,[205–209] takes advantage of the properties of a wide number of organometallic complexes using them as tools for biological applications. These range from metal immunoassays to drugs, radiopharmaceuticals for imaging and therapy passing through applications in peptide synthesis and peptide marking for X-ray diffraction, electronic microscopy, and other purposes. In the case of Re, one of the earliest examples was the condensation of Lukehart's rhenametalla-β-diketones (Scheme 13) with aminoacids to produce α-ketoimine complexes and, therefore provide for amino protection of those aminoacids. Later on, Jaouen and collaborators realized that the high stability of many CO-containing organometallics to air and to physiological conditions enabled their use in the carbonylmetalloimmunoassay (CMIA) technique. Taking advantage of their extremely intense CO vibrations in the IR region (1900–2100 cm^{-1}) where biological molecules do not absorb, steroids, hormones, or drugs labeled with $M(CO)_n$ fragments can be detected by FTIR in the 10^{-12} M range and are well recognized by their antibodies.

CMIA avoids radioisotopes and allows simultaneous parallel assays.[210]

The CMIA work with steroids marked with $Re(CO)_3$ led to the early recognition of the potential of this class of compounds for the diagnosis and therapy of steroid receptor-positive breast cancer. Complex (**184**) shows higher binding to estrogen receptors than the parent steroid. Complex (**185**) also binds to the tamoxyfen receptor and shows an antiproliferative action comparable to hydroxytamoxifen, a potent breast cancer drug.[211]



(**184**)

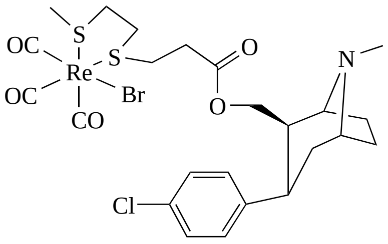


(**185**)

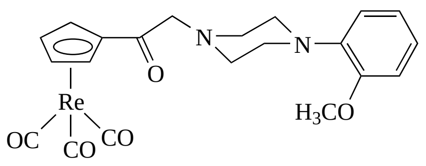
This great ability to selectively target metal pharmaceuticals has led to the possibility of using radioactive compounds to deliver radiation in specific receptors, tissues, organs, or cancer sites. The γ-ray emission and short half-lifetime make ^{99m}Tc the preferred element for imaging, whereas β-emitting ^{186}Re (5 mm range) and ^{188}Re (11 mm range) are preferred for radiotherapeutic purposes (tissue destruction).

As a consequence, Re chemistry has grown parallel to that of Tc using both organometallic and classical coordination complexes. A target-specific radiopharmaceutical must possess high affinity for the selected target but not for others. The 'unnatural' character of organometallic compounds might create distinct advantages compared with 'natural' drugs, which are often subject to unwanted rapid metabolism in vivo. Furthermore, the complex must by thermodynamically and kinetically stable to avoid decomposition and allow for rapid clearance in vivo. This is an advantage of the *fac*-$Re(CO)_3$ core over other Re^{V} classical complexes since it is particularly inert specially when bound to a fac-tripodal ligand system (L_3 or Cp) with an overall octahedral geometry.

Therefore, the bioorganometallic Re complexes comprise two main classes: the $(CpX)Re(CO)_3$ derivatives where CpX represents the Cp ligand substituted with a bioactive molecule with or without an appropriate spacer, for example, a steroid, a protein, a peptide; the *fac*-$Re(CO)_3L_3$ derivatives coordinated to classical N, P, O, S donors that may carry bioactive molecules of the types described above. (**186**; TROTEC-1) is a tropane derivative with an extremely high affinity for human dopamine transporter and (**187**) has a high affinity for the serotonergic receptors.



(**186**)



(**187**)

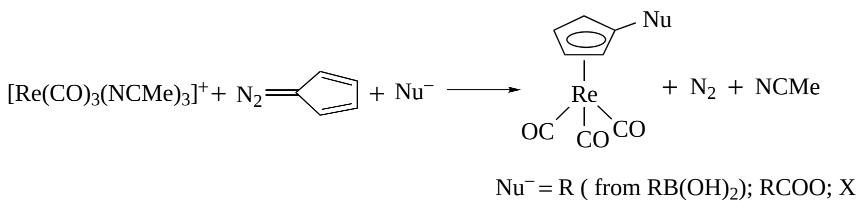
The synthesis of these complexes poses particular problems in the case of the $(CpX)Re(CO)_3$ derivatives because the methods to introduce delicate X functions either in a $CpRe(CO)_3$ complex or binding CpX to low-valent $Re(CO)_3$ precursors like (**1**) or $ReX(CO)_5$ require multistep procedures and/or reaction conditions incompatible with the presence of sensitive X groups. The situation becomes even more difficult when dealing with radioactive isotopes where fast, high-dilution and high-yield methods, and aqueous saline solutions are required.

This situation spurred the search for a number of alternative synthetic methods that have opened new avenues in the field of Re (and Tc) organometallic synthesis.

Still on classic grounds, the use of fulvenes or McMurry coupling to cymantrene ketyl to introduce substituents to the Cp ring in a mild fashion has produced several biologically labeled derivatives.[212]

Among several other methods, Katzenellenbogen developed one-pot reactions of three components like the one in Scheme 36.[213] Alternatively, $(CpX)SnBu_3$ can be generated and reacted in situ with $[Re(CO)_3Br(THF)]_2$.

A major development was introduced by Alberto with the generation of the $Re(CO)_3$ moiety in aqueous solution from $[ReO_4]^-$, BH_3, and 1 atom of CO. The resulting $[Re(CO)_3X_3]^{2-}$ (X = Cl, Br) is easily transformed into $[Re(CO)_3L_3]^+$ (L = NCMe, H_2O). Treatment of aqueous $[Re(CO)_3(H_2O)_3]^+$ with $[CpX]^-$ at pH 7.4 gives

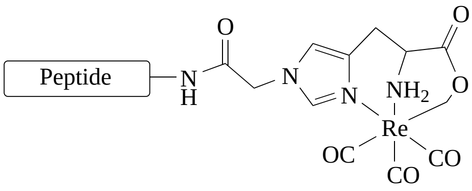


Scheme 36

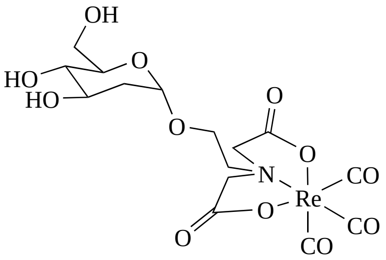
(CpX)Re$(CO)_3$ where X is an acyl group (–COR) in which R carries the biomolecules of interest to target the $Re(CO)_3$ fragment to the required biological site.[214] The so-called double-ligand-transfer reactions also provide a mild synthesis of (CpX)Re$(CO)_3$ derivatized with biomolecules.[215]

Labelling of proteins and peptides with CpRe$(CO)_3$ fragments can be made by peptide bond formation with the carboxylic acid Re(CpCOOH)$(CO)_3$ or by acylation of free amine groups with organometallic succinimidyl esters.

Among the $[Re(CO)_3L_3]^+$ complexes bearing ligand systems (L_3) functionalized with biomolecules, recent advances include fatty acids attached to Schiff-base ligands for myocardial investigations,[216] peptides attached to histidine complexes,[217] (**188**) or glucose derivatives (**189**).[218] Luminescent complexes $[Re(CO)_3$(N-N)(Py-spacer-biomolecule)$]^+$ are powerful fluorophores for bioassays since the biomolecule does not interfere negatively with the luminescence from the metal fragment.[42]



(**188**)



(**189**)

Organometallic compounds appear to be a serious alternative to state-of-the-art labeling techniques as shown in the ongoing preclinical and clinical studies with organometallic-labeled tumor affine peptides and single-chain antibody fragments.[219]

Glossary

Aqua regia: literally 'royal water', so called because it will dissolve gold; a mixture of three parts concentrated hydrochloric acid to one part concentrated nitric acid
Corundum structure: α-aluminum oxide structure
Electrochemical oxidation: oxidation of a solute by passing a direct electrical current through its solution (e.g. chlorine is produced industrially by the electrochemical oxidation of the chloride ion)
Ilmenite structure: the structure of the mineral $FeTiO_3$
Metathetical reaction: a common type of reaction, also known as a double decomposition reaction, in which the anions and cations of the reactants are interchanged in the products (e.g. $AX + BY \leftarrow AY + BX$)
Perovskite structure: the structure of the mineral $CaTiO_3$
Platinum metals: the six platinum metals are ruthenium, rhodium, palladium, osmium, iridium, and platinum
Radiolysis: decomposition of a compound by ionizing radiation such as X- or γ-rays or α-particles
Rutile structure: the structure of the mineral rutile, a form of TiO_2
Spinel structure: the structure of the mineral spinel, $MgAl_2O_4$
Zone refining: a modern method of refining where a narrow ring furnace melts a thin disk in a vertical rod of impure material under an inert atmosphere. Impurities are more soluble in the melt, and as the ring furnace traverses the rod the impurities are swept to the end for eventual discard. The process may be repeated until the desired degree of purity has been achieved

1 INTRODUCTION

Rhodium, a relatively rare and expensive metal, is hard, lustrous, high melting, and difficult to work. It is also resistant to chemical attack and its nobility is reflected both in the small number of binary compounds it forms and the ease with which several of these revert to the element.

The main application of rhodium is the production of catalytic alloys with other platinum metals. These alloys are used to reduce the emission of pollutants from automobile exhausts and to catalyze the formation of nitric acid from ammonia.

Despite its few binary compounds, the element gives rise to many complexes. Table 1 indicates the diversity of complexes formed. Several low oxidation state complexes of the element are important homogeneous catalysts, particularly in the oligomerization, isomerization, *Hydrogenation*, *Hydroformylation*, *Hydroboration*, or *Hydrosilation* of alkenes. Iodorhodium complexes catalyze the industrial-scale carbonylation of methanol to acetic acid.

Rhodium compounds are somewhat toxic and have been used in oncological chemotherapy, but they are less effective than platinum complexes. The expense and rarity of rhodium means that it is rarely a significant pollution hazard, particularly as it is of low inherent toxicity. The occupational exposure limit to dust is $1 mg m^{-3}$ and the LD_{50} for oral ingestion is $200\,mg\,kg^{-1}$ for several species. At these levels, rhodium and its compounds exhibit weak carcinogenicity and adverse reproductive effects have been observed.[1] Nevertheless, rhodium dust and water-soluble rhodium compounds are now found at roadsides as a result of erosion of automobile emission control catalysts.

The inorganic chemistry of rhodium is concerned principally with the complexes in which the element exhibits the oxidation states of I, II, or III, of which Rh^{III} is most common. Oxidation states of −I, 0, IV, and V are rare.

Table 1 Representative rhodium complexes

Oxidation state	d^n	Typical ligands	Examples	Geometry	Comments
−I	d^{10}	PF_3	$[Rh(PF_3)_4]$	Tetrahedral	Rare
0	d^9	PF_3	$[Rh_2(PF_3)_8]$	Linked TBP	Very rare
I	d^8	PR_3	$[RhCl(PPh_3)_3]$	Square planar[a]	Ubiquitous
		dppe	$[Rh(dppe)_2]X$	Square planar	Uncommon
		H, PR_3	$[RhH(PPh_3)_4]$	Monocapped tetrahedron	Common
		$P(OAr)_3$	$[Rh\{P(OAr)_3\}_5]X$	TBP	Uncommon
II	d^7	Cl, PR_3	$[RhCl_2(PCy_3)_2]$	Square planar	Rare
		RCO_2^-, L	$[Rh(O_2CR)_2py]_2$	Lantern[b]	Common
III	d^6	H, PR_3	$[RhH_2Cl(PPh_3)_2]$	Square pyramid	Uncommon
		NH_3, H_2O,	$[Rh(NH_3)_6]^{3+}$	Octahedral	Ubiquitous
		Cl, Br	$[RhCl_6]^{3-}$		
		ox^{2-}, en	$[Rh(ox)_3]^{3-}$		
IV	d^5	F, Cl	$[RhF_6]^{2-}$	Octahedral	Rare
V	d^4	F	$[RhF_6]^-$	Octahedral	Very rare

[a]Distorted. [b]Octahedrally coordinated rhodium.

Rhodium(III) complexes typically contain ammine, halo, or aqua ligands, or the important bidentate ligands 1,2-diaminoethane (en), oxalato, or pentane-2,4-dionato (acac) and are invariably octahedral. Their wide variety is in part a reflection of the slow reactions, which take place at the low-spin d^6 centers, which allow many intermediates, and geometrical or chiral isomers, to be isolated. It is fairly difficult to oxidize rhodium(III) complexes, but they may be reduced to rhodium(I) species in the presence of suitable ligands. However, there is little current work being carried out on the classical rhodium(III) complexes and even less on the higher oxidation states.

The +1 oxidation state has gained importance in the 40 years since its catalytic properties were discovered (*see* ***Rhodium: Organometallic Chemistry***). All isolable Rh^I complexes contain at least one *π-Acid Ligand*, which serves to protect the complexes against aerial oxidation or disproportionation. Reaction of Rh^IL_4 with H_2, HCl, MeI, or Cl_2 (= XY) often occurs via an *Oxidative Addition* reaction, to give rise to $Rh^{III}L_4XY$. Only powerful reducing agents such as potassium amalgam are capable of reducing rhodium(I) complexes.

Dimeric carboxylato complexes comprise virtually all the examples of rhodium(II) complexes. These species, of general formula $[Rh(O_2CR)_2L]_2$, adopt the lantern structure. Four carboxylato ligands bridge the two rhodium atoms; these bridges are supplemented by a single rhodium–rhodium bond. The neutral ligands take up the axial positions to complete the octahedral coordination around the rhodium(II) ion. Apart from metathetical reactions involving either carboxylate or axial ligands, the structure is quite stable and the complexes are neither readily oxidized nor reduced.

As noted above, the other oxidation states are not well represented; the −1 and zero oxidation states are exemplified by $[Rh(PF_3)_4]^-$ and the very similar $[Rh_2(PF_3)_8]$, respectively.

Apart from a few ill-defined oxo species, octahedral hexafluororhodates comprise the bulk of the rhodium(IV) and -(V) complexes isolated.

The key reviews of the inorganic chemistry of rhodium and its complexes are now over a decade old.[2,3] With the possible exception of Griffith's book,[4] earlier reviews usually predate the discovery and application of the important low oxidation state complexes. The reader is referred to these[2–4] for more detailed coverage and references.

2 THE ELEMENT AND ITS BINARY COMPOUNDS

2.1 Occurrence and Applications

Rhodium occurs only to the extent of 10^{-9}% in the earth's crust. Fortunately, it is not evenly distributed, but is found, alloyed with the other platinum metals, to the extent of a few ppm (several grams per tonne) in its ores. The principal locations of these ore bodies are in the Urals near Ekaterinburg (the earliest commercial source) and in the Merensky reef near Pretoria in the Republic of South Africa. The latter is the major source today. Minor sources are found in North America and Zimbabwe. Many platinum metal resources, such as that at Sudbury in Ontario, contain very little rhodium. Various other minor sources are known, and in fact the element was first isolated by Wollaston in 1804 from impure platinum of South American origin.

Rhodium is separated from the other platinum metals either by classical chemical methods or, more recently, by solvent extraction. The latter has the advantage of a more rapid separation, which is financially advantageous with such expensive materials.

The world's supply of rhodium is in approximate balance with demand with erratic releases onto the world market from Russia being counterbalanced by national and industrial stockpiles. These fluctuations in availability are reflected in the spot price, which fell from US\$64 g^{-1} at the millennium to US\$17 g^{-1} by 2001. The current price in 2004 is US\$26 g^{-1}. Of the 2002 world production of 19.0 tonnes and recovered scrap from automobile catalysts of 3.1 tonnes, over 80% was used as rhodium alloy catalysts for automobile emission reduction. The rhodium component is vital in controlling NO_x emissions and looks set to increase in order to meet higher emission control standards.

Gauzes made from a similar alloy catalyze the oxidation of ammonia to nitric acid and represent the second most important application of the metal. Rhodium dies are used in the drawing of glass fibers. Each of these applications uses about 7% of annual metal production. The traditional rhodium/platinum thermocouple or furnace winding applications or electroplating other metals to increase their tarnish resistance or decrease their electrical contact resistance now account for merely 1% of the supply. Rhodium targets in the X-ray tube of X-ray fluorescence spectrometers are probably responsible for erroneous reports of rhodium in archeological samples. Erosion of catalytic gauzes and of thermocouples at high temperatures results in substantial irrecoverable losses. Nevertheless, rhodium is routinely recovered from virtually all materials.

Rhodium compounds and complexes are also commercially important catalysts. The hydroformylation of propene to butanal (a precursor of *bis*(2-ethylhexyl) phthalate, the PVC plasticizer) is catalyzed by hydridocarbonylrhodium(I) complexes. Iodo(carbonyl)rhodium(I) species catalyze the production of acetic acid from methanol. In the fine chemical industry, rhodium complexes with chiral ligands catalyze the production of L-DOPA, used in the treatment of Parkinson's disease. Rhodium(II) carboxylates are increasingly important as catalysts in the synthesis of cyclopropyl compounds from diazo compounds.[5] Many of the products are used as synthetic, pyrethroid insecticides. Hexacyanorhodate(III) salts are used to dope silver halides in photographic emulsions to reduce grain size and improve gradation.

There is little doubt that the catalytic properties of low-valent rhodium compounds have provided the driving force for the rapid expansion of interest in rhodium chemistry over the last four decades.

2.2 The Element

Rhodium was named by Wollaston after its rose colored salts. The hard, silvery, lustrous metal has a specific gravity of 12.41 and crystallizes in the face-centered cubic system (a = 3.803 Å). Modern work implies that there is no change in structure up to the melting point of 1960–1970 °C. Despite this structure, it is difficult to cold work and the rate of work hardening is high, although less so than for either osmium or iridium. It is best worked at 1200 °C.

Modern values for its physical properties are the more reliable since rhodium is difficult to obtain in a highly pure state because of reactions with refractory containers at or near its melting point. The purest samples have been obtained by zone refining. The differing standards of purity can be seen in the range of boiling points (3700–4500 °C) quoted.

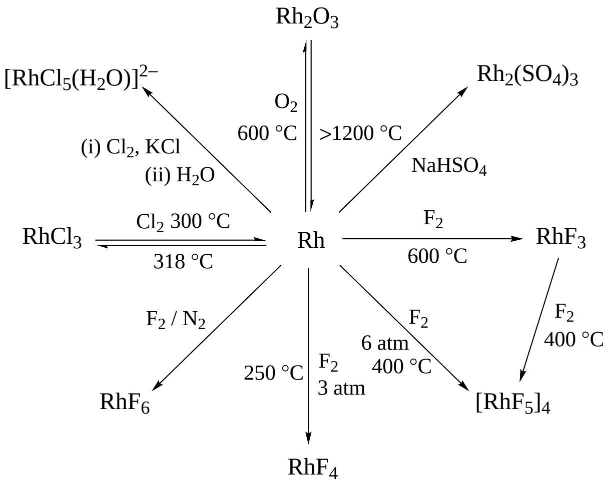
Numerous isotopes of rhodium are known, but only ^{103}Rh is stable. The short half-lives of the remainder mean that few radiochemical applications exist. The heavy isotopes of the element feature among the fission products of uranium and the transuranic elements; they can also be made by neutron irradiation. Light isotopes result from α-bombardment of the metal, and those of high neutron deficiency from bombardment by very heavy ions.

The atomic mass of the single stable isotope is 102.9055. This has a nuclear spin of 1/2, which has proved invaluable in the NMR spectrometry of its diamagnetic complexes.

The *Ground-State* electronic configuration is [Kr]$4d^8 5s^1$. The first, second, and third ionization energies are 7.46, 18.1, and 31.1 eV, respectively.

The massive metal is inert, but very finely divided forms are more reactive, absorbing large quantities of either CO or H_2. While rhodium black or rhodium sponge dissolves in aqua regia or aqueous chlorine under pressure, larger pieces must be fused with sodium hydrogen sulfate to effect dissolution.

At 600 °C the metal reacts with oxygen to form Rh_2O_3, and with chlorine at 300 °C to form $RhCl_3$. The reaction is reversed at 318 °C without lower chlorides being formed.[6] Tri-, tetra-, penta-, or hexafluorides are formed by allowing the metal to react with fluorine under suitable conditions. Hexafluororhodates result from the action of fluorine in admixture with either oxygen or nitrosyl fluoride upon the metal (Scheme 1).



Scheme 1

Iodine vapor attacks the metal above 400 °C to form RhI_3. However, bromine gives an impure product. Pure $RhBr_3$ may be obtained by first allowing the metal to react with an HBr/Br_2 mixture and then brominating the first product at 400 °C.

2.3 Binary Compounds

The sesquioxide (Rh_2O_3) adopts the corundum structure at low temperatures and the perovskite structure at high temperatures. The latter form is usually obtained by heating the element or various compounds at 900–1000 °C. Prolonged heating of $Rh(NO_3)_3$ at 730 °C yields the low-temperature form.

If the sesquioxide is heated with oxygen under pressure, a dioxide is formed that has the rutile structure. Further heating causes reversion to the lower oxide, (equation 1).

$$Rh + O_2 \underset{1050\,°C}{\overset{600\,°C}{\rightleftharpoons}} Rh_2O_3 \underset{-O_2\ 850\,°C}{\overset{+O_2\ 35\,katm}{\rightleftharpoons}} RhO_2 \qquad (1)$$

Various 'rhodates' can be prepared by fusing Rh_2O_3 and other oxides or carbonates. The alkali metal compounds are of general formula M^IRhO_2 (MI = Li, Na, K). Spinels, $M^{II}Rh_2O_4$ (M^{II} = Be, Mg, Zn, Cd, Mn), can be made similarly, but this structure is not adopted by the alkaline-earth compounds, which are less well defined and of lower stability. Indium, yttrium, and lanthanoid rhodates, $M^{III}RhO_3$, have the perovskite structure, but $FeRhO_3$ has the ilmenite structure. Niobium or tantalum rhodates have the rutile structure.

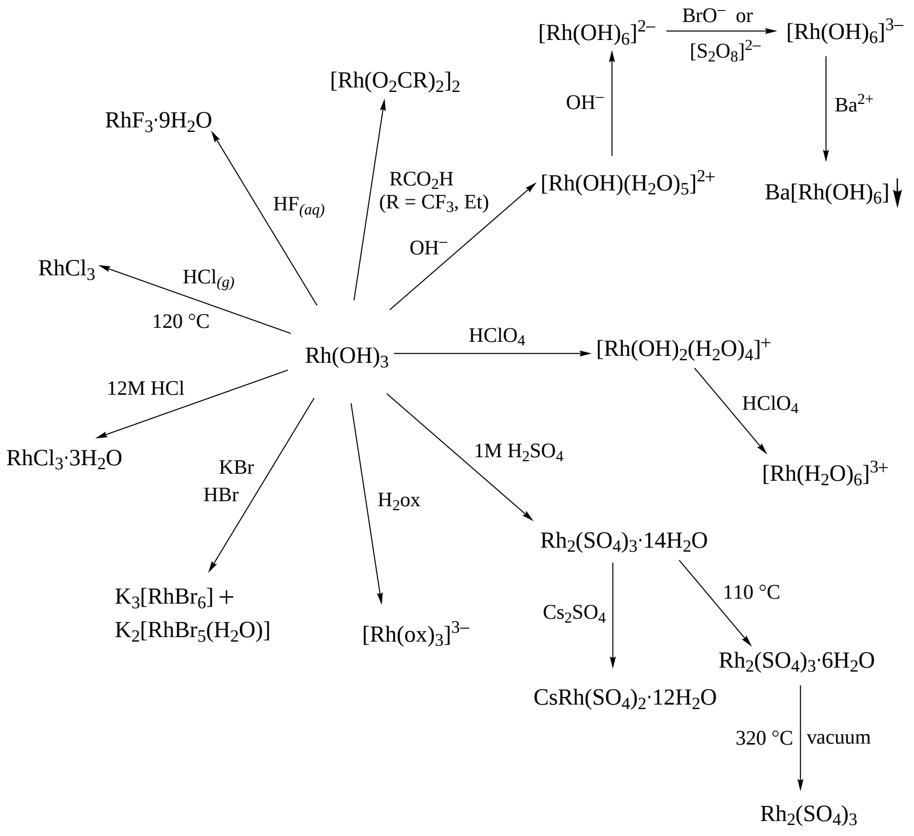
Rhodium(III) hydroxide can be prepared by carefully treating aqueous rhodium trichloride with sodium hydroxide. A purer product can be obtained by dissolving the impure hydroxide in chloric(VII) acid and then reprecipitating the lemon-yellow hydroxide with alkali. The hydroxide is an important source of hydrated binary compounds of rhodium (Scheme 2).

The rhodium/sulfur system is complex and the best defined sulfide is the black Rh_2S_3. This compound can be prepared by heating rhodium and sulfur and subliming the product at 1100 °C.

Similar complexities are found in the Rh/Z (Z = P, As) systems, where the RhZ_3 phases have been found to crystallize with the cobalt triarsenide structure.

As we saw in Section 2.2, the halides are usually prepared by direct interaction of the elements. All four trihalides are known, together with the tetra-, penta-, and hexafluorides. No lower, binary halides are known.

The anhydrous trichloride, obtained by direct combination of the elements is of little use as a starting material for



Scheme 2

the preparation of other rhodium compounds since it is insoluble. To obtain a more synthetically useful trichloride, finely divided rhodium is ground with NaCl and the mixture chlorinated at 550 °C. Leaching the product with water yields $Na_2[RhCl_5(H_2O)]$ (equation 2), from which $Rh(OH)_3$ may be precipitated by careful addition of alkali. Dissolution of the hydroxide in the minimum quantity of 12 M HCl produces a dark red material approximating to $RhCl_3{\cdot}3H_2O$ upon evaporation to dryness. This is the source of nearly all rhodium compounds and complexes (Scheme 3). Additionally, it reacts with CO or alkenes to provide the starting materials for a host of organometallic compounds.

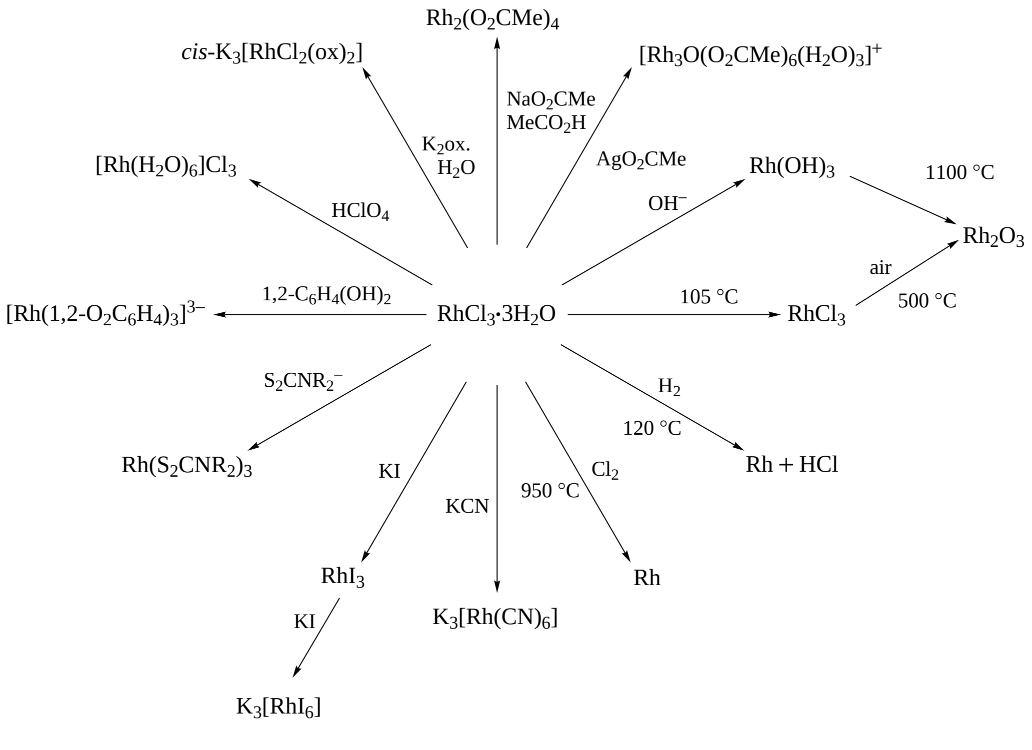
$$Rh + NaCl \xrightarrow[(ii)H_2O]{(i)Cl_2\ 550\,^{\circ}C} K_2[RhCl_5(H_2O)] \qquad (2)$$

3 THE LOWER OXIDATION STATES

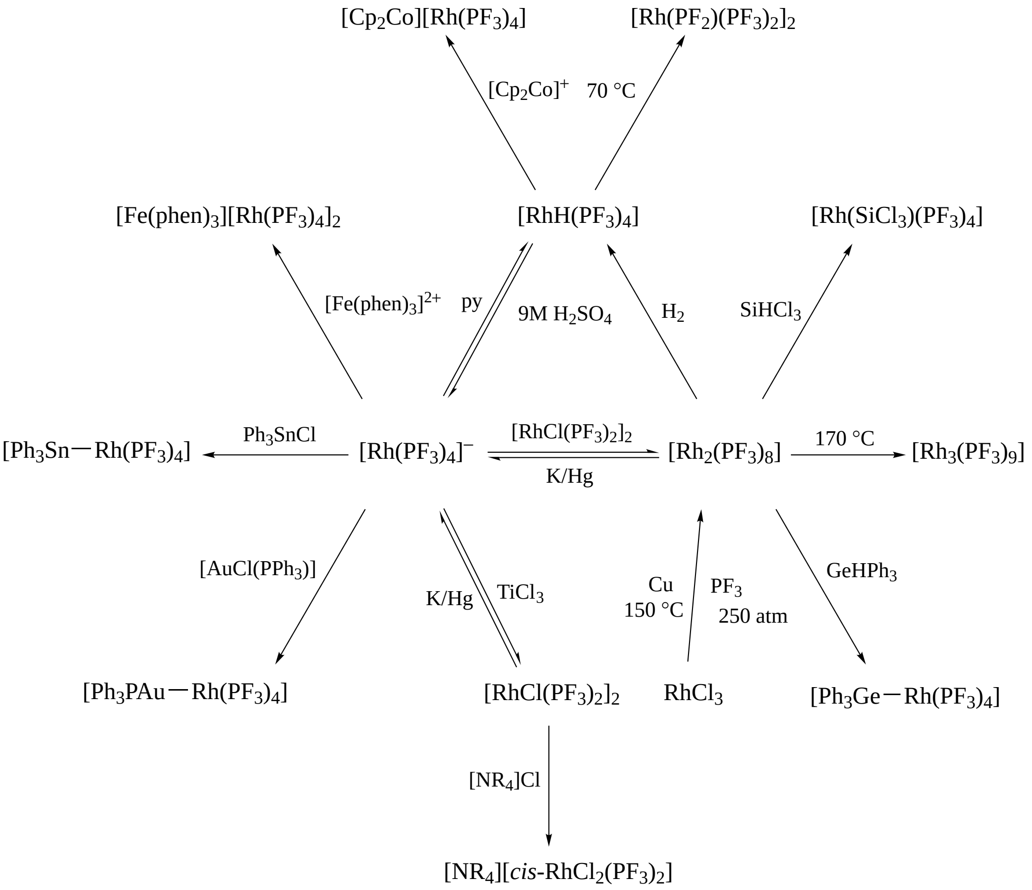
Apart from the many carbonyls, very few complexes exist in the lowest oxidation state Rh−I, and its chemistry is essentially that of the tetrahedral anion $[Rh(PF_3)_4]^-$. This ligand also gives rise to a rare, authentic example of a noncarbonyl rhodium(0) complex. Orange−red, dimeric $[Rh_2(PF_3)_8]$ contains a rhodium−rhodium bond and has trigonal bipyramidal geometry around each metal atom. It can be reduced to $[Rh(PF_3)_4]^-$, which is isoelectronic with tetrahedral $[Co(CO)_4]^-$. The PF_2NMe_2 analog of the anionic complex is known. Reports of (triphenylphosphine)rhodium(0) complexes should be treated with caution, although $[Rh(dppe)_2]$ can be generated electrochemically. Some reactions of these complexes are shown in Scheme 4. Their characteristic property is their ability to form bonds between rhodium and the Group 14 elements.

4 RHODIUM(I) COMPLEXES

The outstanding feature of rhodium(I) chemistry is the general tendency to prefer four coordination to five. Very few five-coordinate, 18-electron complexes of general formula $[RhXL_4]$ or $[RhL_5]X$ have been prepared. The vast majority of rhodium(I) complexes are four-coordinate, 16-electron species. Some are important homogeneous catalysts for a variety of processes including hydrogenation, hydroformylation, homologation, hydrosilation, hydroboration, isomerization, or decarbonylation. The complexes are aided in their catalytic activity by their facile oxidation to rhodium(III) species which in turn undergo *Reductive Elimination* reactions, thus closing the catalytic cycles. Their potential catalytic applications have led to many new rhodium(I) complexes being prepared over the last 25 years.



Scheme 3



Scheme 4

Stable rhodium(I) complexes usually require the presence of at least one π-acid ligand. The presence of bulky π-acid ligands tends to lead to coordinative unsaturation by ligand dissociation, which can enhance the catalytic activity. Tertiary phosphines meet both these requirements and have the added advantage of conferring solubility in organic solvents.

Although most rhodium(I) complexes in this section contain tertiary phosphines, there is an extensive chemistry of rhodium(I) with alkene or carbonyl ligands.

Anionic complexes are rare: there are a few containing PF_3 ligands and still fewer with PPh_3 ligands, and $SnCl_3^-$ forms the dimeric complex $[RhCl(SnCl_3)_2]_2^{4-}$.

4.1 Tricoordinate Complexes

All the isolable tricoordinate complexes such as $[RhX(PCy_3)_2]$ ($X = F, Cl, Br, I, N_3$), prepared via metathetical reactions of $[RhF(cod)]_2$, contain very large tertiary phosphine ligands. These complexes resemble transient intermediates in catalytic cycles. Triphenylphosphine complexes containing the large anionic ligands $N(SiMe_3)_2$ and $N{=}C(CF_3)_2$ are also known.

The 14-electron complexes are highly reactive and decompose even when stored in an inert atmosphere. They readily bind an additional small ligand. In particular, they react with dinitrogen under mild conditions. However, the dinitrogen ligand is easily lost and this property has been exploited in the preparation of other tricoordinate complexes (equations 3–5).

$$[RhF(cod)]_2 + 4PCy_3 \longrightarrow 2[RhF(PCy_3)_2]_2 \xrightarrow{NaX} [RhX(PCy_3)_2] \quad (X = Cl, Br, I, N_3) \qquad (3)$$

$$[RhX(PCy_3)_2] + L \longrightarrow [RhX(PCy_3)L] + PCy_3 \quad (X = Cl, L = SO_2; X = Cl, Br, I, L = N_2) \qquad (4)$$

$$[RhH(N_2)(PR_3)_2] \longrightarrow [RhH(PR_3)_2] + N_2 \quad (R_3 = Bu^t_3, Bu^t_2Ph) \qquad (5)$$

$$[RhCl(PPh_3)_3] + Tl[ClO_4] \longrightarrow [Rh(PPh_3)_3][ClO_4] \qquad (6)$$

There are several salts containing the $[Rh(PPh_3)_3]^+$ cation, such as the perchlorate, which can be obtained from

$[RhCl(PPh_3)_3]$ and $TlClO_4$ (equation 6). Another can be prepared similarly from Tl[*nido*-7-{1-*closo*-1,2-$C_2B_{10}H_{11}$}-7,8-$C_2B_9H_{11}$]. The crystal structures of the above complexes have been determined and both contain distorted T-shaped cations. The Rh−P bonds in the dicarbaborane complex are the longer.

The fluorocarbon acids $H_2C(SO_2CF_3)_2$, $PhCH(SO_2CF_3)_2$, $HN(SO_2CF_3)_2$, $H_2C(SO_2C_8F_{17})_2$, or $C_8F_7SO_3H$ also yield the appropriate $[Rh(PPh_3)_3]X$ salt when they react with hydridotetrakis(triphenylphosphine)rhodium(I). The stereochemically nonrigid cation readily coordinates an additional ligand.

4.2 Four-coordinate Complexes

This is by far the most populous subgroup of rhodium(I) complexes. The vast majority have the general formula $[RhXL_3]$, but two minor types also exist. The first contains a bidentate acido ligand; the second has bridging acido ligands. The complexes of bidentate acido ligands usually have rhodium bound to the two oxygen or sulfur atoms of the ligand, although some complexes of monothioanions are known where these ligands bind additionally through oxygen, nitrogen, or phosphorus. The complexes may be prepared either by cleaving bridged complexes (with or without bridge metathesis) or, more usually, by expelling the acido ligand and one neutral ligand from one of the numerous $[RhXL_3]$ complexes (equations 7–10).

$$[Rh(acac)L_2]_2 + 4PR_3 \longrightarrow 2[Rh(acac)(PR_3)_2] + 4L$$
$$(L = C_2H_4, R_3 = Ph_3, Ph_2Me; L = C_8H_{14}, R_3 = F_2NEt_2, F(NMe_2)_2) \quad (7)$$

$$[Rh(acac)(CO)_2] + 4PR_3 \longrightarrow [Rh(acac)(PR_3)_2] + 2CO$$
$$(R_3 = F_2NEt_2, F(NMe_2)_2) \quad (8)$$

$$[RhXL_2]_2 + 2acacH \longrightarrow 2[Rh(acac)L_2] + 2HX$$
$$(X = Cl, Br, L = P(OPh)_3; X = Cl, L = PF_2NEt_2) \quad (9)$$

$$[RhCl(PPh_3)_3] + M^IS_2Y \longrightarrow [Rh(S_2Y)(PPh_3)_2] + PPh_3 + M^ICl$$
$$(Y = PCy_2, P(OPh)_2, CNMe_2) \quad (10)$$

There are many examples of dimeric complexes containing bridging halo ligands. Phosphorus ligands of high π-acidity tend to form complexes of this type. Their presence so lowers the electron density on the metal that a second, weakly nucleophilic, halo ligand is coordinated. Ligands of lower π-acidity tend to cleave the bridged starting materials, particularly when present in excess. Dimeric alkene or carbonyl complexes are frequently used as the starting materials to prepare this type of complex, in which case the organo ligands are displaced in the following order: ethylene > cycloocta-1,5-diene > carbonyl. This order also reflects the variety of complexes that can be prepared from each precursor (equations 11–13).

$$RhCl_3{\cdot}3H_2O + PAr_3 \xrightarrow[78\,^\circ C]{EtOH} [RhCl(PAr_3)_2]_2$$
$$(Ar_3 = (C_6F_5)_3, Ph_2(C_6F_5), (C_6Cl_5)_3) \quad (11)$$

$$[RhClL_2]_2 + 4L' \longrightarrow [RhClL'_2]_2 + 4L$$
$$(L = C_2H_4; L' = P(4\text{-}C_6H_4Me)_3, PPh_2\{CH_2CH_2SiMe(OMe)_2\}, PF_2NMe_2, PF_2NEt_2; L = \tfrac{1}{2}cod, L' = P(OMe)_3, P(OPh)_3, PF_2(OPr); L = CO, L' = PF_3, P(OPh)_3, P(4\text{-}OC_6H_4Me)_3, P(4\text{-}OC_6H_4Cl)_3) \quad (12)$$

$$2[RhCl(PAr_3)_3] \underset{+PAr_3}{\overset{C_6H_6\ 80\,^\circ C}{\rightleftharpoons}} [RhCl(PAr_3)_2]_2 + 2PAr_3$$
$$(Ar = Ph, 4\text{-}C_6H_4Me) \quad (13)$$

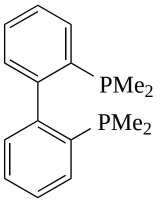
When $[RhH(PPh_3)_4]$ reacts with 4-methoxyacetophenoneanilide in dioxane, orange crystals of $[Rh(OH)(PPh_3)_2]_2$ can be isolated. The anionic complex $[RhCl(SnCl_3)_2]_2^{4-}$ can be prepared from tin(II) chloride and $RhCl_3{\cdot}3H_2O$. It is also possible to prepare this type of complex starting from $[RhXL_3]$ complexes, since the dimeric complexes are much less soluble than the monomers. This lower solubility may also assist the preferential isolation of dimers when hydrated rhodium trichloride reacts with certain tertiary phosphines in ethanolic solution. The halo complexes can serve as the starting materials for the preparation of many other rhodium(I) complexes (Scheme 5).

The structure of several dimers has been confirmed by X-ray crystallography. Unlike $[RhCl(CO)_2]_2$, they are not strongly puckered at the bridge; indeed, the central RhO_2Rh group of $[Rh(OH)(PPh_3)_2]_2$ is planar,[6] as is the $RhCl_2Rh$ core of $[RhCl(PPh_3)_2]_2{\cdot}$ $MeCO_2Et$.

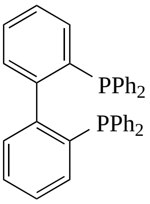
Halo-bridged, dimeric complexes containing bidentate neutral ligands may also be prepared, usually by displacement of organo ligands from dimeric complexes either by the bidentate ligand itself (equation 14) or by hydrogenation of a diene complex (equation 15). There is one instance of rhodium trichloride being reduced to a complex of this type.

$$[RhCl(cod)]_2 + (\mathbf{1}) \longrightarrow [RhCl(\mathbf{1})]_2 + 2cod \quad (14)$$

$$[RhL(cod)]Cl + 2H_2 \longrightarrow [RhClL]_2 + 2C_8H_{14}$$
$$(L = dppe, DIOP, \mathbf{2}) \quad (15)$$

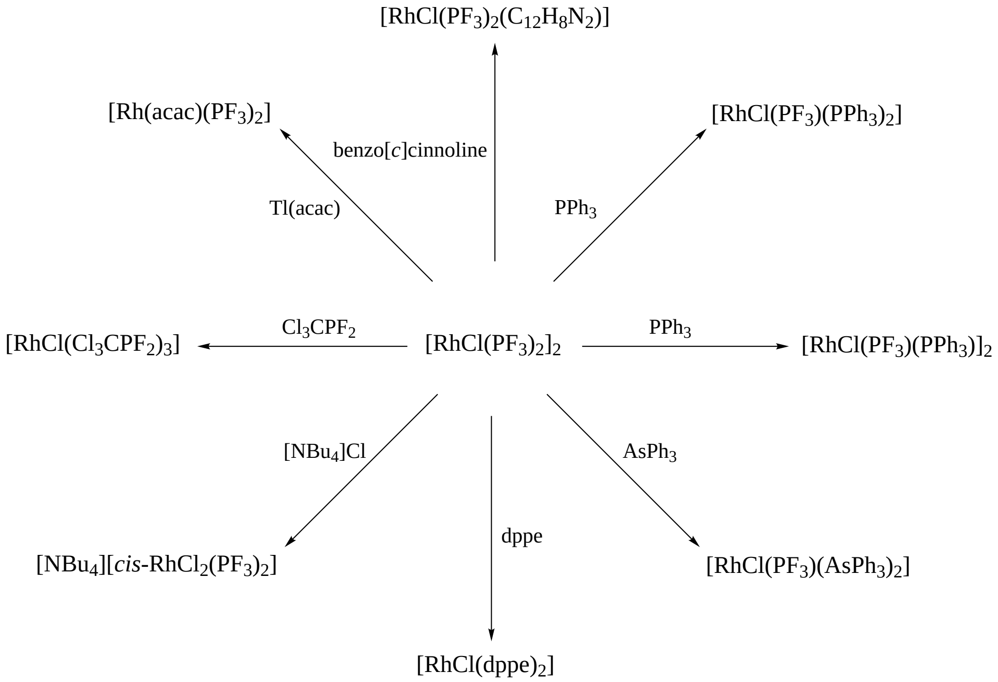


(1)



(2)

The $[RhXL_3]$ species are easily the most important rhodium(I) complexes because of the exceptional catalytic



Scheme 5

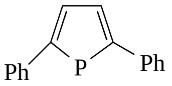
properties of *Wilkinson's Catalyst*, $[RhCl(PPh_3)_3]$, the first successful homogeneous hydrogenation catalyst for alkenes and alkynes. It was later shown to be effective for hydrosilation and decarbonylation reactions.[7]

Of the many different preparative methods known, the standard preparation of $[RhCl(PPh_3)_3]$ is not of wide applicability to other phosphines (equation 16). The best general method for $RhX(QR_3)$ ($Q = P$, As, Sb) is by displacement of alkene ligands from dimeric rhodium(I) complexes (equation 17). This method also avoids using rare and expensive tertiary phosphines as mere reductants.

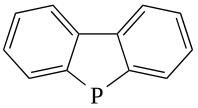
$$RhCl_3{\cdot}3H_2O + 6PPh_3 \xrightarrow[N_2]{EtOH\ 78\,^\circ C} [RhCl(PPh_3)_3] + OPPh_3 \quad (16)$$

$$[RhClL_2]_2 + 6L' \longrightarrow [RhClL'_3] + 4L$$

($L = C_2H_4$; $L' = PPh_3$, $P(4\text{-}C_6H_4OMe)_3$, $P(4\text{-}C_6H_4F)_3$, $P(4\text{-}C_6H_4Me)_3$, $PHPh_2$, $PPh_2(CH_2CH_2SiCl_3)$, PPh_2Me, PPh_2Et, $PPh_2(C_8H_{16}SiCl_3)$, $PPh(C_4H_8NO)_2$, $PPh(C_5H_{10}N_2)$, **3**, **4**, PF_2NMe_2, $AsEtPH_2$, $SPPh_3$; $L = C_8H_{14}$, $L' = PF(NMe_2)_2$, $P(4\text{-}C_6H_4OMe)_3$, $P(4\text{-}C_6H_4Cl)_3$) (17)



(3)



(4)

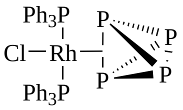
In addition to being a powerful and versatile catalyst, $[RhCl(PPh_3)_3]$ is also the starting point for the preparation of numerous analogs that can be obtained by metathetical reactions. Schemes 6 and 7 show some replacement reactions of the chloro and triphenylphosphine ligands. Despite the $4d^8$ electronic configuration, these rhodium(I) complexes are seldom exactly square planar.

Tetrahydroborate or other hydridic anions produce $[RhH(PPh_3)_3]$, widely used by Robinson's group as the starting point for the preparation of carboxylato and other complexes (equation 18). The IR spectra of $[Rh(O_2CR)(PPh_3)_3]$ show that the carboxylate is monodentate and therefore Rh is four–coordinate; this has been confirmed by X-ray crystallography for the benzoate.

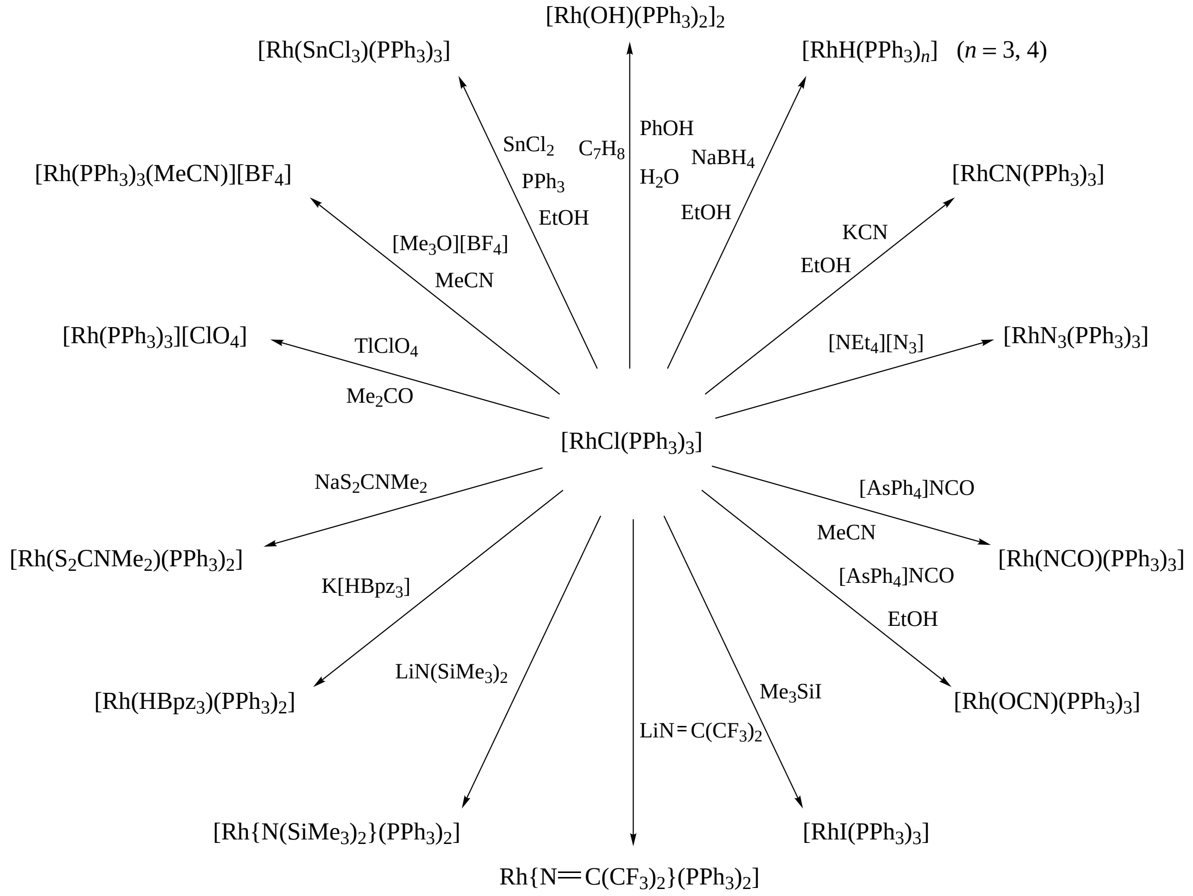
$$[RhH(PPh_3)_4] + RCO_2H \longrightarrow [Rh(OCOR)(PPh_3)_3] + H_2 + PPh_3$$

$$(R = Me,\ Et,\ 4\text{-}C_6H_4NO_2,\ 4\text{-}C_6H_4Cl) \quad (18)$$

When neutral ligands replace PPh_3 in $[RhCl(PPh_3)_3]$, the incoming ligand usually replaces the triphenylphosphine ligand trans to the chloro ligand (Scheme 7). Several of the complexes which can be prepared from $[RhCl(PPh_3)_3]$ exhibit interesting structures, few more so than the *trans*-$[RhCl(PPh_3)_2(P_4)]$ complex (**5**), which contains an η^2-tetrahedral P_4 ligand.



(5)



Scheme 6

The $PX{=}C(SiMe_3)_2$ ligands ($X = F$, Cl) form η^1-complexes upon reaction with $[RhCl(PPh_3)_3]$ in toluene solution. This contrasts with their reactions with d^{10} Ni^0 or Pt^0 species, where both oxidative addition and η^2-coordination may occur.

Another noteworthy species is $[Rh(PPh_3)_3MeCN]^+$, which can be prepared from $[Rh_2(O_2CMe)_2(MeCN)_6][BF_4]_2$ (equation 19). Although MeCN is normally a good leaving group, it is retained in some reactions (equation 20).

$$[Rh_2(O_2CMe)_2(MeCN)_6][BF_4]_2 + PPh_3 \longrightarrow [Rh(PPh_3)_3(MeCN)][BF_4] \quad (19)$$

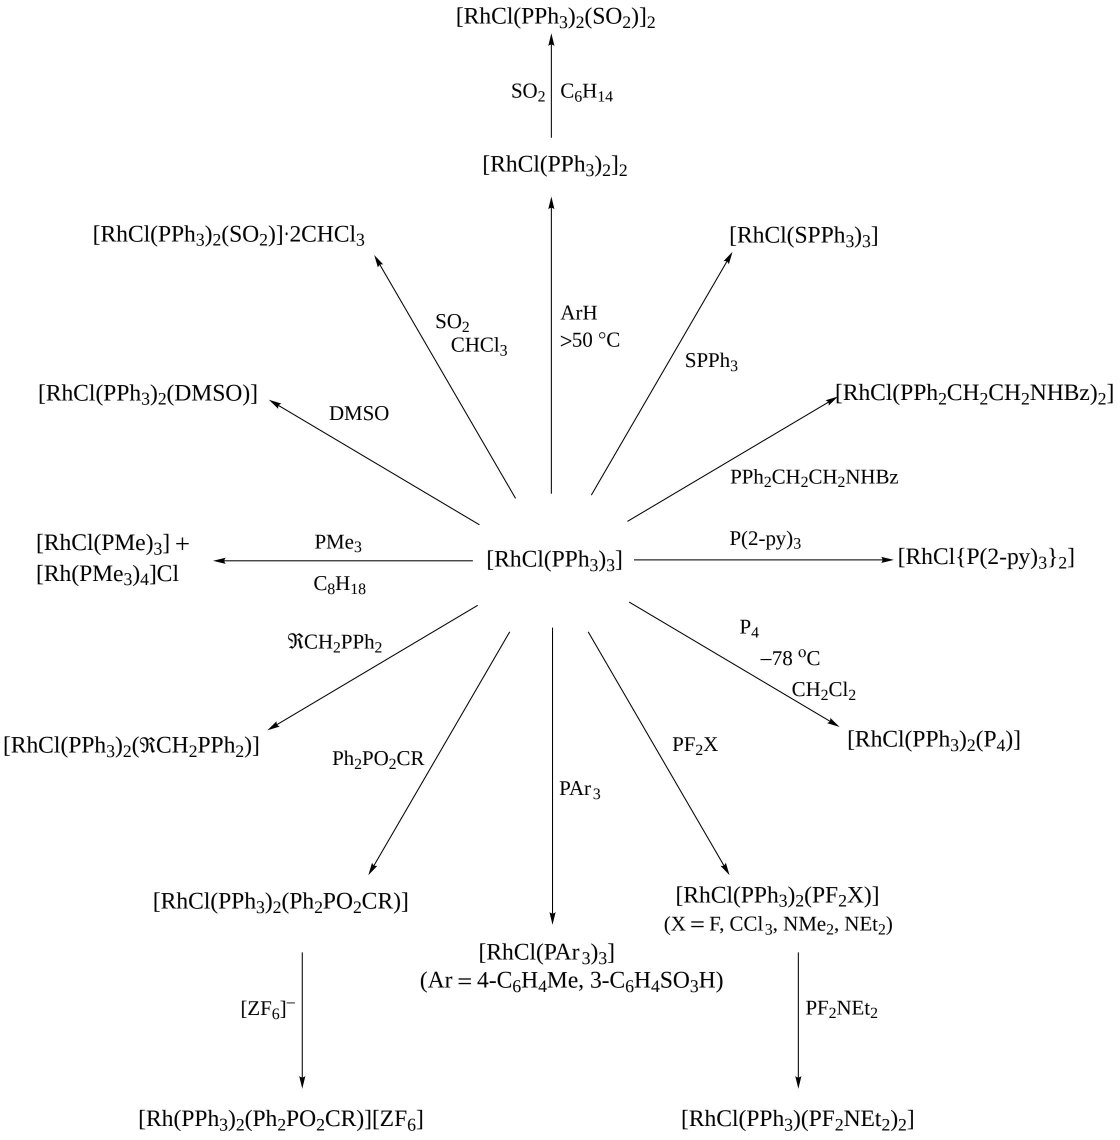
$$[Rh(PPh_3)_3(MeCN)]^+ + P(OMe)_3 \longrightarrow trans\text{-}[Rh(PPh_3)_2(MeCN)\{P(OMe)_3\}]^+ + PPh_3 \quad (20)$$

Replacement of PPh_3 by other tertiary phosphines can give important catalysts. Water-soluble analogs of $[RhCl(PPh_3)_3]$ can be prepared by replacing all three PPh_3 ligands by $Na[PPh_2(3\text{-}C_6H_4SO_3)_3]$ or $Na_3[P(3\text{-}C_6H_4SO_3)_3]\cdot xH_2O$. These complexes find application in the hydrogenation of biologically important substrates, and also exhibit antitumor activity. One major problem in homogeneous catalysis is separating the catalyst from the product. This can be overcome by preparing a heterogenized catalyst, which may be achieved by binding a $RhCl(PPh_3)_2$ residue to a – PPh_2 group attached to a macromolecular support. Typical supports have included cross-linked polystyrene resins or silica. A recent development is the preparation of complexes containing fluorinated tertiary phosphine ligands for use in biphasic catalytic systems.

The mixed anhydrides of diphenylphosphinous acid and heavily substituted alkenoic acids displace one PPh_3 ligand from $[RhCl(PPh_3)_3]$ to form a complex where the anhydride is coordinated through phosphorus. If these products are treated with thallium(I) or silver(I) salts, the anhydride coordinates additionally through the carbonyl oxygen and the chloro ligand is displaced.

There are relatively few complexes of the stoichiometry $[RhL_4]X$. Most of these contain small tertiary phosphines and anions of low coordinating power. The complexes of secondary phosphines are much in evidence and tertiary phosphite complexes are also known.

Much studied recently, $[Rh(PMe_3)_4]Cl$ owes much of its reactivity to the facile loss of a PMe_3 ligand. The other



Scheme 7

complexes are much less reactive (equations 21–23).

$$[RhCl(PPh_3)_3] + 4PHPh_2 + M^IX \xrightarrow[50\,^\circ C]{MeOH} [Rh(PHPh_2)_4]X + M^ICl$$
$$(X = BF_4, PF_6, ClO_4) \quad (21)$$

$$[Rh(PPh_3)_2(cod)][PF_6] + 10PR_3 \longrightarrow [Rh(PR_3)_4][PF_6]$$
$$(R_3 = Ph_2Me, Me_2Ph, Ph(OMe)_2) \quad (22)$$

$$[Rh(PMe_3)_4]Cl + KX \longrightarrow [Rh(PMe_3)_3]X + PMe_3 + KCl$$
$$(X = BPh_4, PF_6) \quad (23)$$

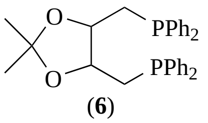
The complexes are usually prepared by displacing ligands from other rhodium(I) complexes. Complexes containing two bidentate ligands may be prepared similarly. Additionally, simultaneous anion metathesis and ligand displacement may be employed when complexes containing poorly coordinating anions are sought.

There are numerous $[Rh(LL)_2]X$ complexes. Probably the most important of these are those complexes containing two chiral bidentate ligands (equations 24–26). The best known, containing the chiral ligand diop (**6**), have been widely employed in homogeneous asymmetric synthesis, where they have proved to be of increasing importance in the pharmaceutical industry (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***).

$$[RhClL^1{}_2]_2 + 4L^2 \longrightarrow 2[RhL^2{}_2]Cl + 4L^1$$
$$(L^1 = C_8H_{14}, L^2 = \text{dppm, dppp, dppb, (+)-DIOP}; L^1 = \tfrac{1}{2}\text{cod},$$
$$L^2 = \text{dmppe, dppv, diars, dpav}) \quad (24)$$

$$[RhCl(cod)]_2 + 4L \xrightarrow{MX} 2[RhL_2]X + 2cod + 2MCl$$
$$(MX = NaBPh_4,\ L = Ph_2PCH_2CH_2SEt,\ Ph_2PCH_2CH_2SPh;$$
$$MX = [NH_4][PF_6],\ L = (Bu^tCH_2)_2PCH_2CH_2P(CH_2Bu^t);$$
$$MX = Ag[PF_6],\ L = \text{dmppe, dpav, diars}) \quad (25)$$

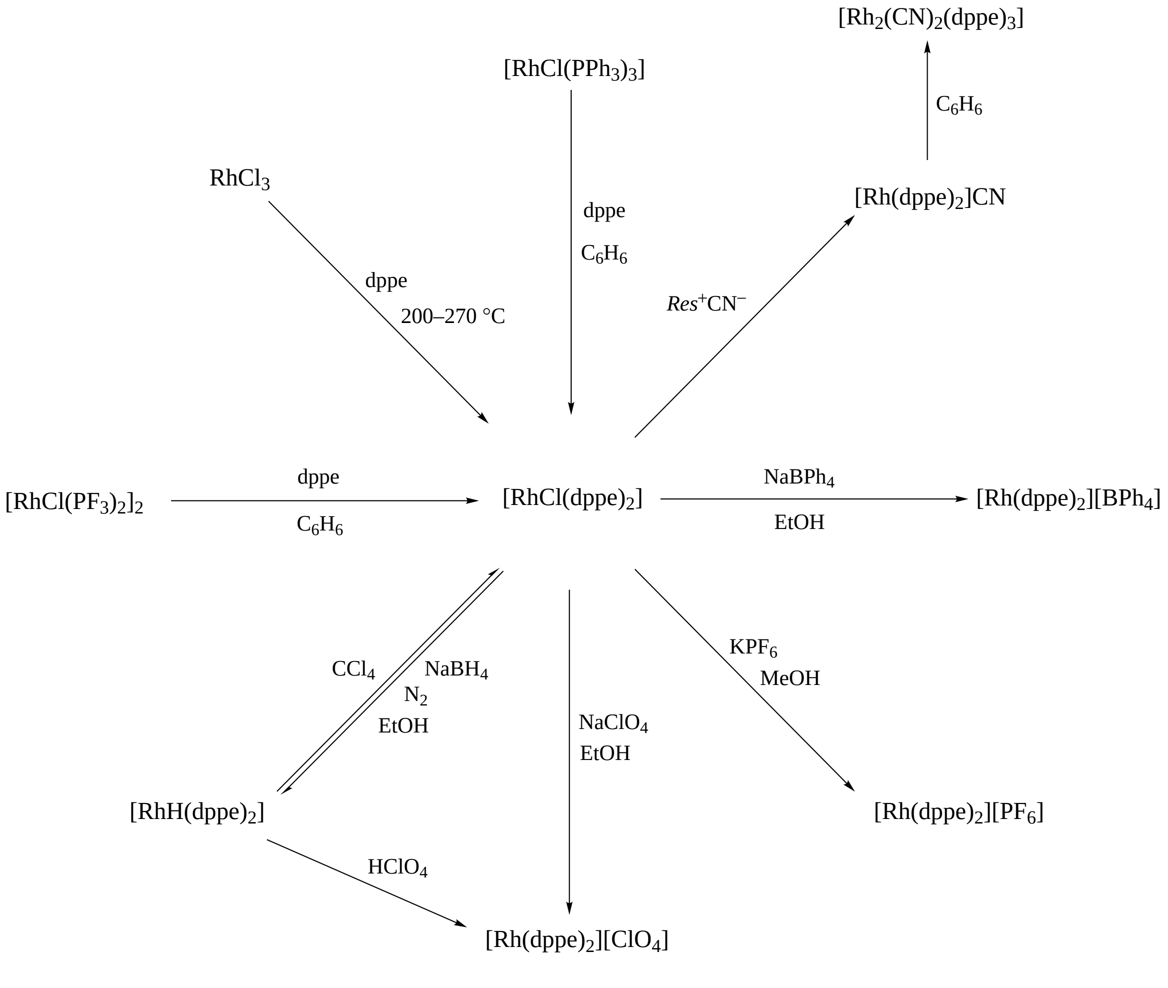
$$[RhCl(CO)_2]_2 + 4dpav + 2NaBF_4 \longrightarrow 2[RH(dpav)_2][BF_4] + 4CO + 2NaCl \quad (26)$$



(**6**)

The reactions of $[Rh(dppe)_2]Cl$ (Scheme 8) show that the major reaction is anion metathesis.

Pentacoordinate complexes adopt two stoichiometries. The neutral hydrido complexes are probably more numerous than the $[RhL_5]X$ salts. The structures of the hydrido complexes are difficult to establish. X-ray crystallographic studies seldom locate the hydrido ligand and its position must be inferred from the disposition of the other ligands. In solution, ^1H NMR studies show the high-field line to be split into a weak multiplet by both rhodium and the phosphorus atoms present. On the evidence available, most complexes appear to have the monocapped tetrahedron structure. The phosphorus ligands found in the hydrido complexes include tertiary phosphines, ditertiary phosphines, and trialkyl phosphites. Chloro complexes are only known for small ligands of high π-acidity such as $PF_2(NMe_2)$. Trialkyl phosphites appear to be the only ligands capable of forming $[RhL_5]^+$ cations. This may again be due to their high π-acidity and their small *Cone Angles*. All the isolated complexes contain the large $[BPh_4]^-$ counter ion, suggesting that the cations are unstable in the presence of small, polarizing anions. The white complexes can be prepared by displacement of alkene ligands from rhodium(I) complexes in the presence of $[BPh_4]^-$ ions. As might be expected, the trialkyl phosphite ligands are easily lost.



Scheme 8

5 RHODIUM(II) COMPLEXES

There are three types of rhodium(II) complex. By far the most common are the dimeric carboxylatorhodium(II) species. Octahedral complexes may also be generated by the radiolysis of aqueous solutions of classic rhodium(III) complexes. Square-planar complexes containing bulky tertiary phosphine ligands can be produced by careful reduction of hydrated rhodium trichloride. The chemistry of rhodium(II) differs very considerably from the well-known monomeric octahedral or tetrahedral cobalt(II) species because cobalt(II) complexes are high-spin d^7 species while rhodium(II) complexes are all low spin. No spin reorientation is required upon oxidation to rhodium(III), so monomeric rhodium(II) complexes are excellent reducing agents.

5.1 Monomeric Complexes

The complexes generated by photolysis or radiolysis of rhodium(III) precursors usually have very short lifetimes. The ammine complexes derived from radiolysis of aqueous solutions of $[RhCl(NH_3)_5]^{2+}$ are easily oxidized. The radiolysis of solutions of $[Rh(bipy)_3]^{3+}$ generates the corresponding rhodium(II) complex, which undergoes disproportionation to rhodium(III) and rhodium(I) complexes, the latter containing only two bipy ligands (equation 27).

$$[Rh(bipy)_3]^{3+} \rightsquigarrow [Rh(bipy)_3]^{2+} \xrightarrow{OH^-} [Rh(bipy)_3]^{3+} + [Rh(bipy)_2]^{+} \qquad (27)$$

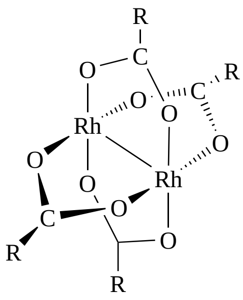
The best test for monomeric rhodium(II) complexes is their paramagnetism since both rhodium(I) and rhodium(III) complexes are diamagnetic. These complexes owe their stability either to the large size of the ligands or their electronic properties. Bulky ligands include porphyrins and tertiary phosphines. Typical tertiary phosphine ligands include tris(2-tolyl)phosphine, di-*t*-butyl(alkyl)phosphines, or tris(cyclohexyl)phosphine. These ligands reduce hydrated rhodium trichloride to the rhodium(II) complexes in ethanol at low temperatures (equation 28), rather than the reflux temperature required to bring about reduction to rhodium(I). Although no authentic rhodium(II) complexes containing tertiary arsines are known, tris(2-tolyl)stibine forms diamagnetic $[RhX_2\{Sb(2\text{-}C_6H_4Me)_3\}]$ complexes when it reacts with rhodium(III) halides. A dimeric structure has been proposed to account for the diamagnetism.

$$RhCl_3{\cdot}3H_2O + P(2\text{-}C_6H_4Me)_3 \xrightarrow[EtOH]{0\,^\circ C} [RhCl_2\{P(2\text{-}C_6H_4Me)_3\}_2] \qquad (28)$$

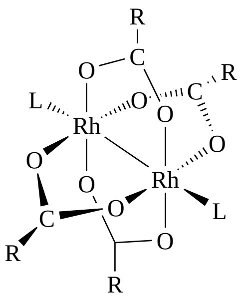
Nonplanar or highly substituted Schiff bases also confer steric protection upon their rhodium(II) complexes. By contrast relatively simple thio ligands such as *N*,*N*-dialkyldithiocarbamates produce stable, square-planar rhodium(II) complexes of the type $[Rh(S_2CNR_2)_2]$ (R = Me, Et); similar anionic *bis*(maleonitriledithiolate) are also known. Neutral complexes are formed by the thiol containing amino acids cysteine, methyl cysteine, or penicillamine. It is noteworthy that these paramagnetic $[Rh(aminoacid)_2]$ complexes can easily be prepared from dimeric, diamagnetic $[Rh(O_2CMe)_2MeOH]_2$.[8]

5.2 Dimeric Complexes

The best-known complexes of this type are the carboxylates (**7**) and their derivatives (**8**). The four bridging carboxylato ligands are supplemented by a single rhodium–rhodium bond. The bond lengths in the cores of these structures are almost independent of the ligands present. In particular, the Rh–Rh bond length increases by only 0.08 Å upon changing the axial ligand, L, from methanol to $P(OMe)_3$ in the acetate complexes. Many other oxo-bridged dimers are known with similar Rh–Rh bond lengths. The principal reaction of the dimers is the substitution of the neutral axial ligands (Scheme 9). The propanoate reacts more rapidly than the acetate, which may partly explain its superior antitumor activity. Many different monodentate ligands can be bound to the axial sites. Oxygen donors, which form blue or green complexes, include water, the lower aliphatic alcohols, dimethyl sulfoxide, and tetrahydrofuran.



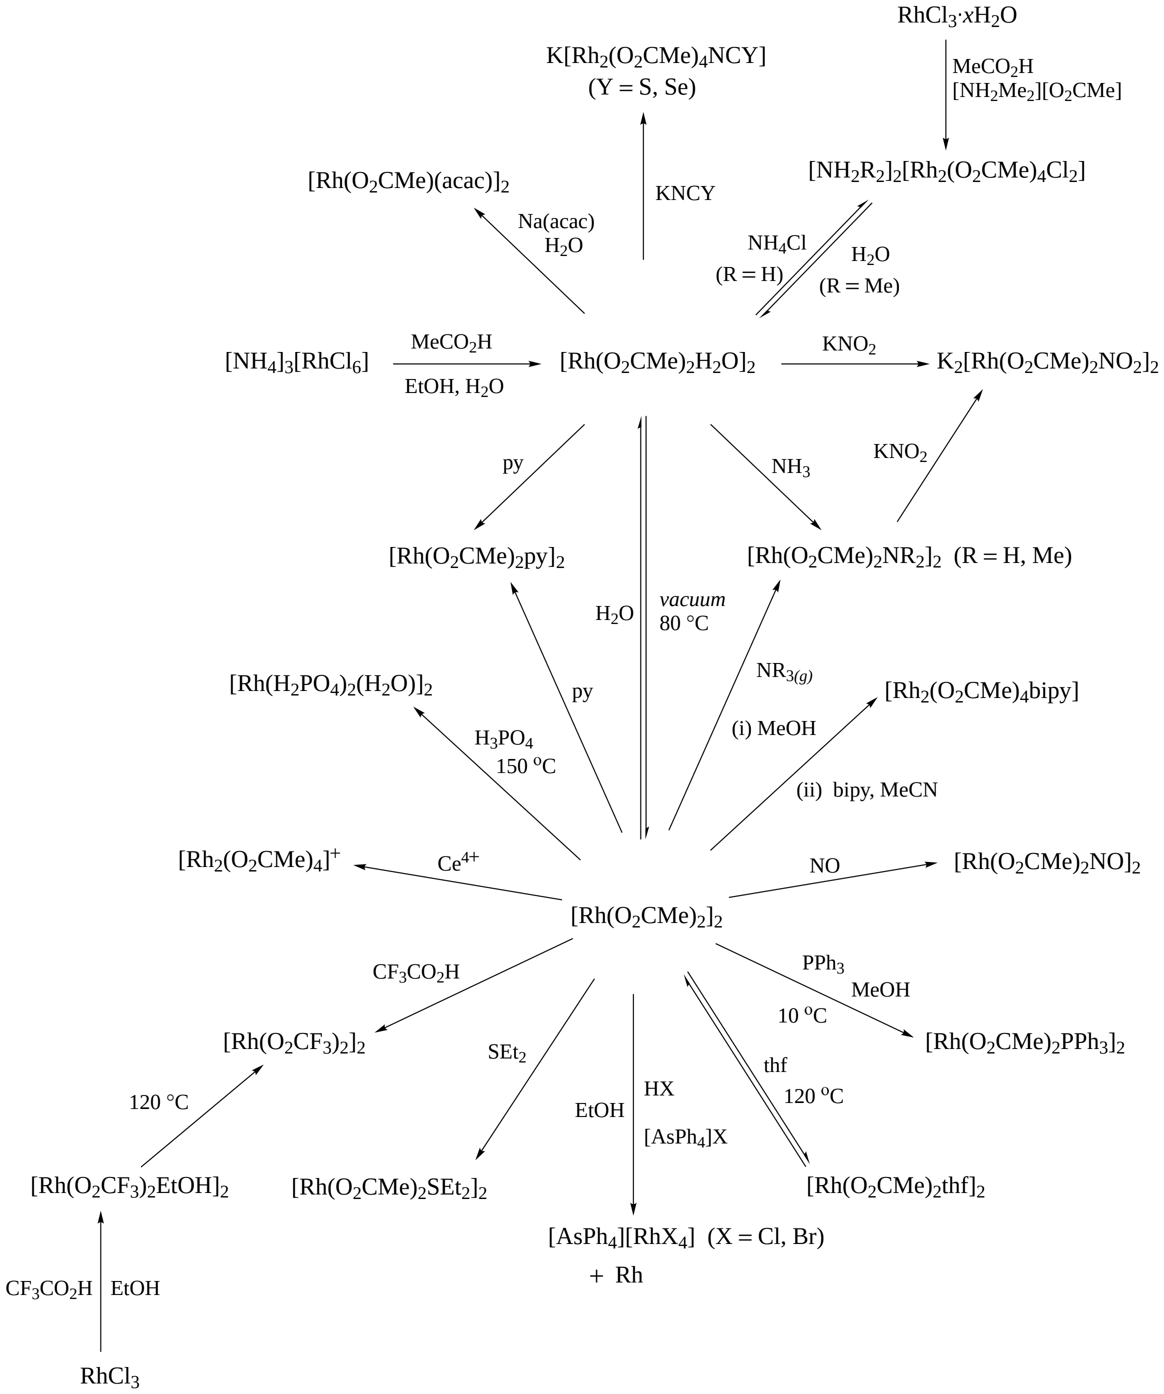
(**7**)



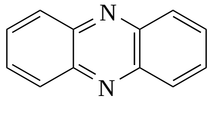
(**8**)

Thiols also bind to these sites, as does chloride ion in forming $[Rh(O_2CR)_2Cl]_2^{2-}$ anionic complexes. Nitrogenous ligands form many complexes, those of ammonia, pyridine, and both primary and secondary amines being well represented. Like the complexes of sulfur ligands, these are red or orange. Diamines also form complexes. Where the diamine geometry is favorable, for example, phenazine (**9**) or tetramethylphenylenediamine (**10**), they form polymeric chains of the type $[-LLRh(O_2CR)_4RhLLRh-]n$.

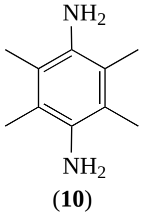
It has recently been shown that 2,2-bipyridine forms the complex (**11**). The importance of this structure is that it demonstrates the possibility of carboxylatorhodium(II) complexes acting in the same way as the well-known cisplatin (*cis*-$[PtCl_2(NH_3)_2]$) in cancer chemotherapy (*see*



Scheme 9

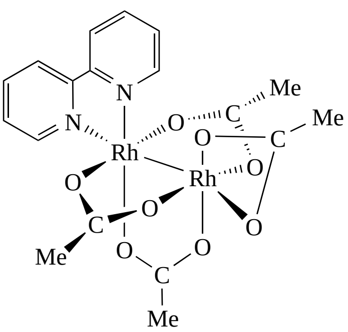


(**9**)



(**10**)

Platinum-based Anticancer Drugs). The latter disrupts mutant DNA by interstrand attachment to two adjacent guanine bases. Previously, it had been believed that the carboxylato complexes could not bind to DNA in this fashion. This may prompt further investigation of the antitumor activity of the rhodium complexes, which induce fewer harmful side effects than the platinum complexes.

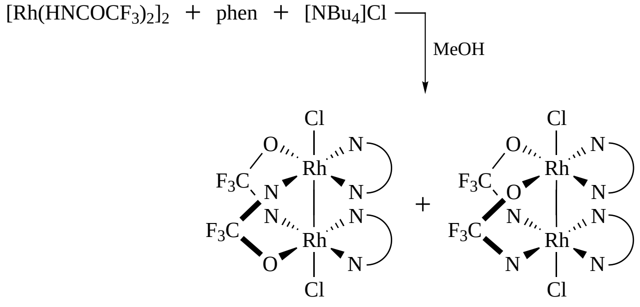


(**11**)

Tertiary phosphines or phosphites may also occupy the axial sites. Their high π-acidity lengthens the Rh–Rh bond, and the colors of their complexes range from red to yellow. Carbonyl, nitrosyl, or isocyanide ligands also lengthen the metal–metal bond. It should be noted that triphenylphosphine does not reduce the carboxylato complexes to rhodium(I) species. Polymeric complexes can be formed by α,ω-dinitriles linking the axial sites of two lantern units. Axial I_2 ligands can link $[Rh(O_2CCF_3)_2]_2$ units without oxidizing them.[9]

The carboxylato ligands also participate in metathetical reactions. These have been exploited to prepare homologous complexes. The carboxylato ligands can be replaced stepwise, and a few mixed carboxylato complexes have been isolated. The carboxylato complexes have been shown to be inefficient alkene hydrogenation catalysts.

Other bidentate ligands can bridge the two rhodium atoms. The complexes of the trifluoroacetamide anion, CF_3CNH^-, have been widely studied. Two isomeric products (**12**) and (**13**) are formed when the $[Rh(HNCOCF_3)_2]_2$ complex is allowed to react with 1,10-phenanthroline and $[NBu_4]Cl$ (equation 29). Of these, only the less symmetric (**12**) undergoes the further reaction with pyridine and $K[PF_6]$ (equation 30). These species again demonstrate the possible interaction between the dimeric complexes and DNA. However, carboxamide complexes show great promise as chiral cyclopropanation catalysts in the reactions between diazoesters and alkenes.[10] Attempts to fine tune the catalytic properties of the complexes make this a very active research area.

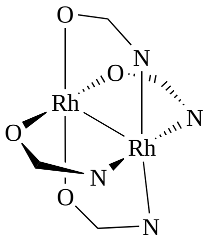


(**12**) (**13**)

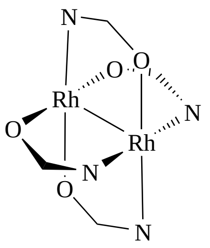
(29)

$$[Rh(HNCOCF_3)Cl(phen)]_2 + 2K[PF_6] \xrightarrow{py} [Rh(HNCOCF_3)(phen)]_2[PF_6]_2 + 2KCl \quad (30)$$

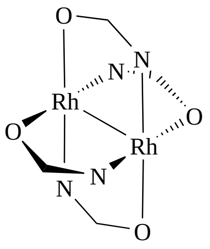
Another class of ligand that forms bridged dimeric complexes includes 6-methyl- or 6-halo-2-oxypyridines. The substituent at the 6-position is essential to discourage axial bonding, particularly when they are prepared via bridge metathesis, although they can be prepared directly from $RhCl_3{\cdot}3H_2O$. When a bidentate ligand coordinates through two different donor atoms the four isomers (**14**)–(**17**) are possible. These are designated the 4,0, 3,1, *cis*-2,2, and *trans*-2,2 isomers, respectively. Examples of all these isomers may be prepared from this class of ligand. Additionally, the 6-methyl-2-oxypyridine ligand can form a tetrameric complex when one of the four oxygen atoms increases its coordination number to four to bridge two 3,1-dimeric units.



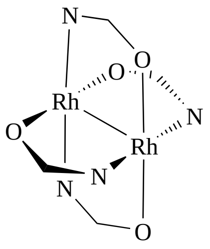
(**14**)



(**15**)



(**16**)



(**17**)

Despite the ubiquity of bridged species, several examples of dimeric unbridged rhodium(II) complexes are known. Heating $[Et_3O][BF_4]$ with $[Rh(O_2CCF_3)_2]_2$ in MeCN forms $[Rh_2(MeCN)_{10}][BF_4]_4$. The cation has Rh–Rh linked, staggered square-pyramidal units.[11] The aqua complex $[(H_2O)_5Rh–Rh(H_2O)_5]^{4+}$ is also known. Several inorganic oxo anions, for example, sulfate, carbonate, hydrogen carbonate, or dihydrogen phosphate, form bridged complexes with the aqua complex (equation 31).

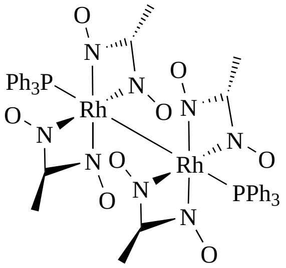
$$[Rh_{2(aq)}]^{4+} + 4[H_2PO_4]^- \longrightarrow [Rh(H_2PO_4)_2(H_2O)]_2 \quad (31)$$

The *bis*(octaethylporphyrin)dirhodium complex is also unbridged. The reduction of $[Rh(dmg)_2Cl_2]^-$ by tetrahydroborate in the presence of PPh_3 forms the unbridged rhodium(II)

complex $[Rh(dmg)_2PPh_3]_2$ (**18**) (equation 32). This complex has axial PPh_3 ligands and a very long Rh–Rh bond of 2.936 Å. The parent complex can be prepared by the reaction of dmgH and $[Rh(O_2CMe)_2]_2$.

$$RhCl_3 + dmgH \xrightarrow{67\%EtOH} H[Rh(dmg)_2Cl_2] \xrightarrow[90\%EtOH]{KOH,\ PPh_3}$$

$$[Rh(dmg)_2Cl(PPh_3)] \xrightarrow[90\%MeOH]{NaBH_4} [Rh(dmg)_2(PPh_3)]_2 \quad (32)$$



(**18**)

6 RHODIUM(III) COMPLEXES

The extensive chemistry of this oxidation state has two facets. The classical complexes containing σ-bonded ligands have been known for nearly two centuries. At the beginning of the twentieth century, they were widely used by Alfred Werner in his fundamental research into the constitution, stereochemistry, and isomerism of coordination compounds.

However, over the last 60 years a new type of chemistry has emerged. Although the first examples, tertiary arsine complexes, were initially prepared as an extension of classical rhodium(III) chemistry, the newer complexes containing π-bonding ligands have been a consequence of the intense interest in the catalytic properties of rhodium(I) complexes. Examples of these ligands also include tertiary phosphines and stibines, although it is debatable to what extent they act as π-acids when coordinated to rhodium(III).

This historical distinction is paralleled by the widely different chemistries exhibited by the two types of complex. The classical complexes are invariably octahedral and react so slowly that studies of their reactions are of kinetic rather than synthetic interest. They are impervious to both oxidation and reduction in aqueous solution.

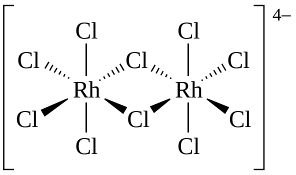
On the other hand, rhodium(III) complexes containing π-bonded ligands are often pentacoordinate and undergo very rapid reductive elimination reactions. It is their ability to undergo this reaction that makes possible much of the important catalytic activity exhibited by lower oxidation state rhodium complexes.

6.1 Complexes of σ-bonding Ligands

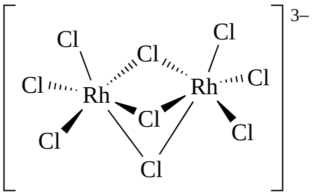
A wide range of rhodium(III) complexes contain halo, aqua, ammine diaminoalkane, or dicarboxylato ligands. Rhodium(III) complexes whose net ionic charge varies from +3 to −3 are known. With complexes that react slowly, it is possible to isolate most intermediate complexes in the interconversions of $[Rh(H_2O)_6]^{3+}$ and $[RhCl_6]^{3-}$ (Scheme 10). The slow reaction rates of these complexes also allow geometrcal isomers to be isolated. Additionally, the *cis*-$[RhX_2(LL)_2]^+$ and $[Rh(LL)_3]^{n+}$ complexes containing bidentate ligands are chiral and may be resolved into their optical isomers.

The complexes of halo or pseudohalo ligands make a convenient starting point for the discussion of those complexes containing monodentate ligands. The hexaiodo complex is unknown, but the other $[RhX_6]^{3-}$ complexes (X = F, Cl, Br, CN, SCN, SeCN) are all well established. In contrast to rhodium(I) complexes, the SCN^- and $SeCN^-$ ions are chalcogenide bound. The stable hexafluororhodate(III) complex is low spin, unlike the corresponding Co^{III} complex, which is a rare d^6 high-spin complex and a powerful oxidizing agent. The hexanitrorhodate(III) ion can be prepared from $[RhCl_6]^{3-}$ (equation 33). The tripotassium salt, like its cobalt(III) analog, is insoluble in water. Di- and trihalo-bridged species, (**19**) and (**20**) respectively, can be formed from $[RhCl_6]^{3-}$ at high temperatures and from $[RhBr_6]^{3-}$ in solution.

$$K_3[RhCl_6] + 6KNO_2 \longrightarrow K_3[Rh(NO_2)_6] + 6KCl \quad (33)$$



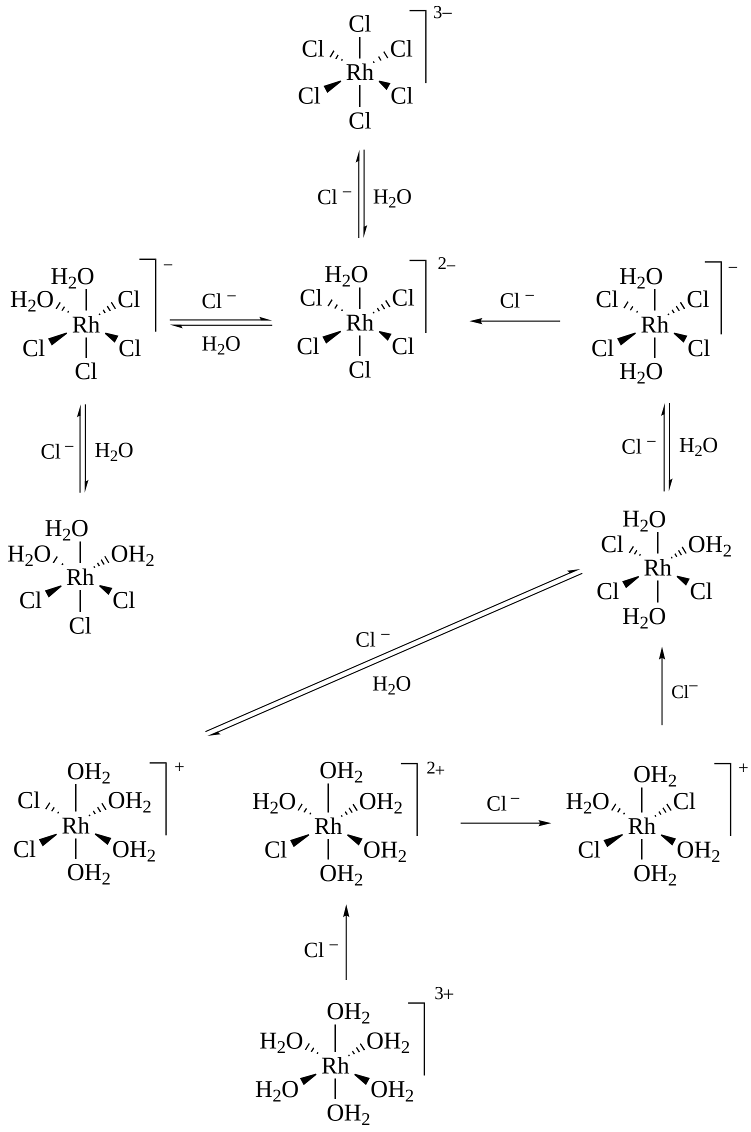
(**19**)



(**20**)

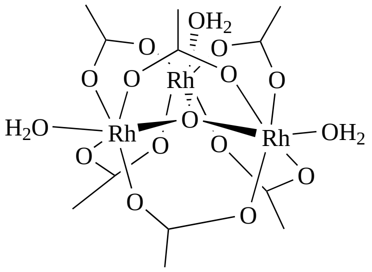
Aquation is the principal reaction in solution. As can be seen in Scheme 10, the trans labilizing effect of Cl^- is greater than that of the aqua ligand. Once the ligands trans to Cl^- are replaced by water, *fac*-$[RhCl_3(H_2O)_3]$ is inert to further aquation. It has also been found that the chloro ligand trans to water in $[RhCl_5(H_2O)]^{2-}$ has the shortest Rh–Cl bond.

The hexaaqua ion is virtually the sole example of a rhodium(III) ion complexed by six monodentate oxygen ligands. Solutions of this ion are acid due to hydrolysis (pKa = 3.3). Its principal reaction is anation, but it is difficult to isolate $[RhX(H_2O)_5]^{2+}$ intermediates since the formation of *trans*-$[RhX_2(H_2O)_4]^+$ is much more rapid. Hydrated rhodium trichloride, nominally $RhCl_3{\cdot}3H_2O$, is a mixture of several aquachloro complexes in which *fac*- and *mer*-$[RhCl_3(H_2O)_3]$ predominate. Since $BaCl_2$ gives no precipitate



Scheme 10

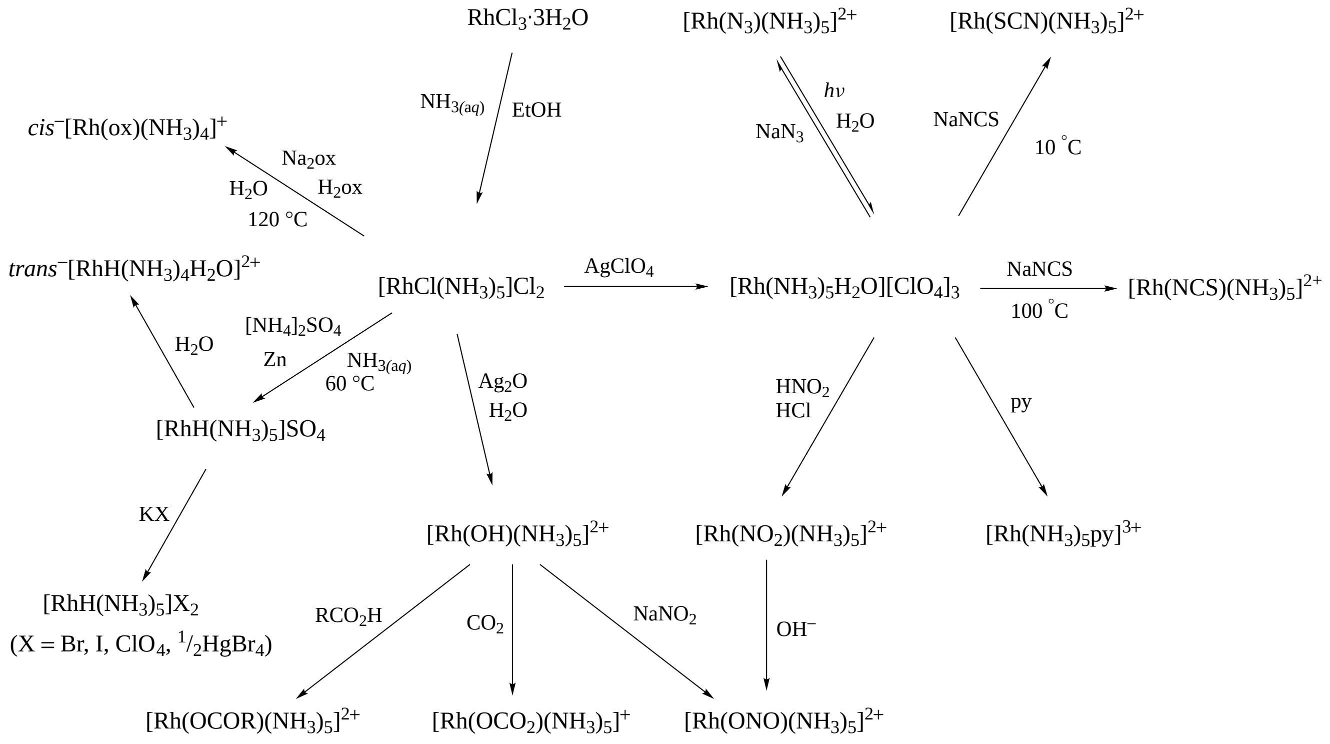
with $Rh_2(SO_4)_3{\cdot}6H_2O$, it is unlikely that it contains the $[Rh(H_2O)_6]^{3+}$ ion, more recent studies imply that dimeric cationic species are formed in aqueous solution. The only rhodium(III) carboxylate known is the unusual oxotrirhodium complex (**21**). This can be prepared either from silver(I) acetate and aqueous $RhCl_3{\cdot}3H_2O$ (Scheme 3) or by ozonization of rhodium(II) acetate.



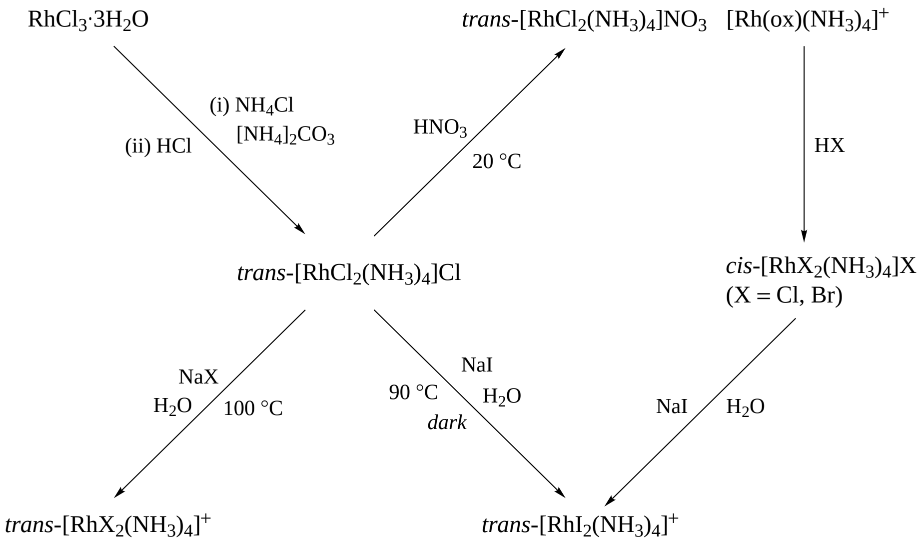
(**21**)

Several dialkyl sulfides form $[RhX_3(R_2S)_3]$ complexes. Some of these have been employed as alkene hydrogenation catalysts; however, they are only weakly active.

The hexaamine complex can only be prepared in sealed tube reactions (equation 34), unless the incorporation of the sixth ammine ligand is catalyzed by ethanol. In contrast, the pentaammine complexes are very accessible, and their anation and aquation reactions (Scheme 11) have been exhaustively studied. However, the exact mechanism of the anation reaction remains in doubt. While an interchange, I, mechanism is involved, conflicting arguments have been advanced for Ia or Id paths. The aquation reaction is catalyzed by Hg^{2+} or OH^-



Scheme 11



Scheme 12

ions.

$$RhCl_3{\cdot}3H_2O + NH_{3(aq)} \xrightarrow{120\,°C} [Rh(NH_3)_6]^{3+} \qquad (34)$$

The tetraammine complexes also undergo several substitution reactions (Scheme 12). Most of these reactions involve the trans isomers, possibly because these are less soluble and more easily isolated than the cis isomers. However, they are overshadowed by the more important $[RhX_2(N{-}N)_2]^+$ analogs (see below). The complex *trans*-$[RhCl_2py_4]Cl$ is an important starting material for other rhodium(III) complexes because of the ease with which the pyridine ligands may be replaced. Its anation

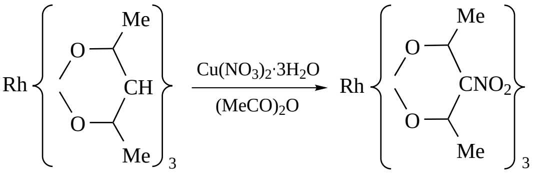
reactions are also a source of other rhodium(III) complexes (Scheme 13).

Both *fac*- and *mer*-triammine complexes have been prepared. Di- and monoammine complexes are neither particularly stable nor important.

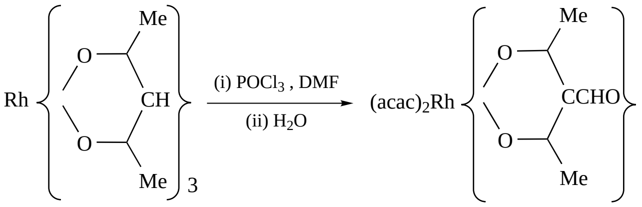
Bidentate oxygen ligands form numerous rhodium(III) complexes. Several tris(β-diketonato) complexes have been prepared from rhodium(III) nitrate (equation 35). The products are extraordinarily stable. They can be resolved into their optical isomers, and survive nitration and formylation reactions (equations 36 and 37). The tris(oxalato)rhodate(III) ion has also been resolved, but the enantiomers undergo slow racemization. Reaction of this complex with refluxing chloric(VII) acid leads to *cis*-$[Rh(ox)_2(H_2O)_2]$, which can be converted into *cis*- or *trans*-$[RhX_2(ox)_2]^{3-}$ complexes.

The important $[Rh(en)_3]^{3+}$ ion can be prepared by a variety of reactions (equations 38 and 39). The ion has been resolved and more recently the (-)-enantiomer has been shown to exist in the L configuration. Owing to its inertness, no ligand-substitution reactions have been reported. However, KNH_2 deprotonates the complex and allows its conversion to other species (equation 40). The tris(bipy) and $[Rh(phen)_3]^{3+}$ complexes have also been prepared and resolved.

$$Rh(NO_3)_3{\cdot}xH_2O + acaH \xrightarrow{pH4} [Rh(acac)_3] \quad (35)$$



(36)



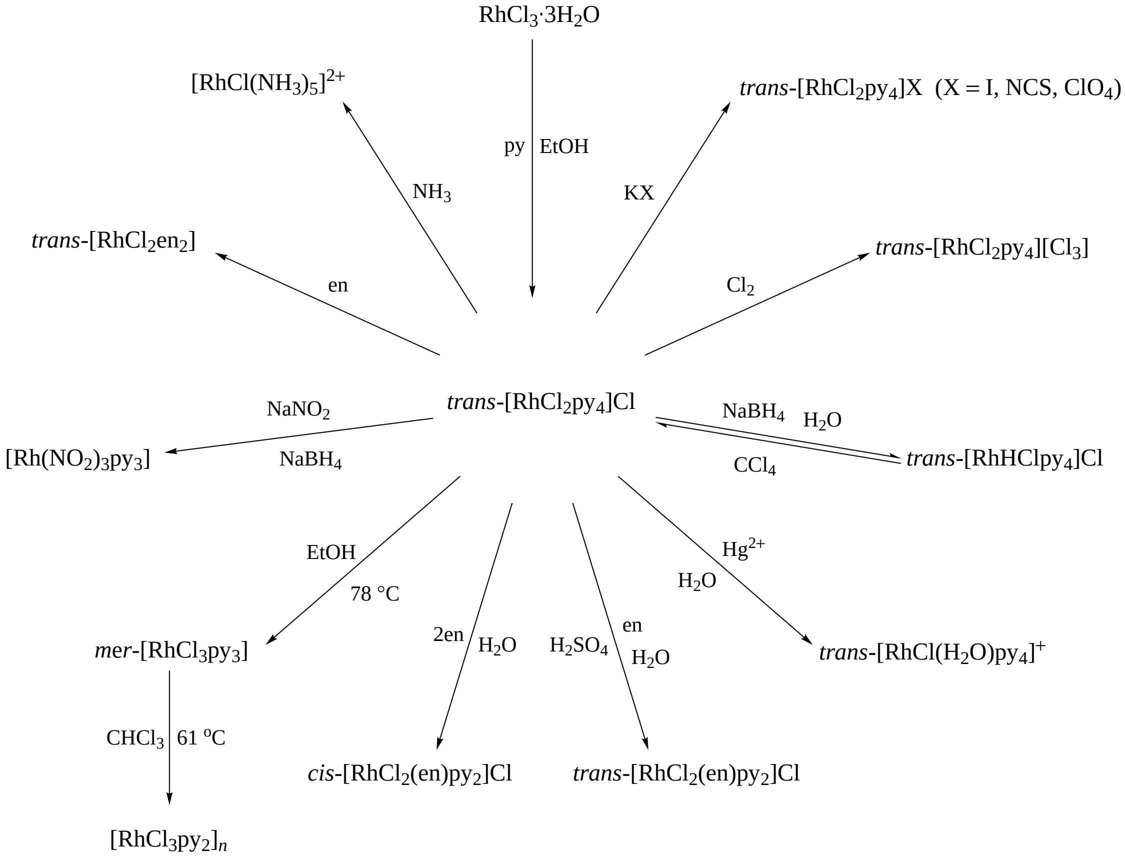
(37)

$$Na_3[RhCl_6] + en{\cdot}H_2O \longrightarrow [Rh(en)_3]^{3+} \quad (38)$$

$$RhCl_3{\cdot}3H_2O + 3en \xrightarrow{EtOH/H_2O} [Rh(en)_3]^{3+} \quad (39)$$

$$[Rh(en)_3]I_3 + KNH_2 \longrightarrow [Rh(en)(en\text{-}H)_2]I$$

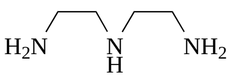
$$\xrightarrow{BF_3} [Rh(en)(enBF_3)_2]I \quad (40)$$



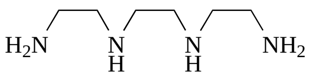
Scheme 13

The *bis*(1,2-diaminoethane) complexes are more reactive, and their aquation and anation reactions have been widely studied (Scheme 14). The *cis*-$[RhX_2(en)_2]^+$ ion may be resolved, and (+)-$[Rh(ox)(en)_2]^+$ has been assigned the Δ configuration. The substitution reactions of the X_2 ligands proceed with retention of configuration.

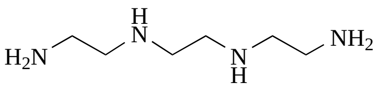
Unlike the $[RhX_2(en)_2]^+$ ions, which can exist as either *cis* or trans isomers, both $[RhX_2(bipy)_2]^+$ and $[RhX_2(phen)_2]^+$ cations and their derivatives are exclusively *cis* (cf. the exclusively *trans*-$[RhCl_2py_4]^+$ ion above). Complexes of rhodium(III) with polydentate nitrogen ligands can also be prepared. Tridentate diethylenetriamine (**22**) forms $[Rh(dien)_2]I_3$ when allowed to react with rhodium trichloride in the presence of NaI. The trichloride salt can be obtained by metathesis with AgCl. The reactions of 1,4,7-triazacyclononane inorganic complexes are of current interest (Scheme 15).[12]



(**22**)

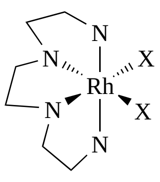


(**23**)

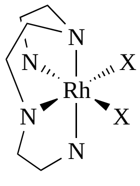


(**24**)

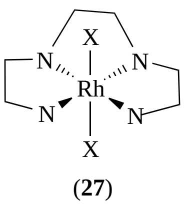
The quadridentate ligands trien (**23**), taud (**24**), 1,4,7,10-tetraazacyclododecane, and 1,4,8,11-tetraazacyclotetradecane all form rhodium(III) complexes. Both the cyclic ligands form predominantly *cis*-$[RhCl_2(N_4)]^+$ complexes when their hydrochlorides react with aqueous rhodium trichloride in the presence of a base. All three possible isomers (**25**)–(**27**) of the $[RhX_2(trien)]$+ cation have been characterized. The ligand (**24**) forms *trans*-$[RhCl_2(taud)]^+$, which may be prepared from either rhodium trichloride or *trans*-$[RhCl_2py_4]^+$. Both cis and trans products are formed from 1,4,8,11-tetraazacyclotetradecane and $RhCl_3 \cdot 3H_2O$. Each complex undergoes anation and metathetical reactions, and the cis complex can be resolved into its optical isomers. Other macrocyclic tetradentate ligands such as porphyrins or phthalocyanines form complexes where the four nitrogen atoms occupy the four equatorial coordination sites.



(**25**)



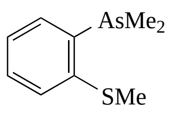
(**26**)



(**27**)

6.2 Complexes of π-bonding Ligands

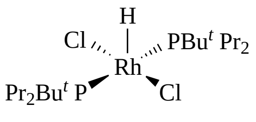
Although some of these complexes are obtained from rhodium(III) precursors, most arise from oxidative additions to rhodium(I). An indication of the diversity of rhodium(III) complexes that can be obtained from $[RhCl(PPh_3)_3]$ is given in Scheme 16. Just as was the case with rhodium(I), there are very few anionic complexes containing π-bonding ligands. The general formula of the anions is $[RhX_4L_2]^-$. There are also some interesting complexes containing the thioarsine (**28**), in which the ligand occurs in both anion and cation.



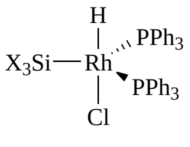
(**28**)

The majority of the pentacoordinate cationic complexes contain at least one hydrido ligand, although some are known to contain bulky neutral ligands. The latter may be regarded as the rhodium(III) analogs of the tricoordinate rhodium(I) complexes (see Section 4.1 above), from which most have been prepared by oxidative addition reactions.

The hydrido complexes, in turn, can be regarded as the analogs of the $[RhHL_2]$ complexes in which coordinative unsaturation is a consequence of the high trans effect of the H^- ligand. They exhibit either trigonal bipyramidal or square pyramid geometry. The hydrido ligand occupies the apical position in the *bis*(*t*-butyldipropylphosphine) complex (**29**), which can be prepared from $RhCl_3 \cdot 3H_2O$. More usually the complexes are prepared by oxidative addition of monohydrides to rhodium(I) complexes. Two very important catalyst types can be prepared by adding either a hydrosilane or borane[13] to $[RhCl(PPh_3)_3]$. The hydridocatecholborane derivative catalyzes the hydroboration of alkenes; oxidation and hydrolysis of the resulting boranes produces alcohols.



(**29**)



(**30**)

The numerous $[RhHCl(SiX_3)(PPh_3)_2]$ complexes (**30**) are potent hydrosilation catalysts for alkenes, alkynes, ketones, and other organic substrates containing either an active hydrogen or a multiple bond.[7] Many examples have been isolated in hydrosilation reactions. The complex $[RhHCl(SiAr_3)(PPr^i{}_3)_2]$ is square pyramidal but *mer*-$[RhHCl(SiHAr_2)(PMe_3)_3]$ complexes are formed from $[RhCl(PMe_3)_4]$ and $SiHAr_3$.[14] Besides being important catalysts, the complexes are also the source

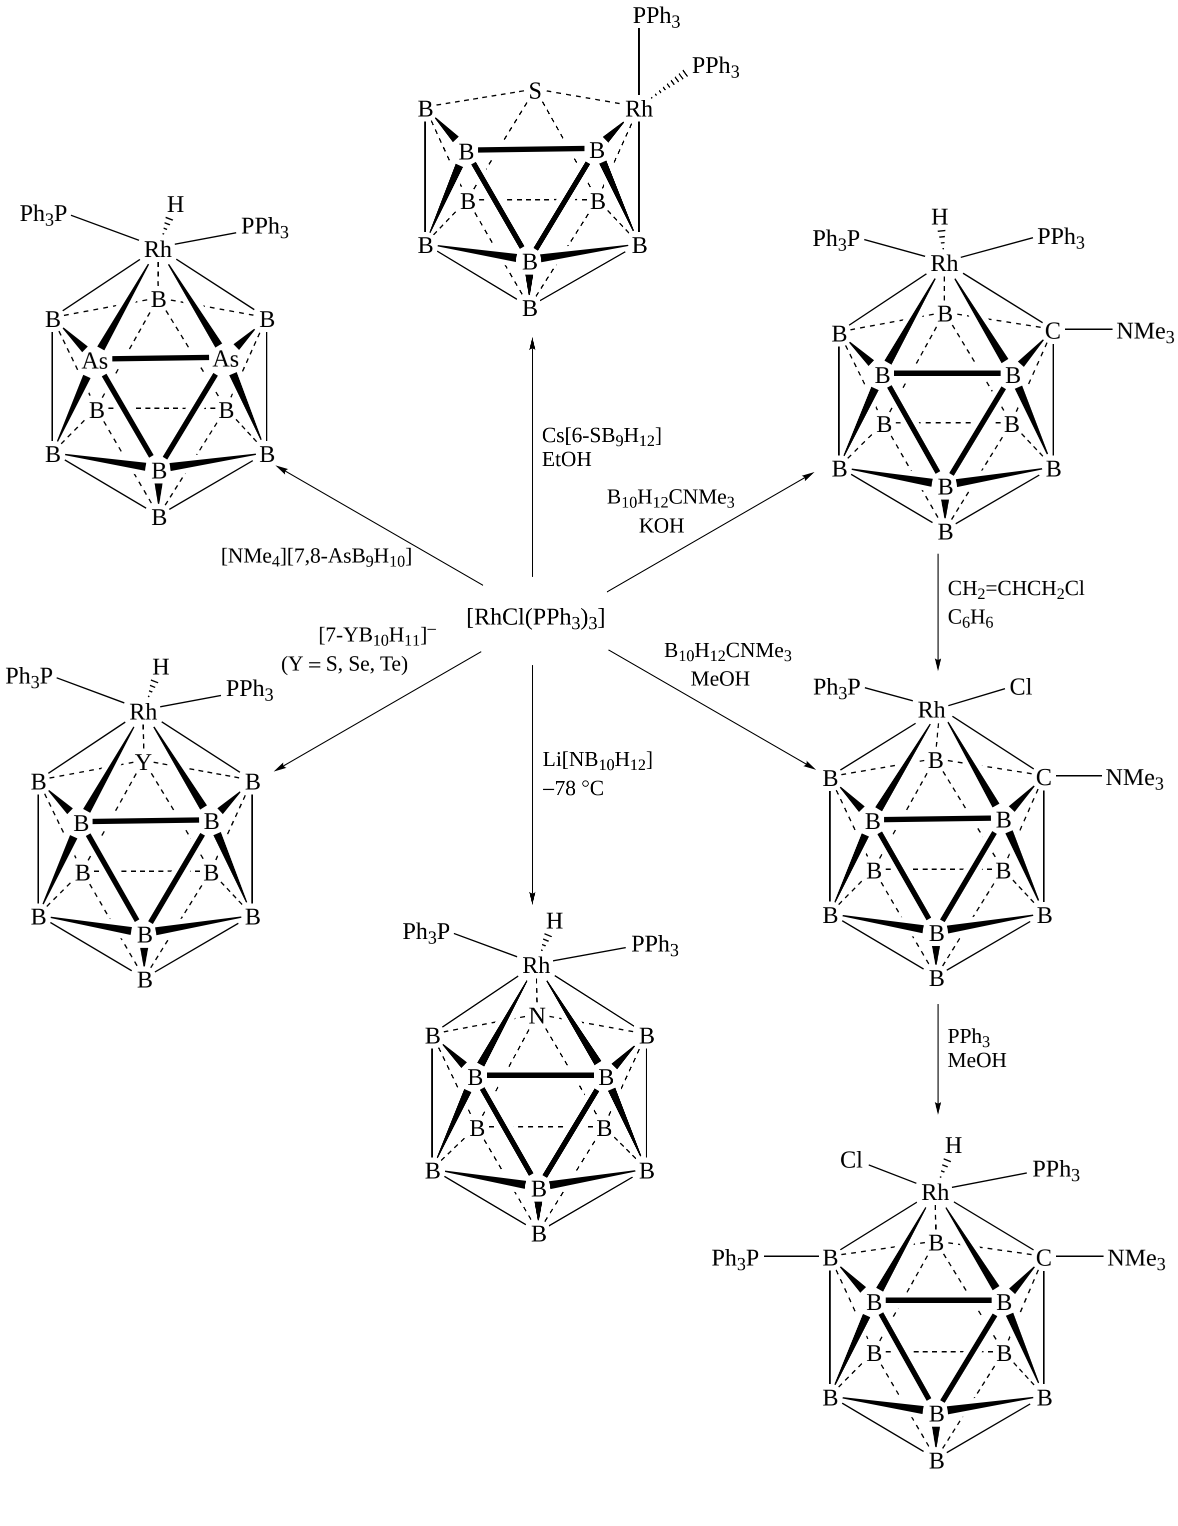
of many other rhodium complexes (equations 41 and 42). Germyl analogs are known, but excess $GeHCl_3$ converts $[RhCl(PPh_3)_3]$ to the $[Rh(GeCl_3)_6]^{3-}$ anion.

$$[RhHCl\{Si(OEt)_3\}(PPh_3)_2] \xrightarrow{\text{dppe}} [RhCl(dppe)(PPh_3)] \qquad (41)$$

$$[RhHCl\{Si(OEt)_3\}(PPh_3)_2] + HCl \longrightarrow [RhHCl_2(PPh_3)_2] + SiH(OEt)_3 \qquad (42)$$

Another important subgroup of monohydrido complexes can be prepared by the oxidative addition of *nido*-heteroborane anions to $[RhCl(PPh_3)_3]$ (Scheme 17). Further, the *closo*-dicarborane complex is the starting material for the preparation of other rhodium(III) borane complexes (Scheme 18). They are also weakly active hydrogenation catalysts.



Scheme 17

Several pentacoordinate monohydrido complexes can add an additional, small, neutral ligand to form complexes of the type [$RhHX_2L_2L'$]. The dihydrido complexes are conveniently prepared by the oxidative addition of dihydrogen to rhodium(I) complexes dissolved in inert organic solvents. Chlorinated solvents are unsuitable since the hydrido complexes produced may reduce them with formation of HCl and contaminate the product with monohydrido complexes (see Scheme 16). A characteristic stoichiometric reaction of many dihydrides is the addition of a third neutral ligand to form [RhH_2XL_2L']

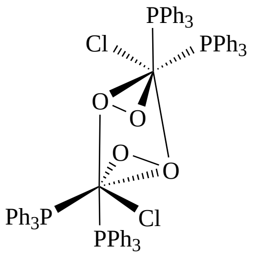
complexes (equation 43). However, the principal reaction of the dihydrides is the catalytic reduction of C=C bonds. The hydrido complexes can be characterized by reference to the high-field line in their ^1H NMR spectra and the presence of a weak band at ca.2000 cm^{-1} in their IR spectra attributable to ν_{Rh-H}.

$$[RhH_2Cl(PPh_3)_2] + py \longrightarrow [RhH_2Cl(PPh_3)_2py] \quad (43)$$

Pentacoordinate complexes can also arise from reactions between rhodium(I) complexes and dioxygen. The reactions between the complexes and dioxygen under very slightly different conditions can, however, easily give rise to other products.

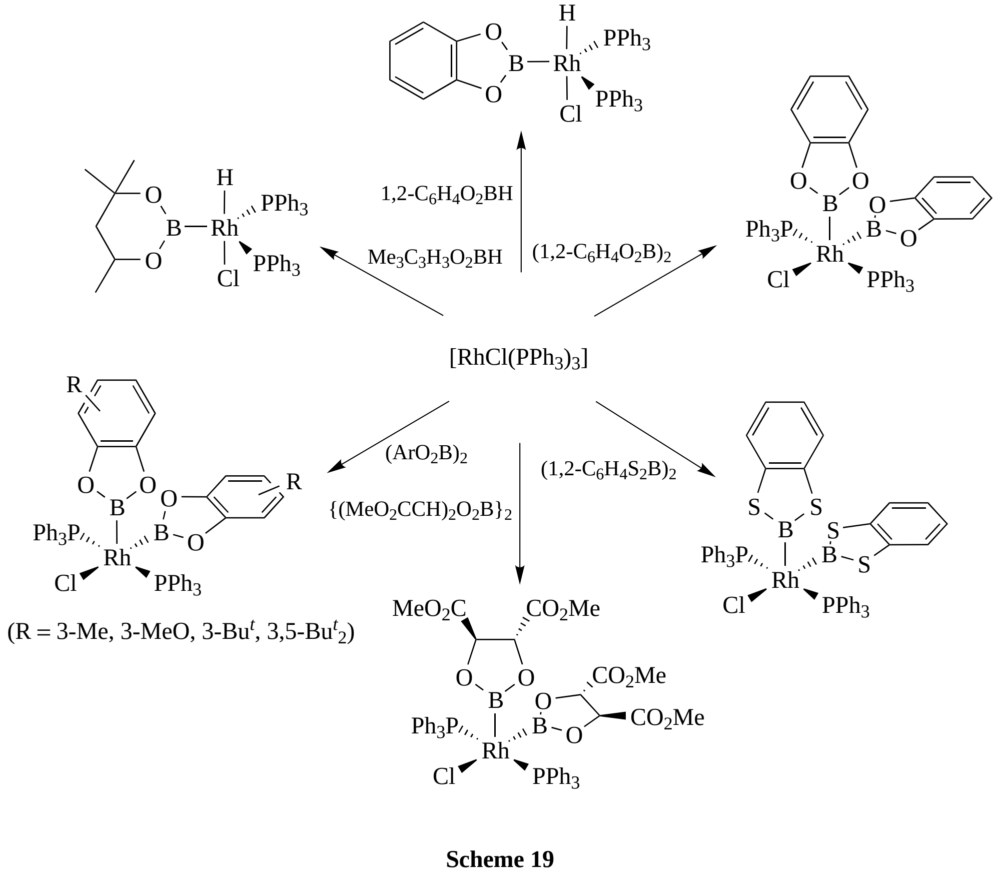
Chlorotris(triphenylphosphine)rhodium(I) forms $[RhCl(O_2)(PPh_3)_n]$ ($n = 2$, 3) or $[RhCl(O_2)(PPh_3)_2]_2$. The last complex is six coordinate and has structure (**31**). Ligand oxidation can also occur. A diagnostic test for the presence of O_2 ligands is a band at 870–900 cm^{-1}, attributable to ν_{O-O}, in the IR spectrum.



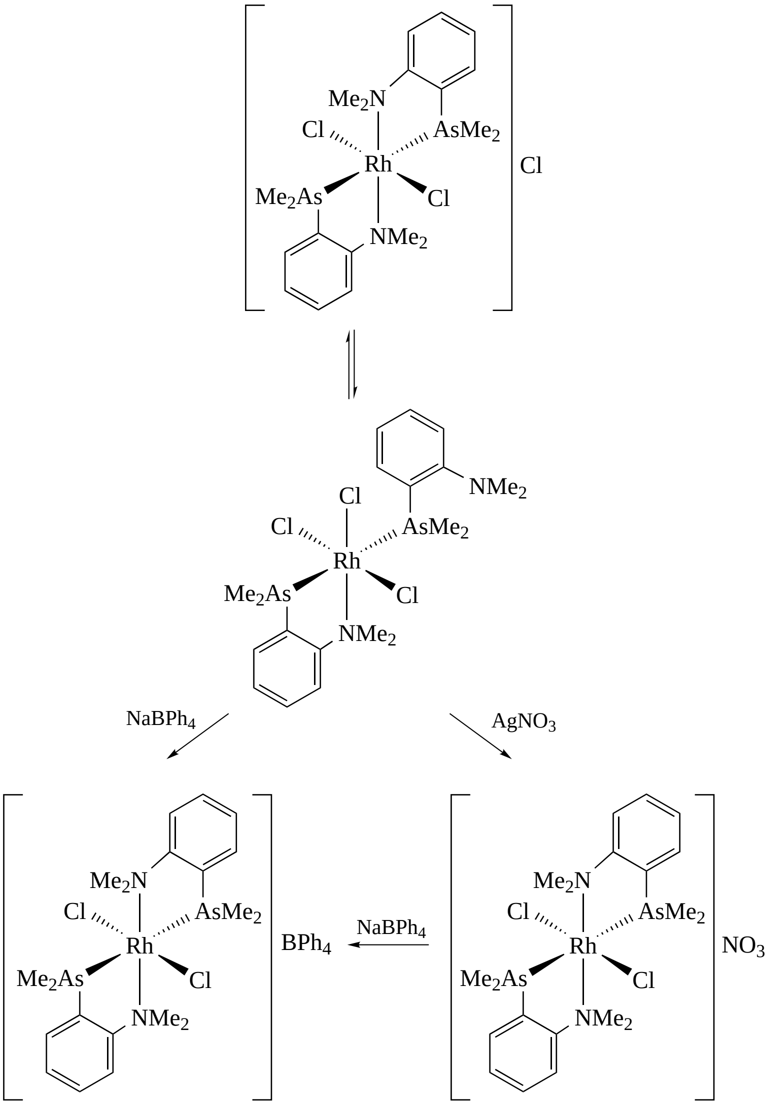
(**31**)

Another catalytically important type of pentacoordinate complex has recently been prepared by the oxidative addition of *bis*(benzoborazoles) to $[RhCl(PPh_3)_3]$. The boryl groups are labile – hence their complexes' ability to catalyze borylation of organic substrates – and can be replaced by other boryl groups (Scheme 19).[13] Trimethyl phosphine forms $[RhCl(BO_2C_6H_4)_2(PMe_3)_3]$ when allowed to react with $[RhCl(BO_2C_6H_4)_2(PPh_3)_2]$, but PEt_3 merely replaces the PPh_3 ligands to form a trigonal bipyramidal product.

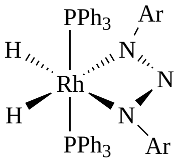
Many complexes that appear to be pentacoordinate are actually six coordinate by virtue of the presence of a bidentate anion or an uncharacteristically bidentate neutral ligand. The former type are exemplified by complexes containing 1,3-diaryltriazenido (**32**) or disulfur anions. Both examples may be prepared by oxidative addition reactions. Those complexes of uncharacteristically bidentate ligands may be prepared by allowing rhodium(III) halides to react with a stoichiometric deficiency of the ligand. A second neutral ligand may become bidentate when a chloro complex undergoes a metathetical reaction with an anion of low coordinating power or isomerizes in a polar solvent (Scheme 20).



Scheme 19

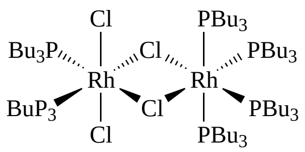


Scheme 20

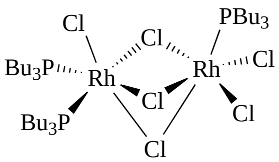


(**32**)

$$3[RhCl_3(PBu_3)_2]_2 \longrightarrow [Rh_2Cl_6(PBu_3)_3] + mer\text{-}[RhCl_3(PBu_3)_3] \quad (44)$$



(**33**)



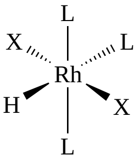
(**34**)

Dinuclear complexes can also have the same empirical formulas as pentacoordinate complexes. Their ^{31}P NMR spectra show that they adopt the noncentrosymmetric structure (**33**). Monomeric trialkylphosphine complexes are difficult to prepare and attempts at purification often lead to disproportionation (equation 44). The trihalo-bridged dimers adopt structure (**34**), in which each phosphorus atom is trans to a different chloro bridge.

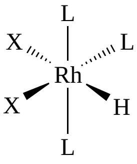
Despite the high trans effect of the hydrido ligand there are also many six-coordinate hydrido complexes of general formula $[RhHX_2(ZR_3)_3]$ (X = halide; Z = P, As). These complexes have two isomeric forms designated α and β and are shown in structures (**35**) and (**36**), respectively. They can

be distinguished by means of IR or NMR spectrometry. The action of bases causes reductive elimination of hydrogen halide and the formation of a rhodium(I) complex (equation 45). Similarly, the $[RhX_3L_3]$ complexes can exist as *fac* or *mer* isomers. The *fac* isomers are formed only by the smallest tertiary phosphines or arsines and are easily outnumbered by the meridional complexes. Virtually no attempts have been made to study the chemical reactions of the *fac* complexes.

$$[RhCl(PEtPh_2)_3] \underset{PhNH_2}{\overset{HCl}{\rightleftharpoons}} \alpha\text{-}[RhHCl_2(PEtPh_2)_3] \qquad (45)$$

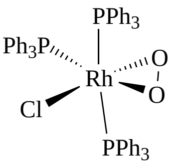


(**35**)



(**36**)

There are very few $[RhX_2L_4]X$ complexes, although numerous analogs containing two bidentate neutral ligands have been prepared (see below). Perhaps the most important are the dioxo complexes (**37**), arising from the addition of dioxygen to rhodium(I) complexes. The presence of a peroxo ligand has been confirmed by X-ray crystallography. Dioxygen complexes are well represented and indeed even disulfur analogs have been prepared from cyclo-octasulfur. The dioxygen complexes react with the lower oxides of nonmetals to form complexes containing oxyanions. Complexes containing ditertiary phosphines may be prepared from rhodium(III) halides, by displacing monodentate ligands from rhodium(III) complexes, or by oxidative addition to rhodium(I) complexes (Scheme 21). Strangely, there seem



(**37**)

to be no *tris*(ditertiary phosphine or arsine) analogs of $[Rh(en)_3]^{3+}$ or $[Rh(bipy)_3]^{3+}$.

The tridentate ligands (**38**)–(**40**) form rhodium(I) complexes. The complexes of the first two ligands readily undergo oxidative addition to form rhodium(III) complexes. The complex [RhCl(**38**)] also adds either SO_2 or BF_3 to form pentacoordinate rhodium(I) complexes. The tetradentate ligands (**41**) (Z = P, As) and (**42**) and the hexadentate ligand (**43**) form both rhodium(I) and (III) complexes. By contrast, the tri(tertiary arsine) ligand (**44**) fails to reduce hydrated rhodium trichloride and forms both *fac*- and *mer*-trihalorhodium(III) complexes.

7 THE HIGHER OXIDATION STATES

The number and variety of compounds in oxidation states of four or greater is dramatically lower than for rhodium(III). Essentially only oxo and halo species are formed, and none of these are cationic.

Binary rhodium(IV) compounds are confined to the purple red tetrafluoride and the black dioxide. The hydrated dioxide may be prepared by oxidizing rhodium(III) compounds, either with chlorine or electrochemically. Attempts to dehydrate this material lead to decomposition. No cationic rhodium(IV) complexes have been characterized unambiguously, but both $[RhCl_6]^{2-}$and $[RhF_6]^{2-}$ are well established. The alkali metal salts of the hexafluororhodate(IV) ion are all isomorphous with their platinate(IV) analogs.

The hexahalorhodate(IV) complexes are best prepared by oxidizing the solid hexahalorhodate(III) species with the appropriate halogen. The hexafluororhodate ion is relatively easily hydrolyzed, but the hexachloro anion is a powerful oxidizing agent. In water, it disproportionates to chlorine and aquarhodium(III) species. Indeed, the blue species (Claus' blue) formed on oxidation of rhodium(III) species by chlorine, bromate(I), or ozone in aqueous solution have been shown to be peroxorhodium(III) compounds. Thus, only $Cs_2[RhCl_6]$ (obtained by oxidation with $[Ce(NO_3)_6]^{2-}$) can be precipitated from aqueous solution before decomposition occurs.[15] The hexachlororhodate(IV) ion is also very rapidly reduced via an *Outer-Sphere Reaction* when allowed to react with the $[Ru(phen)_3]^{2+}$ ion. The greater stability of the hexafluoro complex is exemplified by the solid-state preparations of $[O_2][RhF_6]$ and $[NO]_2[RhF_6]$. All the hexahalorhodate(IV) complexes are paramagnetic and are presumably low-spin d^5 species.

A number of poorly characterized materials such as $Na_2[RhO_3]$ or $Sr_4[RhO_6]$ have been reported in the literature. However, most of these materials have been found to be contaminated with rhodium(III) species.

Rhodium(V) is even less well represented than rhodium(IV). The only binary compound is the ruby red, tetrameric pentafluoride. The only complex is $[RhF_6]^-$. Bright yellow $M^I[RhF_6]$ salts (M^I = Na, K, Rb, Cs, but not Li) have been prepared by heating $RhCl_3$ and M^ICl in IF_5 or ClF_5. The sodium salt is paramagnetic and contains the low-spin d^4 rhodium(V) ion. Alkaline-earth salts can also be prepared if gaseous ClF_5 is used as the fluorinating agent. The anions are very moisture sensitive and require strictly anhydrous conditions. Nevertheless, they can be converted to salts of the $O_2{}^+$, NO^+, or $[YF_6]^+$ (Y = Kr, Xe) cations. The colors observed in $[BiO_3]^-$ oxidations of rhodium(III) salts have been associated with the +5 and even +6 oxidation states, but good evidence is lacking.

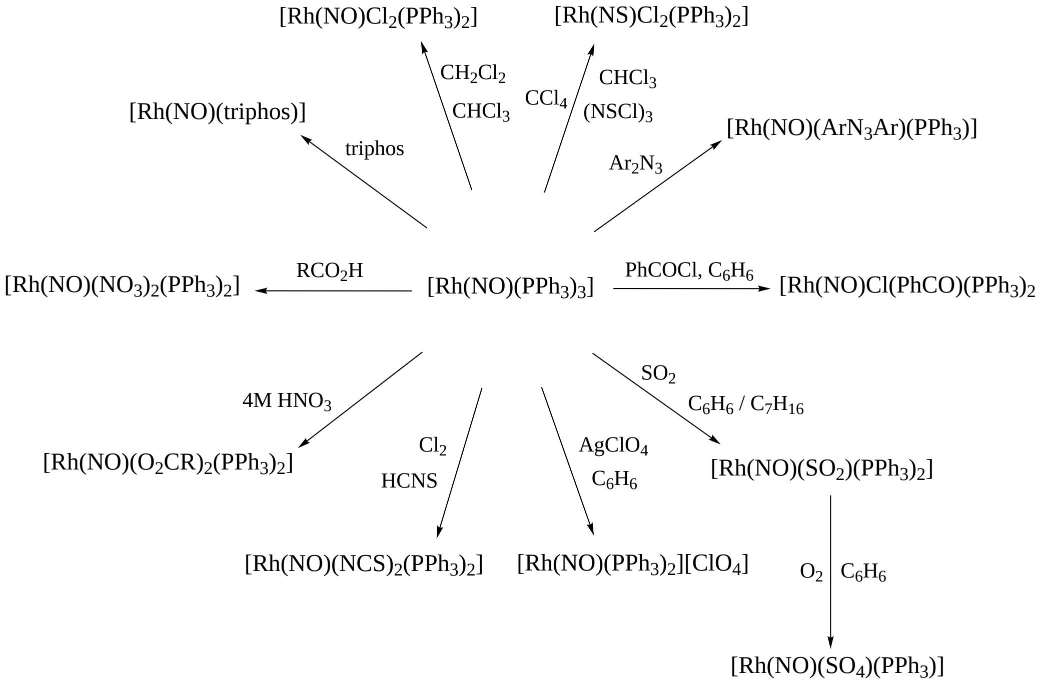
8 NITROSYL COMPLEXES

Although rhodium forms far fewer *Nitrosyl Complexes* than its neighbor in the *Periodic Table*, ruthenium, over 50 nitrosyl rhodium complexes are known, in addition to some ill-characterized ternary halorhodium nitrosyls. Three main series of complexes exist, with general formulas $[Rh(NO)L_3]$, $[RhX_2(NO)L_2]$, and $[Rh(NO)L_4]X$. There are also a few dinitrosyls of the type $[Rh(NO)_2L_2]X$.

8.1 [Rh(NO)L$_3$]Complexes

The most convenient preparation of the triarylphosphine complexes is from *N*-methyl-*N*-nitrosotoluene-4-sulfonamide and hydrated rhodium trichloride in the presence of the phosphine (equation 46). Other, less convenient, routes to this class of compound exist. The crimson-red crystals of the tris(triphenylphosphine) complex (**45**) contain three independent molecules, each of which has a bent nitrosyl group. In the gas phase or in solution $[Rh(NO)(PF_3)_3]$ appears to contain a linear Rh–N–O group, although this may be an artifact of the methods of structure determination. The very reactive triphenylphosphine compound converts other metal complexes to their nitrosyls (equations 47–49) and itself undergoes a variety of addition and ligand-substitution reactions (Scheme 22). The sulfur dioxide complex is noteworthy in that the ligand is bound through both sulfur and oxygen.

$$RhCl_3{\cdot}3H_2O + PPh_3 + 4\text{-}MeC_6H_4SO_2N(NO)Me \xrightarrow{NaBH_4} [Rh(NO)(PPh_3)_3] \qquad (46)$$

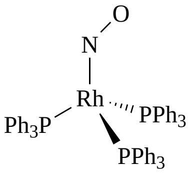


Scheme 22

$$[Rh(NO)(PPh_3)_3] + [FeCl_2(diphos)] \xrightarrow{thf} [Fe(NO)_2(diphos)] \quad (47)$$

$$[Rh(NO)(PPh_3)_3] + [CoCl(PPh_3)_3] \xrightarrow{C_6H_6} [Co(NO)(PPh_3)_3] \quad (48)$$

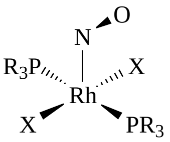
$$[Rh(NO)(PPh_3)_3] + [NiCl_2(PPh_3)_2] \xrightarrow{C_6H_6} [Ni(NO)Cl(PPh_3)_3] + [RhCl(PPh_3)_3] \quad (49)$$



(**45**)

8.2 [RhX$_2$(NO)L$_2$] Complexes

The most convenient preparation of the archtypical complex [RhCl$_2$(NO)(PPh$_3$)$_2$] again involves the reaction between *N*-methyl-*N*-nitrosotoluene-4-sulfonamide and hydrated rhodium trichloride. Many other preparative methods exist; in particular, several other nitrosyl complexes can be converted to [RhCl$_2$(NO)(PPh$_3$)$_2$]. Dichloro(nitrosyl)*bis*(triphenylphosphine)rhodium has the square-pyramidal structure (**46**). The nitrosyl group is bent and both nitrogen and oxygen atoms lie on the RhP$_2$ plane. Surprisingly, the analogs of this complex cannot be obtained from it by metathetical reactions but must instead be prepared from the appropriate starting materials. Indeed, this class of compound is singularly unreactive, in marked contrast to [Rh(NO)L$_3$].



(**46**)

Analogs of the dichloro complex are prepared by a variety of methods, many of which are specific for single compounds. The dibromo complexes can be prepared using nitrosyl bromide or from *N*-methyl-*N*-nitrosotoluene-4-sulfonamide and rhodium tribromide. Replacement of the tribromide by the trichloride and an alkali metal iodide gives diiodo complexes (equations 50 and 51).

$$RhX_3{\cdot}nH_2O + 4\text{-}MeC_6H_4SO_2N(NO)Me \xrightarrow[EtOH]{N_2} [RhX_2(NO)(PPh_3)_2] \quad (X = Cl, Br) \quad (50)$$

$$RhCl_3{\cdot}3H_2O + MI + PR_3 + 4\text{-}MeC_6H_4SO_2N(NO)Me \xrightarrow[EtOH]{N_2} [RhI_2(NO)(PR_3)_2] \quad (R = Et, Bu, Ph, 4\text{-}C_6H_4Me, 4\text{-}C_6H_4Cl) \quad (51)$$

Nitric acid converts hydridorhodium(I) complexes to the *bis*(nitrato) complex (equation 52). Other examples

of these complexes can be obtained from silver nitrate and a six-coordinate carbonyldichloronitrosyl complex. It is also possible to prepare a green chloro nitro complex from chlororhodium(I) complexes and oxides of nitrogen or NOCl (equations 53 and 54). However, no dinitro complex has yet been prepared. *Bis*(carboxylato) complexes are prepared very simply by the reaction of carboxylic acids with aerated solutions of $[Rh(NO)(PPh_3)_3]$ (equation 55). Most of these methods are equally applicable to the production of triphenylarsine complexes. The dihalo complexes may also be prepared from $AsPh_3$ and halonitrosylrhodium complexes. Although all these complexes are believed to have structure (**46**), *cis* basal ligands must be present in $[Rh(NO)Cl(NO_2)(dppe)]$ and $[Rh(NO)(SO_4)(PPh_3)_2]$. The latter structure has also been established for $[Rh(NO)Br_2\{P(OPh)_3\}_2]$. Some thionitrosyl complexes of this stoichiometry have also been prepared but are of doubtful provenance.

$$[RhH(PPh_3)_3] + HNO_3 \longrightarrow [Rh(NO_3)_2(NO)(PPh_3)_2] \quad (52)$$

$$[RhCl(PPh_3)_3] + 4NO \xrightarrow{C_6H_5Cl} [RhClNO_2(NO)(PPh_3)_2] \quad (53)$$

$$trans\text{-}[RhCl(CO)(PPh_3)_2] + NOCl \longrightarrow [RhClNO_2(NO)(PPh_3)_2] \quad (54)$$

$$[Rh(NO)(PPh_3)_3] + RCO_2H \xrightarrow[Me_2CO]{O_2} [Rh(NO)(OCOR)(PPh_3)_2]$$

$$(R = Me, Et, 4\text{-}C_6H_4Me, 4\text{-}C_6H_4NO_2, 4\text{-}C_6H_4Cl, CF_3, C_2F_5, C_6F_5) \quad (55)$$

8.3 Cationic Complexes

Both mono and dinitrosyl cations may be prepared. Salts of the tetrahedral dinitrosyl cation can be prepared either from rhodium nitrosyls (equation 56) or by addition of nitric oxide to ionic rhodium(I) complexes (equation 57). Both nitrosyl groups in complex (**47**) are bent. The action of dppe upon the *bis*(triphenylphosphine) complex produces N_2O. Penta- and hexacoordinate mononitrosyl cations are more common and are usually prepared by the action of $NOPF_6$ or $NOBF_4$ on rhodium(I) complexes in organonitrile solvents (equation 58). The principal reactions of the complexes are substitutions of the nitrile ligands (equations 59–61). A noteworthy feature of (**48**), $[Rh(NO)(MeCN)_3(PPh_3)_2]^+$, is that the MeCN ligand trans to the bent nitrosyl group is said to be bent.

$$[Rh(NO)(PPh_3)_3] + Ag[ClO_4] \xrightarrow{C_6H_6} [Rh(NO)_2(PPh_3)_2][ClO_4] \quad (56)$$

$$[Rh(nbd)(PPh_3)_2][PF_6] + 2NO \longrightarrow [Rh(NO)_2(PPh_3)_2][PF_6] \quad (57)$$

$$[Rh(cod)_2][PF_6] + NOPF_6 \xrightarrow{MeCN} [Rh(NO)(MeCN)_4][PF_6]_2 \quad (58)$$

$$[Rh(NO)(MeCN)_4][PF_6]_2 + Na_2S_2CNMe_2 \longrightarrow [Rh(NO)(S_2CNEt_2)_3][PF_6] \quad (59)$$

$$[Rh(NO)(MeCN)_4][PF_6]_2 + dppe \longrightarrow [Rh(NO)(dppe)_2][PF_6]_2 \quad (60)$$

$$[Rh(NO)(MeCN)_4][PF_6]_2 + PPh_3 \longrightarrow [Rh(NO)(MeCN)_2(PPh_3)_2][PF_6]_2 \quad (61)$$

1 INTRODUCTION

The organometallic chemistry of rhodium continues to comprise a substantial portion of the field of organotransition metal chemistry. Some highlights of the work published since the appearance of the previous report[1] include substantial progress in the activation of C–H bonds in homogeneous systems, the synthesis of a large number of complexes containing vinylidene (=C=CRR′) and allenylidene (=C=C=CRR′) ligands and the chemistry of rhodium alkyl complexes containing tridentate nitrogen-donor ligands in place of the more traditional phosphine ligands.

A comprehensive work covering the organometallic chemistry of rhodium for the period 1982–1994[2] has appeared as have reviews of rhodium allenylidene complexes,[3] cationic rhodium arene complexes,[4] and the involvement of rhodium complexes in C–C coupling reactions.[5] Rhodium complexes are mentioned in a review of the use of ''short bite'' ligands (particularly DPPM) in cluster synthesis[6] and in reviews of the organometallic chemistry of porphyrin compounds,[7] complexes containing both heavy main group elements and transition metals,[8] complexes containing σ-π bridging vinyl, alkenyl, and related ligands,[9] complexes of polyynes,[10] homogeneous catalysis in water,[11] ''very mixed'' metal–carbonyl cluster compounds (e.g. $Cp_2Cr_2Rh(COD)(\mu_3\text{-}S)_2(\mu\text{-}SBu^t)(CO)_2$),[12] and the transition metal assisted oligomerization of phosphaalkynes.[13]

The emphasis in the present chapter will be on recent developments in the area of organorhodium chemistry, and as there have been few reports of new synthetic methodologies, the new practitioner is referred to the previous report[1] for references to established procedures.

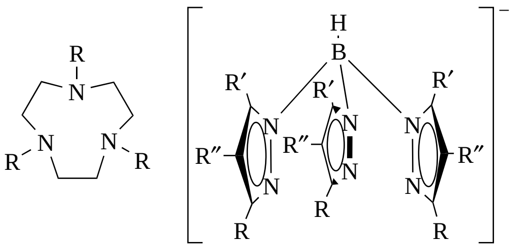
2 COMPOUNDS WITH RHODIUM–CARBON σ-BONDS

2.1 Alkyl and Aryl Complexes

In contrast to the impression that might be gained from earlier work, the presence of ''soft'' phosphine or arsine ligands is not required for the preparation of stable alkyl or aryl rhodium complexes. Considerable use has recently been made of the tridentate, nitrogen-donor ligands Cn (**1**, R = H (also called tacn)), Cn* (**1**, R = Me), and Tp′ (**2**, R = R′ = Me; R″ = H) in studying reactions of alkylrhodium complexes, particularly those involving reductive eliminations to form C–H bonds, where mounting evidence for the formation of σ-complexes (*see* ***Dihydrogen Complexes & Related Sigma Complexes***) of hydrocarbons with rhodium has been obtained. These ligands are considered to be analogs of the cyclopentadienyl ligands but with different steric and electronic properties.

Alkylation of $CnRhCl_3$ by standard methods (equation 1) yields $CnRhR_3$ (R = Me,

$$(Cn)RhCl_3 \xrightarrow{\text{xs RLi}} \xrightarrow{\text{MeOH}} (Cn)RhR_3 \quad (1)$$



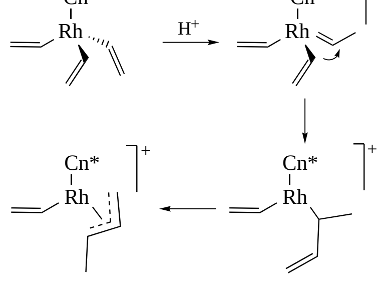
(**1**) (**2**)

Et, Ph, vy, Bu^n, *n*-hexyl, *n*-decyl). Protonation of $CnRhR_3$ (R = Me, Et, Ph, Bu^n, *n*-hexyl, *n*-decyl) with two equivalents of HOTf followed by addition of a phosphorus ligand (L = PMe_3, $P(OMe)_3$) and reduction with $NaBH_4$ (equation 2) yields alkyl hydride (*see* ***Hydride Complexes of the Transition Metals***)

$$(Cn)RhR_3 + HOTf \longrightarrow (Cn)Rh(R)(OTf)_2 \xrightarrow{L} (Cn)Rh(R)((OTf)OTf \xrightarrow{NaBH_4} (Cn)Rh(R)((L)(H)OTf \quad (2)$$

complexes [CnRh(H)R(L)]Otf, which together with some Cn* analogs, were used to study the reductive elimination of alkane (RH). For R = Me, the half-life for the elimination of methane at 80 °C was 7 h indicating this to be a particularly stable alkyl hydride complex of rhodium. Heating [CnRh(H)R(L)]OTf (R = *n*-Bu, *n*-hexyl, *n*-decyl) in benzene forms $[CnRh(H)(C_6H_5)(L)]OTf$ via the activation of a C–H bond (*see* ***Alkane Carbon–Hydrogen Bond Activation***) of benzene by the reductive elimination product, {(Cn)Rh(L)}. The same process using [CnRh(D)R(L)]OTf led to deuterium incorporation into *both* terminal methyl groups of the product alkane leading to the proposal that the eliminated alkane remains associated with the {CnRh(L)} fragment, presumably via an Rh···H–C interaction (*see* ***Dihydrogen Complexes & Related Sigma Complexes***), and that the metal migrates down the alkane chain through a series of such interactions.[14]

Protonation of $Cn^*Rh(vy)_3$ with HOTf yields the allyl complex $[Cn^*Rh(vy)(\eta^3\text{-}CH_2CHCHMe)]OTf$ (see also Section 4.1) in which coupling of two of the vinyl groups is proposed to proceed via an alkylidene intermediate (equation 3).[15]

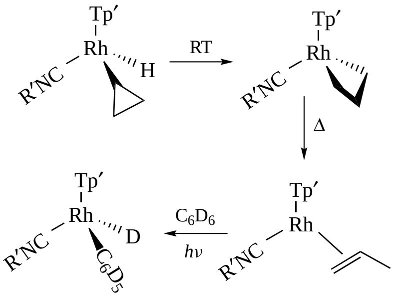


(3)

The starting point for the formation of alkylrhodium complexes containing the Tp′ ligand is $Tp'Rh(CNR')Cl_2$ ($R' = CH_2CMe_3$), which is prepared by replacement of the weakly bound acetonitrile ligand in $Tp'Rh(NCMe)Cl_2$ by the isocyanide. Conversion of this to the alkyl hydrides Tp′Rh(CNR′)(H)(R) (R = CH_2CD_3, Pr^n, Pr^i, vy, *cyclo*-C_3H_5) (*see* ***Hydride Complexes of the Transition Metals***) proceeds via equation (4). When R = *cyclo*-C_3H_5, rearrangement to the

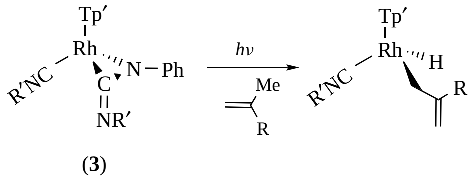
$$Tp'Rh(CNR')Cl_2 \xrightarrow{RMgX} Tp'Rh(CNR')(R)Cl \xrightarrow{Cp_2ZrH_2} Tp'Rh(CNR')(R)(H) \quad (4)$$

metallacylcobutane isomer occurs readily and is proposed to involve reductive elimination to give a σ-cyclopropane complex followed by insertion of the metal into a strained C–C bond. On heating, this rearranges again to the isomeric propene complex from which the olefin is liberated under photolysis with the solvent benzene undergoing C–H oxidative addition (*see* ***Alkane Carbon–Hydrogen Bond Activation***) to the reactive {Tp′Rh(CNR′)} fragment (equation 5).



(5)

Reduction of Tp′Rh(CNR′)(vy)Cl with $CpZrH_2$ forms Tp′Rh(CNR′)(vy)(H), which rearranges at room temperature to the ethylene complex $Tp'Rh(CNR')(\eta^2\text{-}C_2H_4)$. To explore the regiochemistry of the C–H oxidative addition process in related systems, the {Tp′Rh(CNR′)} fragment was generated by photolysis of (**3**) in three liquid olefins. For R = H and Me, oxidative addition occurs at a methyl C–H bond (*see* ***Alkane Carbon–Hydrogen Bond Activation***) to form the corresponding allyl hydride (equation 6). When R = Me, C–H reductive elimination occurs over three days at room temperature in benzene solution to form the propene complex

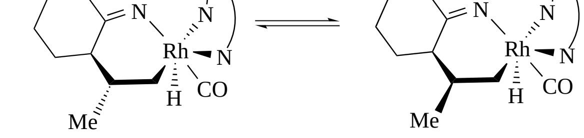


(**3**)

(6)

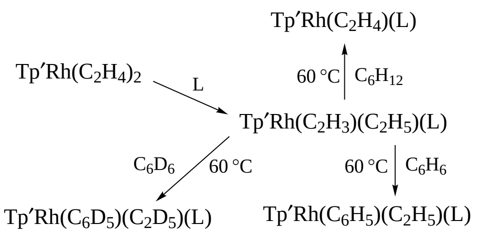
Tp′Rh(CNR′)(η^2-CH$_2$=CHMe), while for R = Me, the reductive elimination occurs more readily and the olefin complex is less stable so that the ultimate product is the benzene activation product Tp′Rh(CNR′)(H)(C_6H_5). Photolysis of (**3**) (*see* ***Photochemistry of Transition Metal Complexes***) in liquid *t*-butylethylene leads to oxidative addition of a vinylic C–H (*see* ***Alkane Carbon–Hydrogen Bond Activation***) bond yielding Tp′Rh(CNR′)(H)(CH=CHCMe$_3$), presumably because the bulk of the *t*-butyl group prevents this end of the molecule getting sufficiently close to the metal. This vinyl hydride complex is considerably more resistant to reductive elimination than the allyl hydride species and again the ultimate decomposition product is Tp′Rh(CNR′)(H)(C_6H_5). The methyl hydride complex Tp′Rh(CNR′)(H)(CH_3) in C_6D_6 solution at room temperature undergoes H/D exchange to initially form Tp′Rh(CNR′)(H)(CH_2D) and more slowly the solvent activation product Tp′Rh(CNR′)(D)(C_6D_5) plus CH_3D. The rate of reductive elimination of methane in C_6H_6/C_6F_6 mixtures depends on the concentration of benzene. Both observations are consistent with the presence of a rhodium–methane σ-complex (*see* ***Dihydrogen Complexes & Related Sigma Complexes***), which forms subsequent to the reductive elimination.[16]

Photolysis of Tp′Rh(CO)$_2$ in alkane solution (*see* ***Photochemistry of Transition Metal Complexes***) forms Tp′Rh(CO)(H)(R) (R = *n*-pentyl, *n*-hexyl, *n*-heptyl, *i*-octyl) via oxidative addition of a C–H bond (*see* ***Alkane Carbon–Hydrogen Bond Activation***) to the reactive intermediate {Tp′Rh(CO)}. The wavelength dependence of the quantum yield suggests the involvement of two different excited states of differing reactivity. The lack of a thermal reaction in the dark suggests that a species with an η^2-Tp′ ligand is not involved. The analogous reaction with the modified tris-(pyrazolylborate) ligand (**4**) resulted in oxidative addition of a C–H bond of the isopropyl substituent to the metal to form the pair of isomers shown in equation (7). These were shown to thermally

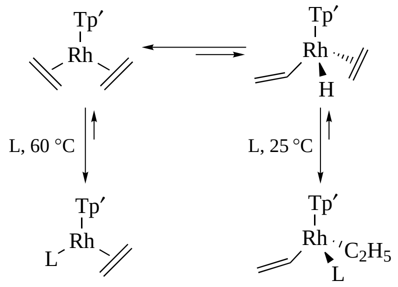


(7)

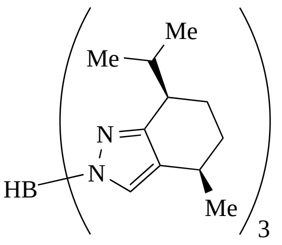
interconvert via a rate-determining C–H reductive elimination/oxidative addition process within a single arm of the ligand, and without inversion of configuration at the metal.[17] The reaction of Lewis base ligands (L = py, MeCN) with Tp′Rh(C_2H_4)$_2$ and subsequent chemistry is outlined in equation (8). These results are interpreted as shown in equation (9).



(8)



(9)



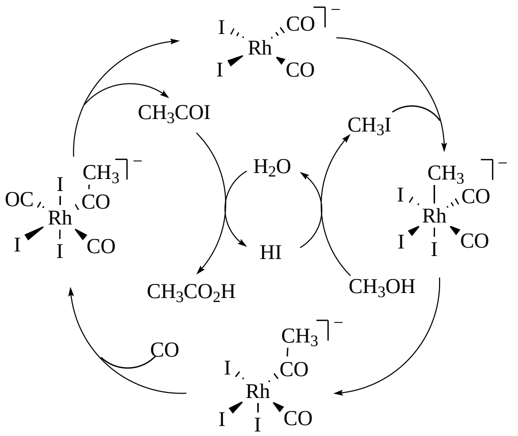
(**4**)

The key feature is the presence of a small equilibrium quantity of the vinyl hydride complex Tp′Rh(H)(CH=CH$_2$)(η^2-C_2H_4) formed by C–H oxidative addition of one of the ethylene ligands. The formation of Tp′Rh(C_2H_5)(C_6H_5)(L) and its deuterated analog are postulated to arise from coordination of benzene to the ethylene-loss species {Tp′Rh(η^2-C_2H_4)} followed by C–H oxidative addition (*see* ***Alkane Carbon–Hydrogen Bond Activation***).[18]

A series of more highly substituted (R = R′ = Me, CF$_3$; R′ = H. R = CF$_3$; R′ = Me; R″ = H. R = Me; (R,R′) = -(CH$_2$)$_3$-, -(CH$_2$)$_4$-) and unsymmetrical (R = Ph; R′ = Me; R″ = H on two pyrazolate rings and R,R′ = Me, Ph; Me,Me; Et,Et on the third), examples of (**2**) ($Tp^{R,R'}$) were used to prepare ($Tp^{R,R'}$) RhL$_2$ (L = CO, L$_2$ = COD). Experimental and theoretical studies of the structures and conformational preferences of these complexes were performed.[19]

Several further experimental and theoretical studies of the oxidative addition of methyl iodide to Rh(I) complexes have been reported, in part because of its importance in the rhodium-catalyzed carbonylation of methanol (*see* ***Carbonylation Processes by Homogeneous Catalysis***) to

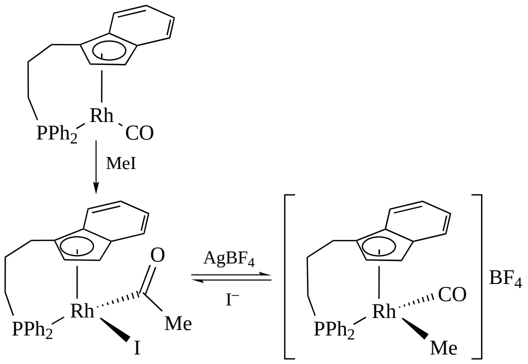
acetic acid (equation 10).



(10)

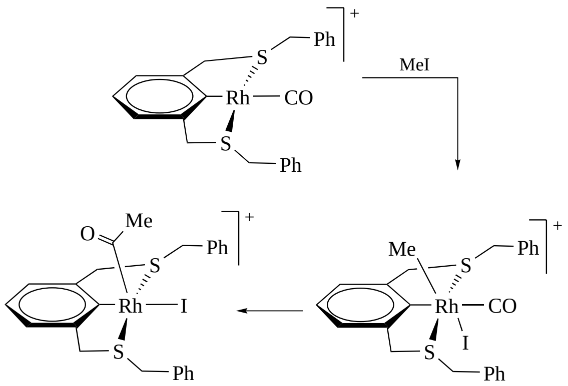
These include the reaction with (η^2-Tp′)Rh(L)(CO) (L = PMe_3, PMe_2Ph, $PMePh_2$, PPh_3) where the initial product is [(η^3-Tp′)Rh(L)(CO)Me]I, and slow conversion to the acyl derivative (η^3-Tp′)Rh(L)(C=(O)Me)(I) ensues. The second order kinetics, a correlation of rates with the basicity of L and a large negative value for $\Delta S^{\ddagger}$ indicate an associative activation process. The much lower reactivity of analogous bis(pyrazolyl)borate complexes suggests that the ability of Tp′ to change from η^2 to η^3 coordination at some point on the reaction coordinate is important to facilitating the process.[20] With [Rh(μ-Cl)(Pr^i_3P)$_2$]$_2$ and $RhCl(PEt_3)_3$ at −20 °C, methyl iodide (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation***) forms 5- and 6-coordinate oxidative adducts, respectively, but with (Pr^i_3P)$_2$Rh(η^2-OTf), no reaction occurs at room temperature even in the presence of excess methyl iodide. Evidently, the nature of the anionic ligand (chloride is the better donor) and possibly the coordination number at Rh(I) are important factors for the success of the reaction.

A low (circa 1%) steady state concentration of $[Rh(CH_3)(CO)_2I_3]^-$ has been detected spectroscopically when salts of $[RhI_2(CO)_2]^-$ are dissolved in methyl iodide confirming the identity of the proposed initial oxidative adduct of methyl iodide to $[RhI_2(CO)_2]^-$ in the methanol carbonylation process (*see* ***Carbonylation Processes by Homogeneous Catalysis***) (right side of equation 10). The transition state for this initial step has been explored by ab initio calculations (*see* ***Molecular Orbital Theory***) and two reasonable models were obtained. Both involve attack of the metal on the methyl group with the more energetically favored occurring opposite the iodine. This is the ''classical'' model for the transition state that leads to an inversion at carbon, and is also preferred on the basis of a comparison of the observed and calculated kinetic isotope effects of the reaction. The other plausible transition state involves attack adjacent to iodine and leads to retention at carbon.[21] Another computational study explored the conversion of $[Rh(CH_3)(CO)_2I_3]^-$ to $[Rh(C(=O)CH_3)(CO)I_3]^-$ (lower right of equation 10) using DFT methods (*see* ***Molecular Orbital Theory***), from which it was concluded that it is a migratory insertion process with the methyl group migrating to a carbonyl ligand.[22] In a related study, spectroscopic and structural evidence for this migration of a methyl group between rhodium and a coordinated carbonyl ligand were obtained, as outlined in equation (11). In the first step, the diastereomer shown comprises 89% of the product acyl



(11)

complex and the subsequent deinsertion/insertion processes occur stereospecifically indicating movement of the methyl group.[23] Both the oxidative addition and methyl migration steps have been independently studied in detail in the system depicted in equation (12).[24] Also reported is the cis oxidative addition of methyl iodide to both



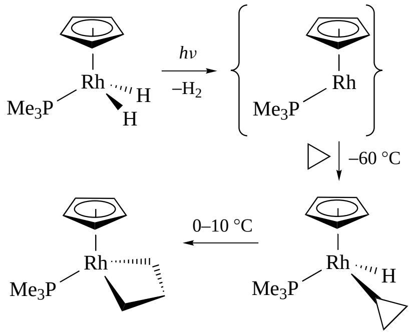
(12)

rhodium centers in Pd{(μ-pz)(μ-SBu^t)Rh(CO)(P(OMe)$_3$)}$_2$, which is followed by methyl migration to carbon monoxide on both centers such that the two acyl ligands formed are on the same side of the mean molecular plane.[25]

Laser flash photolysis (*see* ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds*** and ***Photochemistry of Transition Metal Complexes***) coupled with rapid infrared analysis of the solution species has proved a powerful tool for the detection of unstable intermediates, and has seen considerable application on experimental studies of the C–H oxidative addition reaction (*see* ***Alkane Carbon–Hydrogen Bond Activation***). Application to toluene solutions of Cp*Rh(PMe_3)(η^2-C_2H_4) has allowed detection of the intermediate Cp*Rh(PMe_3)(η^2-toluene), and by following the subsequent conversion to Cp*Rh(PMe_3)(H)(C_6H_4Me),

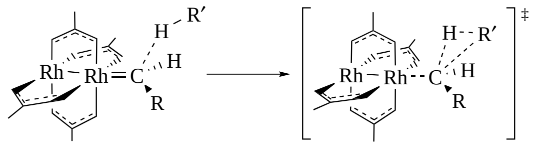
activation parameters for the C–H oxidative addition process have been derived. In a related study, the reductive elimination of this last species and analogous aryl hydride complexes showed that the activation barrier for the process increased and the transition state became ''looser'' as the substituents on the aryl group became more electron-withdrawing. It appears now that η^2-coordination of arenes to {Cp*Rh(PMe$_3$)} and related coordinatively unsaturated species precedes C–H oxidative addition, and control of the degree to which this occurs seems to depend on the extent to which the η^2-coordination disrupts the resonance stabilization of the arene.[26]

With the development of powerful methods for molecular orbital calculations (e.g. DFT) (*see* ***Molecular Orbital Theory***), several computational studies of the C–H oxidative addition (*see* ***Alkane Carbon–Hydrogen Bond Activation***) process have been undertaken. One has used {CpRh(PH$_3$)} to model the reactive intermediate {Cp*Rh(PMe$_3$)} proposed for the reaction shown in equation (13). The results



(13)

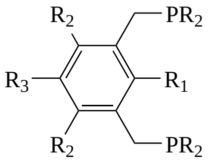
suggest that reaction occurs from a singlet potential-energy surface via an initial σ-H–C$_3$H$_5$ complex through a single transition state to the cyclopropyl hydride complex, which is the kinetic product. They also indicate that the subsequent thermal rearrangement to the metallacyclobutane complex proceeds via C–H reductive elimination to the same σ-H–C$_3$H$_5$ complex followed by metal insertion into a C–C bond (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation***) (see also equation 5).[27] In contrast, DFT calculations on the oxidative addition of methane to {CpM(L)} (M = Rh, Ir; L = CH$_2$, CO, SH$_2$, PH$_3$) suggest that C–H oxidative addition should proceed from the triplet state since it is said that the singlet-triplet splitting (*see* ***Electronic Structure of Organometallic Compounds***) correlates with both $\Delta H^\ddagger$ and ΔH for the process, but no comments are made in the previous paper about this difference.[28] A third study used ab initio methods to probe the preference for intermolecular C–H oxidative addition, as modeled by {CpRh(PH$_3$)} + CH$_4$, versus an intramolecular process involving a ligand substituent as modeled by {CpRh(PH$_2$R)} (R = Me, Et). The conclusion is that the intermolecular process has a lower activation barrier.[29] In an elaborate computational study, DFT methods that included quantization of vibrational energy, addition of zero-point energy and tunneling effects were used to probe the conversion of RhCl(η^2-H$_2$CH$_2$)(PH$_3$) to RhCl(H)(CH$_3$)(PH$_3$). At 200 K, the calculated rate constant was increased by a factor of 194 over that calculated using classical mechanics to describe the atomic motions along the reaction coordinate. So far there appear not to be sufficient experimental data for comparison.[30] A final paper used DFT methods to explore the C–H activation step in the Rh$_2$(OAc)$_4$ catalyzed coupling of a diazo compound with an alkane that finds significant application in organic synthesis (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions*** and ***Organic Synthesis using Transition Metal Carbonyl Complexes***). The results indicate that the diazo compound should coordinate to an axial site on the dinuclear complex via carbon with back-donation of electron density into the C–N σ^* orbital, facilitating extrusion of N$_2$ and formation of an intermediate carbene complex (see also Section 2.4 and ***Carbene Complexes***). The highly electrophilic carbene carbon then attracts the C–H bond of the alkane leading to the development of a three-center transition state (equation 14).[31]



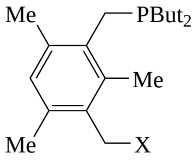
(14)

The early ideas that C–H oxidative addition (*see* ***Alkane Carbon–Hydrogen Bond Activation***) requires constraining the C–H bond to be close to the metal have been shown to be incorrect as many examples of unconstrained, intermolecular C–H oxidative addition are now known. Nevertheless, a considerable number of reports continue to appear on activation of C–H and C–C bonds in constrained, intramolecular systems. One series uses the ''pincer'' ligands (**5**) and (**6**). Reaction of (**5**) (R = Bu^t; R$_1$ = Et; R$_2$ = R$_3$ = H) with [Rh(μ-Cl)(L)$_2$]$_2$ (L = C$_2$H$_4$, COE) forms (**7**), which on prolonged heating converts to (**8**), conditions under which analogs with a methyl, trifluoromethyl, or β,β,β-trifluoroethyl group in place of the ethyl group were stable. This indicates (**8**) formed by β-H elimination, with the bulk of the tridentate ligand enforcing the necessary coordinative unsaturation in (**7**) and then enhancing the dissociation of the product olefin. Complex (**8**) can also be obtained directly from [Rh(μ-Cl)(L)$_2$]$_2$ (L = C$_2$H$_4$, COE) and (**5**) (R = Bu^t; R$_1$ = R$_2$ = R$_3$ = H) by oxidative addition of the C–R$_1$ (=H) bond. The insertion of Rh into the sp^2-sp^3 C–C bond (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation***) in forming (**7**) rather than a C–H or a sp^3-sp^3 C–C bond is suggested to be kinetically controlled. To further explore the factors controlling preferences for C–H (*see* ***Alkane Carbon–Hydrogen Bond Activation***) versus C–C (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation***) activation in these types of complexes, the reaction of (**6**) (X = OMe) with [Rh(COE)$_2$S$_n$]BF$_4$ (S = THF, MeOH, acetone) was performed leading to isolation of a mixture of (**9**)

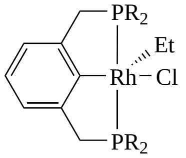
and (**10**), which on heating or on evaporation of the solvent converted to (**11**).



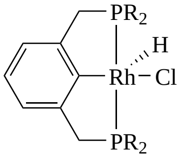
(**5**)



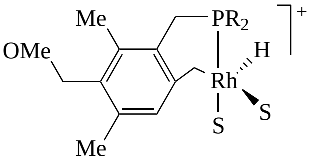
(**6**)



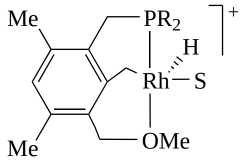
(**7**)



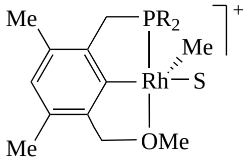
(**8**)



(**9**)

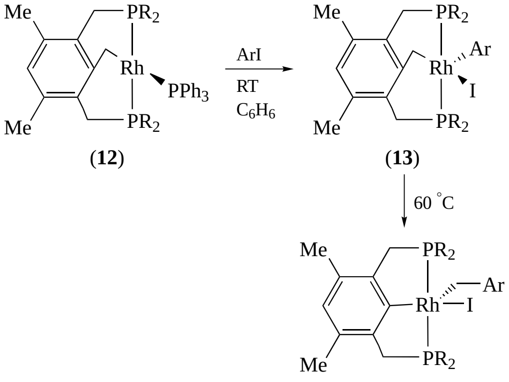


(**10**)



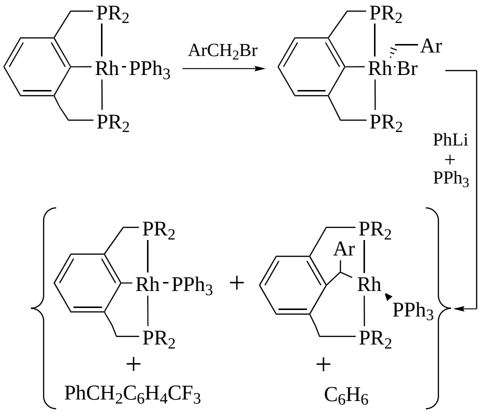
(**11**)

Molecular orbital calculations (*see* ***Molecular Orbital Theory***) indicate that the presence of a highly coordinatively unsaturated 14-electron Rh center is important for both C–C and C–H activation, but that for C–C activation to occur, the methoxy group of the ligand has to be coordinated to bring the central C–CH_3 bond close to the metal. Presumably, coordination of the solvent to the starting Rh(I) complex prevents (**6**) from binding as a bidentate ligand so this condition is not initially met. Removal of solvent permits additional binding of the methoxy substituent, and following reductive elimination, C–C activation occurs. In contrast to some of the computational studies mentioned earlier, a ''direct'' C–H oxidative addition (without initial formation of a σ-complex) is indicated by the calculations. Reaction of (**5**) (R = Ph; $R_1 = R_2 =$ Me; $R_3 =$ H) with Rh(H)$(PPh_3)_4$ forms the C–H activation product, (**12**), which oxidatively adds aryl iodides (Ar = Ph, *p*-XC_6H_4 (X = Me, OMe, CF_3), 3,5-$(CF_3)_2C_6H_3$) (equation 15). Complexes (**13**) on heating undergo transfer of



(**12**) (**13**) (**14**) (15)

a methylene group to form (**14**). This is proposed to occur via reductive elimination of the two Rh–C bonds in (**13**) followed by insertion of the metal into the C–CH_2Ar bond (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation***). To probe the feasibility of the reverse transfer (**14** to **13**), an analog of (**12**) was reacted with ArCH_2Br (Ar = *p*-$CF_3C_6H_4$) and then with phenyl lithium followed by triphenylphosphine (equation 16). The phenyl lithium replaces the bromide ligand to

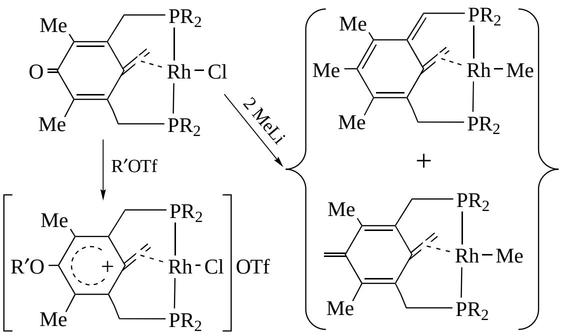


(16)

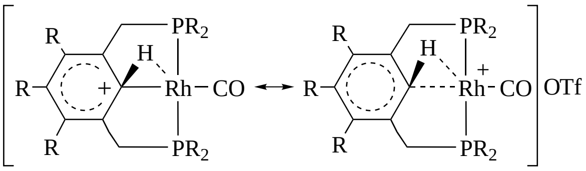
yield an intermediate with three Rh–C bonds, and coordination of the phosphine induces competitive reductive elimination of either the phenyl and benzyl groups to form the product pair on the left or the benzyl group with the Rh–C bond to the ligand. The latter process is followed by activation of a benzyl C–H bond and reductive elimination of benzene to form the product pair on the right.

Reaction of (**5**) (R = Bu^t; $R_1 =$ H; $R_2 = R_3 =$ H, OMe) with $[Rh(\eta^2\text{-}C_2H_4)(CO)(THF)_{1,2}]OTf$ at room temperature forms a species formulated as (**15a,b**). The crystal structure shows the presence of an agostic hydrogen on the ring carbon adjacent to the metal indicating that oxidative addition of this C–H bond to the metal has not occurred, and so this is presumably a precursor to complexes like (**8**). That the agostic hydrogen is not in the plane of the attached ring is taken to indicate that this ring exhibits some degree of arenium

character. In deliberate attempts to generate arenium character in the central ring of the pincer ligand, the reaction sequence of equation (17) ($R = Bu^t$;

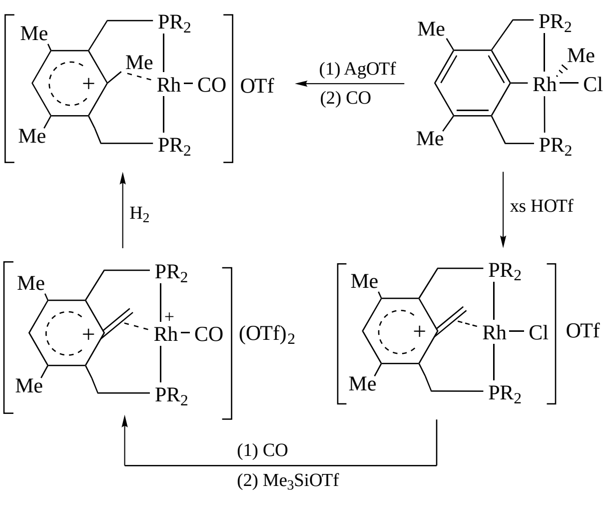


(17)

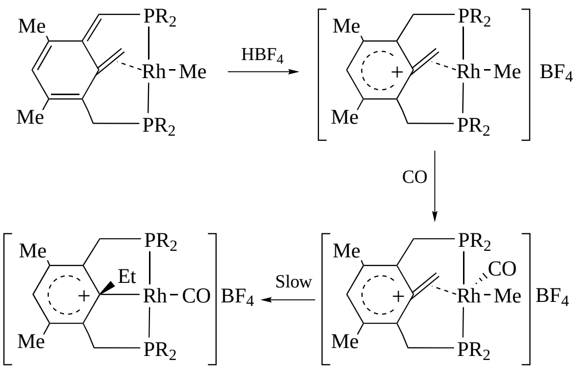


(**15a**) (**15b**)

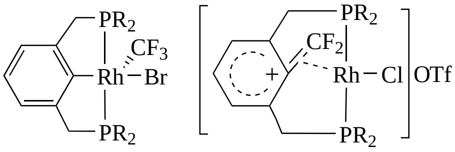
$R' = H, SiMe_3$) was performed. The structure of the cationic complex showed a significant averaging of the C–C distances in the six-membered ring as compared with the quinoid precursor indicating it to be formulated as a methylene arenium cation. The two products of the reaction at the right of this scheme are characterized as metal stabilized xylylenes. Under forcing conditions, (**5**) ($R = Bu^t$; $R_1 = CF_3$; $R_2 = R_3 = H$) reacts with $[Rh(\mu\text{-}Cl)(L)_2]_2$ ($L = C_2H_4$, COE) with cleavage of the C–CF_3 bond to form (**16**). Protonation of (**16**) with HOTf yields the difluoromethylene arenium salt (**17**). Similar processes occur with the systems shown in equations (18) and (19), where both methylene



(18)

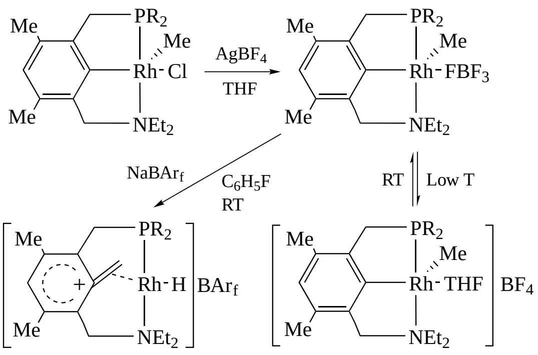


(19)



(**16**) (**17**)

arenium and methyl arenium cations were generated. The alkyl arenium compounds appear to have considerably less positive charge in the ring than do the methylene arenium analogs. This proposed to be the result of stabilization of the arene form via an agostic interaction of the $C_{ipso}-C_{alkyl}$ bond with the metal. The transformations depicted in equation (19) indicate that direct transfer of an alkyl group to the methylene arenium cation does not occur. Most recently, reaction of (**6**) ($X = NEt_2$) with $[Rh(\mu\text{-}Cl)(COE)_2]_2$ has been reported to proceed via oxidative addition of the central methyl group to the metal as observed in related systems. Chemistry following chloride abstraction from the initial product in THF solution is outlined in equation (20). The formation of the methylene

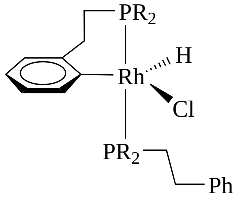


(20)

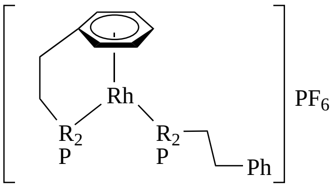
arenium cation in this instance is proposed to be the result of the noncoordinating character of the solvent fluorobenzene and the counterion $[BAr_f]^-$ (*see* ***Boron: Organoboranes***) that forces a high degree of unsaturation upon the 14-electron metal leading to methyl transfer to the ring followed by β-H elimination.[32,33]

While ligands like (**5**) that force a C–H bond close to rhodium could be expected to facilitate C–H activation (*see*

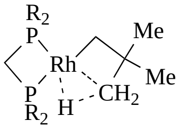
Alkane Carbon–Hydrogen Bond Activation), such behavior might not be expected of a monophosphine. However, in the reaction of $[Rh(\mu\text{-}Cl)(COE)_2]_2$ with four equivalents of $PhCH_2CH_2PBu^t{}_2$, this is observed as the product in (**18**) and conversion to (**19**) occurs on chloride abstraction (see also (**174**), Section 42).[34] A related situation is obtained when $[Rh(\mu\text{-}Cl)(Bu^t{}_2PCH_2PBu^t{}_2)]_2$ is treated with neopentyl lithium where the highly unsaturated, 14-electron metal in the product, (**20**), is stabilized by an agostic interaction.[35]



(**18**)

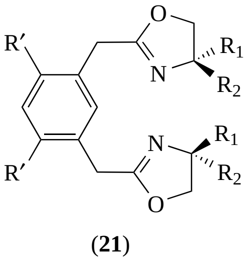


(**19**)

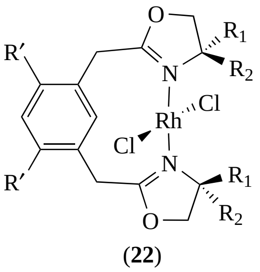


(**20**)

Recent work has also focused on the bis(oxazoline) ligands (**21**) ($R_1 = R_2 = Me$. $R_2 = H$; $R_1 = Me$, Et, Pr^i, Bu^i, Bu^t, Ph. $R' = H$, Me). Reaction with $RhCl_3{\cdot}3H_2O$ forms (**22**) in which there is an agostic interaction with the endo methyl group when $R_1 = R_2 = R' = Me$. On successive reactions with dimethyl zinc (*see* ***Zinc: Organometallic Chemistry***), AgOTf, and $NaBAr_f$, (**22**) ($R' = Me$, $R_2 = H$, $R_1 = Pr^i$) forms (**23**) where methyl migration to the aromatic ring (via C–C reductive elimination) occurs on reaction with neutral ligands to form (**24**) ($L = CO, C_2H_4$).[36]

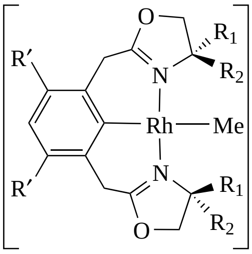


(**21**)

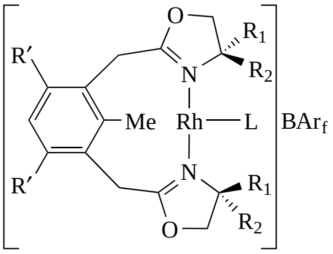


(**22**)

The migratory insertion reactions of ethylene into Rh–H and Rh–C bonds (*see* ***Organic Synthesis using Transition Metal Carbonyl Complexes***; ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***, and ***Organic Synthesis Using Metal-mediated Coupling Reactions***) have been explored by DFT calculations (*see* ***Molecular Orbital Theory***) on $[CpRh(PH_3)(C_2H_4)R]^+$ (R =



(**23**)



(**24**)

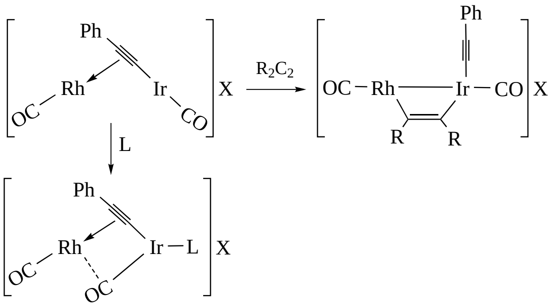
H, Me). Inclusion of relativistic effects was found to be important for results on the model to agree with experiment. For R = H, the calculated transition state was calculated to be close to the reactants, while for R = Me, the transition state is product-like. Both the ethyl and propyl products show an agostic interaction with a β-hydrogen.[37] A second study used DFT methods to explore the oxidative addition of the C–F bond in fluoromethane to unsaturated Rh(I) species modeled by $\{Rh(X)(PH_3)_2\}$ (R = H, Me, Cl). The activation barrier was found to correlate with the magnitude of the singlet-triplet splitting and to be lowered by the presence of π-donor ligands.[38]

2.2 Dinuclear Complexes

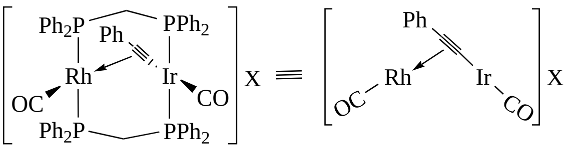
Considerable interest continues to be shown in the chemistry of dinuclear complexes (*see* ***Dinuclear Organometallic Cluster Complexes***), particularly heterometallic species, containing metal–carbon σ-bonds to determine the extent to which the two metals may be involved in the cleavage and formation of C–H and C–C bonds (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation*** and ***Alkane Carbon–Hydrogen Bond Activation***). With the symmetrical complex $[Rh(\mu\text{-}pz)(CNBu^t)_2]_2$, methyl iodide adds (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation***) to both metal centers forming $[Rh_2(\mu\text{-}pz)_2(\mu\text{-}I)(Me)_2(CNBu^t)_4]I$ but with $(COD)Rh(\mu\text{-}pz)_2Rh(CNBu^t)_2$, only the metal coordinated to the isocyanide reacts. Evidently that metal is more basic. Similar results are seen with RCH_2Cl (R = vy, C(=O)Me, C(=O)OMe, Ph) where both metals are alkylated in the former complex but only one is alkylated in the latter complex. Both these results suggest that the metal atoms are acting independently in the oxidative addition. By contrast, addition of one equivalent of I_2 to $[Rh(\mu\text{-}pz)(CNBu^t)_2]_2$ forms the *symmetrical* adduct $[Rh(\mu\text{-}pz)I(CNBu^t)_2]_2$. The difference is attributed to the polarity of the C–I bond in methyl iodide, which makes it susceptible to attack by a nucleophilic metal while the nonpolar iodine functions more as a simple oxidizing agent. This is also suggested by the observation that $[Rh(\mu\text{-}pz)(CNBu^t)_2]_2$ can be oxidized to $\{[Rh(\mu\text{-}pz)(MeCN)(CNBu^t)_2]_2\}^{2+}$ by two equivalents of ferricinium hexafluorophosphate, and on reaction of the cation with iodide ion, $[Rh(\mu\text{-}pz)I(CNBu^t)_2]_2$ is again formed. In the case of $RCHCl_2$ (R = H, C(=O)Me,

C(=O)OMe, Ph), [Rh(μ-pz)(CNBu^t)$_2$]$_2$ forms Rh$_2$(μ-pz)$_2$(μ-CHR)Cl$_2$(CNBu^t)$_4$ and here the unsymmetrical dimer also gives an analogous product.[39]

Most numerous are reports on heterobimetallic complexes bridged by two DPPM ligands. The first example is (**25**) (X = BF_4^-, OTf^-). As depicted below, only the ligands in the equatorial plane of this and related complexes will be shown in the ensuing discussion for simplicity. Neutral ligands, L (=C_2H_4, various allenes) add to iridium in (**25**) to cause one carbonyl ligand to become semi-bridging while dimethylacetylene dicarboxylate (R = CO_2Me) oxidatively adds across both metals (equation 21). Allyl halides undergo simple

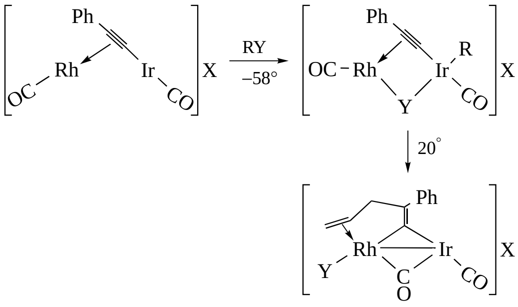


(21)



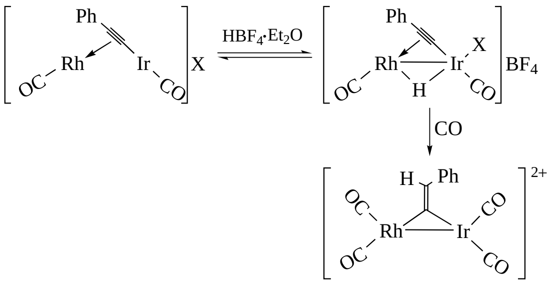
(**25**)

oxidative addition (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation***) to (**25**) at a low temperature but on warming, C–C coupling with the acetylide occurs (equation 22 (R = CH_2CHCH_2; Y = Cl, Br)). Protonation of (**25**)



(22)

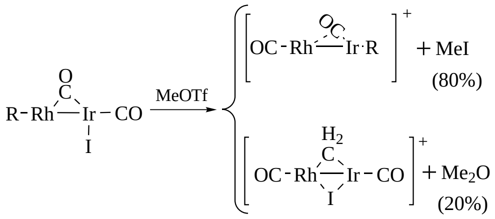
probably occurs initially at iridium, but the characterized product contains a bridging hydride ligand, which is induced to couple with the acetylide ligand and form a vinylidene-bridged species (equation 23). In contrast to internal alkynes, terminal



(23)

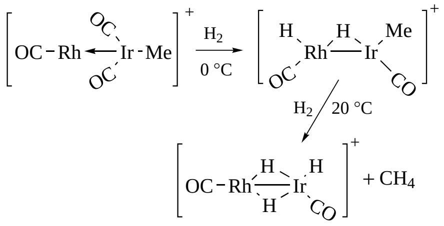
alkynes undergo C–H oxidative addition (*see* ***Alkane Carbon–Hydrogen Bond Activation***) to the iridium center in (**25**) to form a bis-acetylide complex.[40]

The neutral complex Rh(CO)(μ-DPPM)$_2$Ir(CO)$_2$ is unreactive toward even excess methyl iodide but is alkylated by MeOCH$_2$I and then methyl triflate (equation 24 (R = MeOCH$_2$)). It can, however, be methylated at iridium by methyl triflate and the

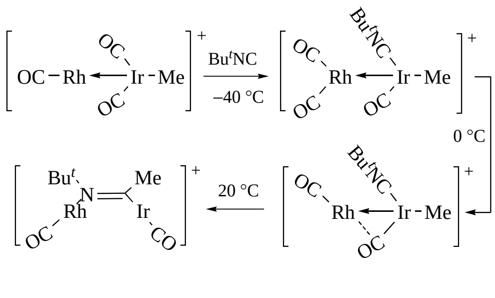


(24)

subsequent reactions of this cationic methyl derivative with dihydrogen and with isocyanides are outlined in equations (25) and (26). The coupling of the methyl group with

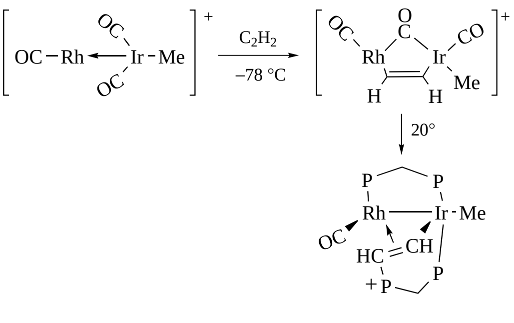


(25)



(26)

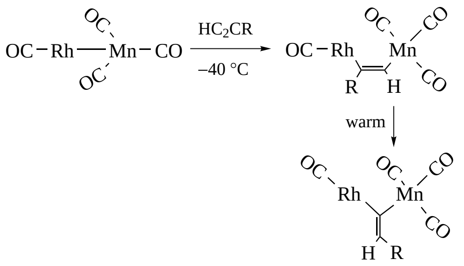
the isocyanide is of note particularly since, in the reaction of the methyl complex with acetylene, the alkyne oxidatively adds to both metals to initially form the dimetallated olefin complex but then couples with one of the DPPM ligands and not with the methyl group (equation 27).[41] By contrast, in the same reaction with dimethylacetylene



(27)

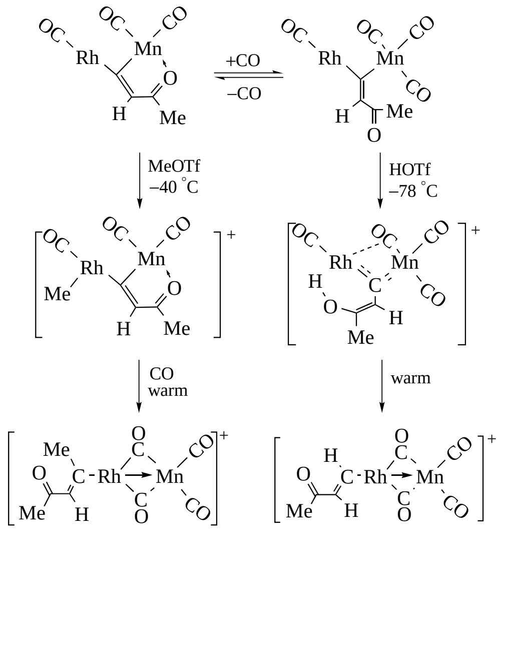
dicarboxylate, following the formation of an intermediate dimetallated olefin complex, coupling with the methyl group does occur. With phenyl acetylene, oxidative addition of the alkyne C–H bond to iridium occurs at a low temperature to form an acetylide hydride species, which on warming eliminates methane and ultimately reacts with a second alkyne by C–H oxidative addition to give $[Rh(CO)(\mu\text{-}H)(\mu\text{-}DPPM)_2(\mu\text{-}\eta^1{:}\,\eta^2\text{-}C{\equiv}CPh)Ir(C_2Ph)(CO)]^+$.[42]

At a low temperature, $Rh(CO)(\mu\text{-}DPPM)_2Mn(CO)_3$ oxidatively adds 3-butyne-2-one to form a dimetallated olefin complex, which rearranges on warming to the vinylidene-bridged isomer (equation 28 (R = C(=O)Me)). This last complex reacts



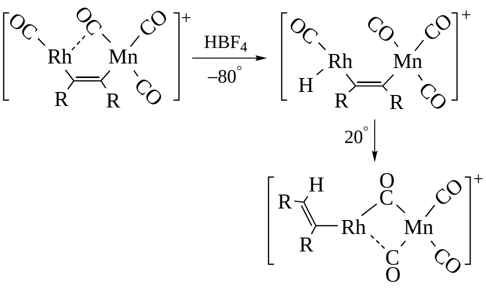
(28)

with triflic acid and methyl triflate as shown in equation (29). With the alkynes RC≡CR,



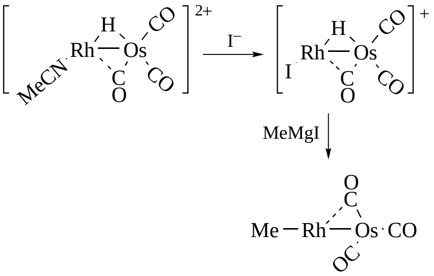
(29)

$Rh(CO)(\mu\text{-}DPPM)_2Mn(CO)_3$ also forms dimetallated olefin complexes, which can be converted to vinyl derivatives by protonation (equation 30 (R = CF_3, CO_2Me)).

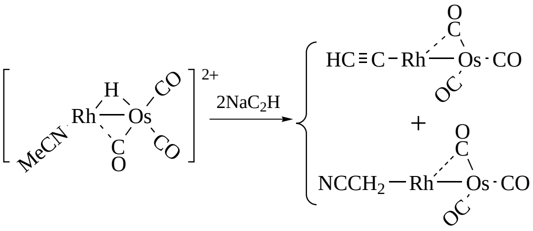


(30)

Protonation of $[Rh(CO)(\mu\text{-}DPPM)_2Os(CO)_3]^+$ by $HBF_4\cdot Et_2O$ in acetonitrile forms $[Rh(MeCN)(\mu\text{-}CO)(\mu\text{-}H)(\mu\text{-}DPPM)_2Os(CO)_2]^+$, some of whose chemistry is outlined in equations (31) and (32). The reaction of $[Rh(CO)(\mu\text{-}DPPM)_2Os(CO)_3]^+$ with *n*-butyl lithium



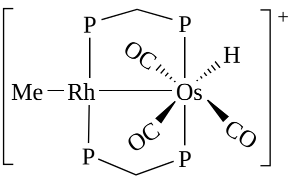
(31)



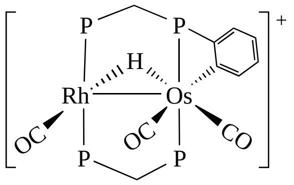
(32)

results in abstraction of a proton from the methylene carbon of one DPPM ligand rather than alkylation of one of the metal atoms, and the same product is obtained if the first step of equation (32) is performed under a CO atmosphere. Protonation of $Rh(Me)(\mu\text{-}DPPM)_2Os(CO)_3$ (see equation 31) at −80 °C occurs at osmium to form (**26**). On warming, the methyl group migrates to osmium via an intermediate in which the hydride ligand bridges both metals, methane is eliminated, and the resulting coordinatively unsaturated osmium atom undergoes oxidative addition of an *o*–C–H bond of one DPPM phenyl group to yield (**27**).

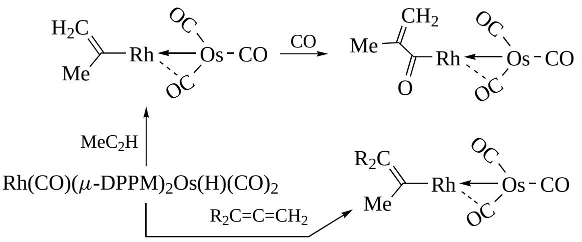
The neutral hydride complex $Rh(CO)(\mu\text{-}DPPM)_2Os(H)(CO)_2$ reacts with propyne and allenes to form vinyl derivatives (equation 33 (R = H, Me)). That the vinyl groups are



(**26**)

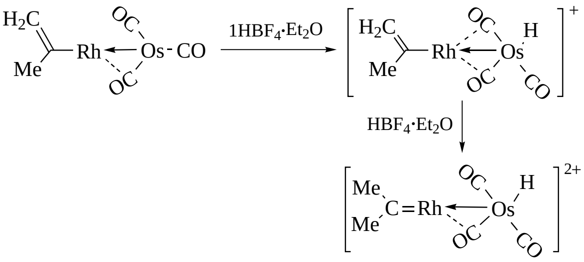


(**27**)



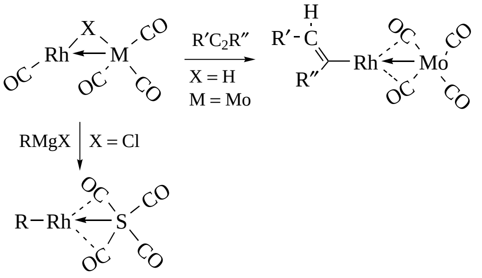
(33)

attached to rhodium despite the expectation of a stronger Os–C bond is attributed to the formal configuration Rh^I/Os^0 being favored. In the case of allene itself, a minor amount of $(\eta^3\text{-}C_3H_5)Rh(\mu\text{-DPPM})_2(CO)_3$ is also seen. All of the vinyl complexes react with one equivalent of H^+ or Me^+ at the osmium center, while a second equivalent of H^+ adds to the β-carbon of the vinyl group to convert this substituent to an alkylidene (equation 34) (see also Section 2.4).



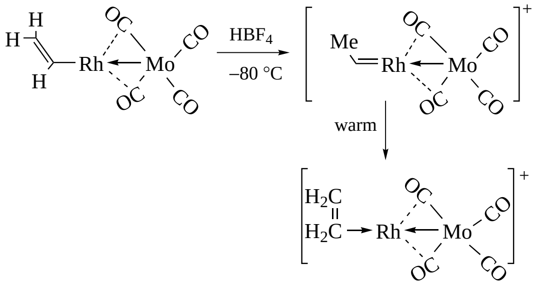
(34)

Vinyl complexes can also be obtained from the reaction of $Rh(CO)(\mu\text{-H})(\mu\text{-DPPM})_2M(CO)_3$ with alkynes (equation 35 (X = H; M = Mo: R′ = R′ = CF_3, CO_2Me. R′ = H; R″ = C(=O)Me, CO_2Me), while action of Grignard reagents on the chloride-bridged analogs forms related compounds (equation 35) (X = Cl; M = Mo; R = vy, Me, Ph,



(35)

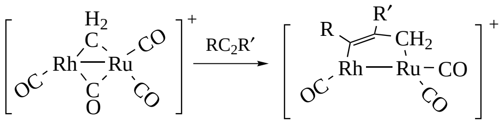
$CH_2CH{=}CH_2$. M = W; R = vy). With benzylmagnesium chloride under CO, this latter reaction forms the acyl complexes $Rh(C(=O)CH_2Ph)(\mu\text{-DPPM})_2M(CO)_4$ M = Mo, W). The vinyl complex from equation (35) is protonated at a low temperature to give an ethylidene derivative, which on warming rearranges to an ethylene complex (equation 36).



(36)

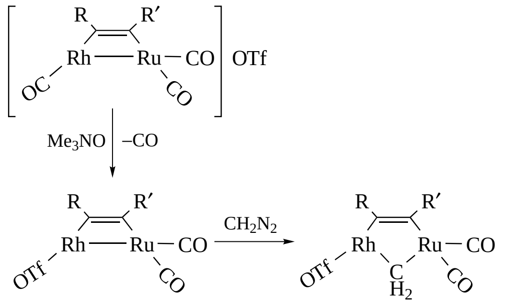
Because conversion of the ethylidene ligand to the ethylene ligand is facile, attempts to couple the ethylidene ligand with alkynes failed and only substitution of the olefin by the alkyne occurred.[42]

In the Rh/Mo and Rh/W complexes, it was hoped to study the effect that the two different metals might have on C–C and C–H coupling reactions (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***), but in most instances, it proved impossible to put a hydride or a second organic ligand on one of the metal atoms. This goal was realized to some extent in the Rh/Ru system depicted in equation (37) (R = R′ = CO_2Me, CO_2Et, CF_3. R = Me; R′ = $CH(OEt)_2$, CH_2OH). It is



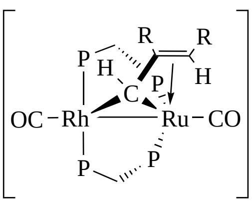
(37)

proposed that initial addition of the alkyne occurs at the coordinatively unsaturated rhodium center. Attempts to effect the coupling in the ''reverse'' direction by adding the methylene unit to an alkyne complex were unsuccessful, as C–C coupling did not occur (equation 38). Decarbonylation of the coupling product obtained from equation (37) forms

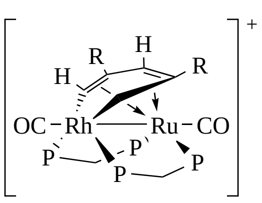


(38)

the alkylidene-bridged species (**28**), and only in the case where R = CH_2OH did more extensive coupling occur to give (**29**).[43]

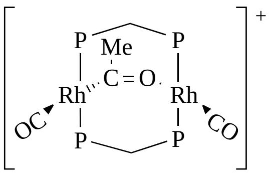


(**28**)

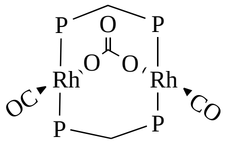


(**29**)

The dirhodium complex $Rh_2(CO)_3(\mu\text{-DPPM})_2$ reacts with methyl triflate to form the acetyl-bridged complex (**30**), which on heating loses a carbonyl ligand and undergoes methyl migration to the metal yielding $Rh_2(CO)(Me)(\mu\text{-CO})(\mu\text{-DPPM})_2$. This complex is fluxional via a methyl-bridged intermediate.[44] The carbonate-bridged complex (**31**) is formed when $(\eta^3\text{-}C_3H_5)Rh(Pr^i{}_2PCH_2PPr^i{}_2)$ reacts with an excess of methyl formate.[45]

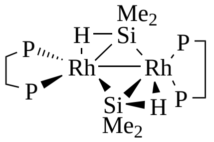


(**30**)

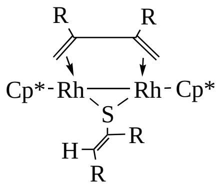


(**31**)

Diarylsilanes react with $[Rh(\mu\text{-H})(dippe)]_2$ to form $[Rh(\mu\text{-SiAr}_2)(dippe)]_2$, but with dimethylsilane the product is (**32**), which is a catalyst precursor for the dimerization of diphenylsilane (*see* ***Silicon: Inorganic Chemistry***).[46] The initial reaction of $[Cp^*_2Rh_2(\mu\text{-CH}_2)_2(\mu\text{-SH})]BPh_4$ with dimethylacetylene dicarboxylate is the insertion of one alkyne into the S–H bond but the second equivalent of alkyne couples with both methylene groups to form (**33**).[47]



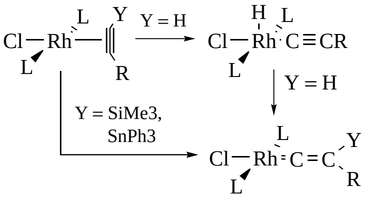
(**32**)



(**33**)

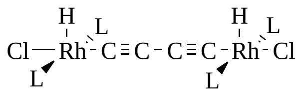
2.3 Vinylidene and Allenylidene Complexes

A considerable amount of work has been done in this area, which has been spurred in part by interest in the synthesis of multimetallic complexes in which the metal atoms are connected by unsaturated chains of several carbon atoms that may serve as ''molecular'' wires. The initial and still most widely employed synthetic route to vinylidene complexes involves addition of four equivalents of a trialkylphosphine ($L = PPr^i_3$ hereafter unless otherwise specified) to $[Rh(\mu\text{-Cl})(COE)_2]_2$, forming the coordinatively unsaturated fragment $\{Rh(PPr^i_3)_2\}$ (probably weakly solvated), which is reacted in situ with a terminal alkyne (equation 39 ($Y = H$; $R = CR'R''X$ (R', $R'' = H$, alkyl, aryl; $X = OH$, OMe, NH_2, Cl))). Depending on the conditions and the nature of R,

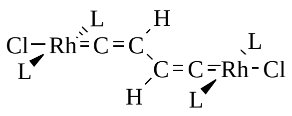


(39)

some or all of the species shown can be isolated when $Y = H$, although often the whole transformation can be carried out in one pot. The C–H oxidative addition step can be initiated thermally or photochemically as can the conversion of the acetylide hydride to the vinylidene. More recently, an alternate route using silyl and stannyl alkynes (*see* ***Silicon: Inorganic Chemistry*** and ***Tin: Organometallic Chemistry***) has been developed that provides for a greater range of substituents on the vinylidene group. A third route uses $\{Rh(PPr^i_3)_2\}$ together with RR′C=CHCl (R = Me; R′ = Me, Ph. RR′ = $-(CH_2)_5-$) in the presence of sodium. This does not work with $Me_2C{=}C{=}C{=}CHCl$ as this allene simply coordinates unchanged to the rhodium via the central C=C. Expanding on the original route (equation 39), $\{Rh(PPr^i_3)_2\}$ reacts with butadiyne to form (**34**) that is converted to (**35**) on heating.



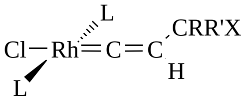
(**34**)



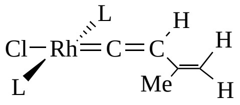
(**35**)

The reactivity of vinylidene complexes depends to a significant extent on the substituents of the β-carbon. For example, dehydration of (**36**) (R = R′ = Me; X = OH, NH_2, Cl) with deactivated alumina forms the vinyl vinylidene complexes (**37**), but for R = H, Ph; R′ = Ph; X = OH, the allenylidene complex (**38**) is the product. Diazomethane reacts with (**38**) (R = Ph; R′ = Ph, CF_3, Bu^t) to couple a methylene fragment to the allenylidene ligand and form (**39**), which isomerizes to (**40**) on heating. Complex (**40**), with iodide in place of chloride, can be obtained directly from (**38**) on reaction with methyl iodide as the carbon source in the presence of KI and Na_2CO_3. In further investigations of C–C coupling processes (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***), reaction of $(\eta^3\text{-}C_3H_5)Rh(PPr^i_3)_2$ with two equivalents of HC≡CCH(Ph)OH yielded the vinylidene acetylide complex (**41**) (R = CH(Ph)OH), but with $HC{\equiv}CCPh_2OH$, only the bis(acetylide), $Rh(H)(C{\equiv}CCPh_2OH)_2L_2$ forms. This

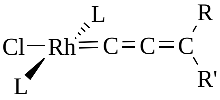
reacts with a third equivalent of the alkyne to form (**42**) via (**43**) (R = CPh_2OH) as a proposed intermediate. Photolysis (*see **Photochemistry of Transition Metal Complexes***) of Rh(H)(C≡$CCPh_2OH)_2L_2$ promotes vinylidene formation (**41**), (R = CPh_2OH) where coupling (*see **Organic Synthesis Using Metal-mediated Coupling Reactions***) of the acetylide and vinylidene ligands is promoted by addition of neutral ligands to form (**44**) (R = CPh_2OH), while treatment of the hydride complex with deactivated alumina in the presence of chloride ion yields (**45**), possibly via the intermediacy of an acetylide allenylidene complex generated by the dehydration of an initially formed vinylidene species.



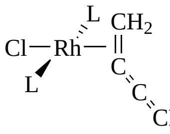
(**36**)



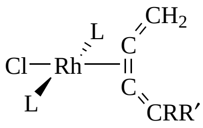
(**37**)



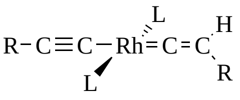
(**38**)



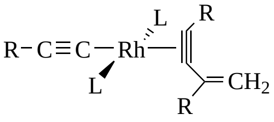
(**39**)



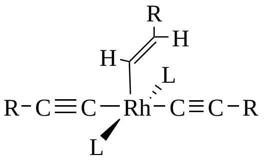
(**40**)



(**41**)

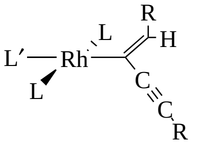


(**42**)

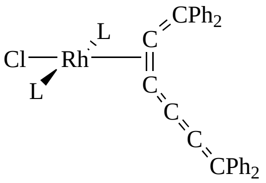


(**43**)

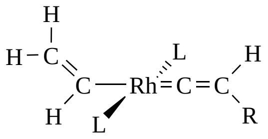
A stereoselective coupling (*see **Organic Synthesis Using Metal-mediated Coupling Reactions***) of alkyl, aryl, or vinyl groups to a vinylidene ligand and subsequent conversion to an allyl ligand has been achieved by the reaction of Rh(=C=CHR)ClL_2 (R = H, Bu^t, Ph) with vinylmagnesium bromide to first form (**46**). This is converted to (**47**) by reaction



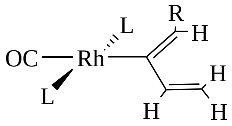
(**44**)



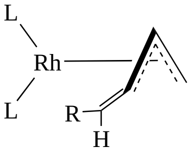
(**45**)



(**46**)



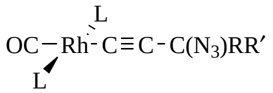
(**47**)



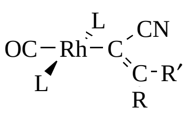
(**48**)

with CO or to (**48**) (see Section 4.1) on mild heating in benzene solution.

More elaborate coupling reactions (*see **Organic Synthesis Using Metal-mediated Coupling Reactions***) include the reaction of Rh(=C=C=CRR′)$(N_3)L_2$ (R = R′ = Ph, *p*-$MeOC_6H_4$. R = Ph, R′ = Bu^t) with carbon monoxide which promotes migration of the azide group to the γ-carbon forming (**49**). This loses dinitrogen to give (**50**) and reacts with $[Me_3O]BF_4$ to yield

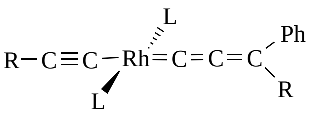


(**49**)

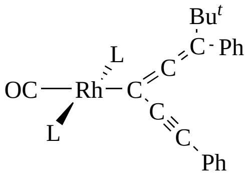


(**50**)

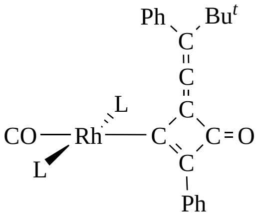
[{Rh(=C=C=CRR′)$L_2\}_2(\mu$-$N_3)]BF_4$. The fluoro analog of (**38**) (R = Ph; R′ = Bu^t, Ph) reacts with Ph_3Sn-C≡C-C≡C-$SnPh_3$ to form [(R(Ph)C=C=C=)$RhL_2]_2$ (μ-C≡C-C≡C-) and with Ph_3Sn-C≡CPh (*see **Tin: Organometallic Chemistry***) to yield (**51**). Coupling of the acetylide and allenylidene fragments in (**51**) is initiated by addition of CO at a low temperature forming (**52**) and on warming CO, incorporation ensues to give (**53**). In a similar fashion, (**54**) converts to (**55**).



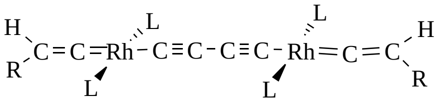
(51)



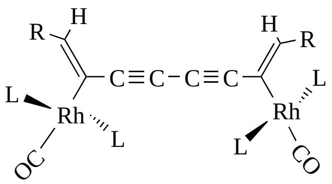
(52)



(53)



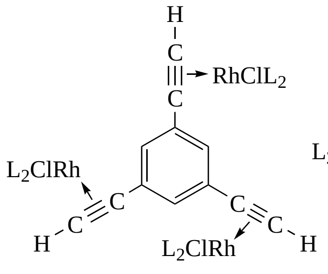
(54)



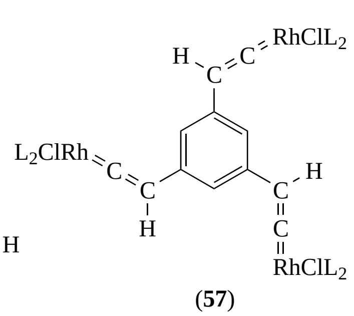
(55)

The migratory insertion of the allenylidene unit into Rh–O bonds occurs when Rh(=C=C=C(Ph)R)(OR″)L_2, prepared from (**38**) (R = Ph, *p*-tolyl; R′ = Ph) and K[OBu^t] in benzene/*t*-butanol followed by reaction with R″OH (R″ = Ph, MeC(=O)), is reacted with CO forming Rh{–C≡C–C(Ph)(OR″)R}(CO)L_2.

In transformations analogous to those in equation (39), {Rh(PPr^i_3)$_2$} fragments have been attached to the alkynyl substituents of 1,3,5-triethynylbenzene and various diethynylbenzenes and naphthalenes, and converted to vinylidenes as illustrated in (**56**) and (**57**).[48–50]



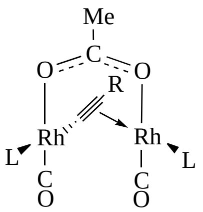
(56)



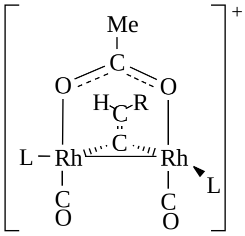
(57)

The process by which vinylidene complexes are formed from η^2-alkyne complexes has been explored by MP2 calculations (*see* ***Molecular Orbital Theory***) on RhCl(PH_3)$_2$(η^2-C_2H_2) to model the steps depicted in the top row of equation (39). The C–H oxidative addition step appears facile but there is a high barrier for the migration of the hydrogen as H^+ to the β-carbon of the alkynyl ligand. Related MO/MM calculations on Rh(H)Cl(C_2H)(PPr^i_3)$_2$ indicate that for the second step, an intermolecular hydrogen transfer has a much lower barrier than does the intramolecular process. Similar calculations were done for (PP_3)M^+ (M = Co, Rh) interacting with acetylene, which also gave a low barrier for C–H oxidative addition where M=Rh. Since no vinylidene complexes were formed in this rhodium system, no calculations were performed for the acetylide to vinylidene transformation although in the cobalt analog it again appears that the hydrogen moves as a proton.[51,52] DFT calculations (*see* ***Molecular Orbital Theory***) have been used in conjunction with FT−Raman spectroscopy on the complexes *trans*-[RhX(L)(PPr^i_3)$_2$] (X = F, Cl, Br, I, Me, C≡CPh; L = CO, =C=CH_2, =C=CHPh,) to obtain a trans influence series for the ligands X, which increase in the order shown.[53]

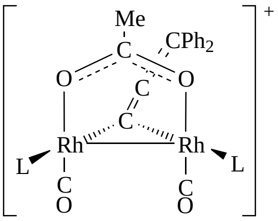
Protonation of (**58**) (L = Pcy_3; R = Ph, CO_2Me, $SiMe_3$) with HBF_4·Et_2O forms the vinylidene-bridged complex (**59**), while analogous protonation of the unsymmetrical isomer of (**58**) (R=C(OH)Ph_2) yields the allenylidene-bridged species (**60**).[54] A final route to a vinylidene-bridged dinuclear complex is the reaction of [Rh(μ-pz)(CNBu^t)$_2$]$_2$ with CH_3CCl_3 and triethylamine in benzene to yield Rh_2(μ-C=CH_2) (μ-pz)$_2$(CNBu^t)$_4Cl_2$.[55]



(58)



(59)

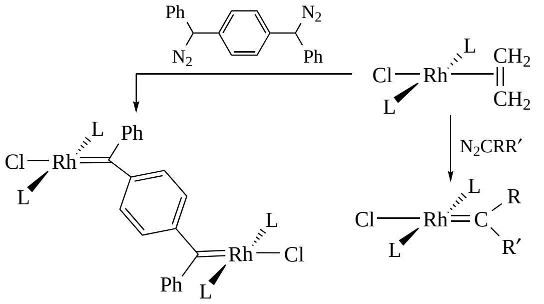


(60)

2.4 Carbene Complexes

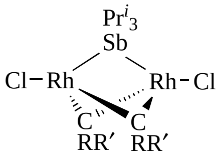
The complex *trans*-[RhCl(η^2-CH_2=CH_2)($SbPr^i_3$)$_2$] has proven a suitable synthon for a variety of mono- and bimetallic

carbene complexes (*see* ***Carbene Complexes***) (equation 40 (L =

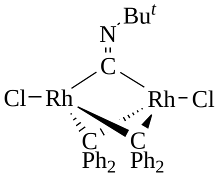


(40)

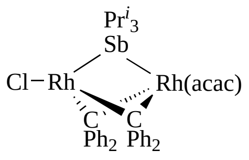
$SbPr^i_3$: R = R′ = Ph, *p*-tol, *p*-anis. R = Ph; R′ = CF_3)). In the mononuclear complexes, the stibine ligands (*see* ***Antimony: Organometallic Chemistry***) can be replaced by trialkylphosphines and – arsines, and when R = R′ = Ph, the carbene moiety couples (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***) with carbon monoxide, *t*-butylisocyanide, or ethylene to form, respectively, $Ph_2C{=}C{=}O$, $Ph_2C{=}C{=}NBu^t$, or $Ph_2CHCH{=}CH_2$. Heating $Rh({=}CRR')ClL_2$ (L = $SbPr^i_3$: R = R′ = Ph, *p*-tol. R = Ph; R′ = *p*-tol) forms dinuclear (**61**) containing a *bridging* tertiary stibine ligand. When R = R′ = Ph, (**61**) reacts with CO to form an apparently polymeric material formulated as $[Rh({=}CPh_2)Cl(CO)]_n$ but with *t*-butylisocyanide the product is (**62**). With one equivalent of Tl(acac), (**61**) converts to (**63**), in which the bridging stibine ligand can be replaced by trimethylphosphine giving (**64**). This is converted to (**65**) on reaction with chlorotrimethylsilane.



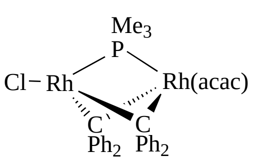
(**61**)



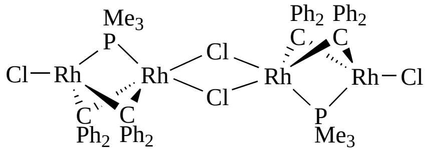
(**62**)



(**63**)

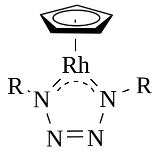


(**64**)

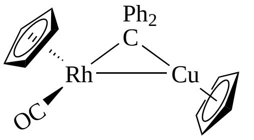


(**65**)

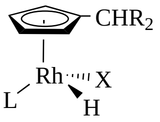
Treatment of $Rh({=}CRR')ClL_2$ (L = $SbPr^i_3$, $PPr^i_{3-n}Ph_n$ (n = 0–3); R = Ph; R′ = Ph, *p*-tol) with sodium cyclopentadienide forms $CpRh({=}CRR')L$ in good yield. When L = $SbPr^i_3$, this ligand can be replaced with CO or $CNBu^t$, but when L = PPr^i_3, coupling of these molecules with the carbene ligand again occurs. In an attempt to generate a ketamine by a similar C–N coupling, $CpRh({=}CPh_2)L$ (L = $SbPr^i_3$, PPr^i_3) was reacted with an aryl azide but the product obtained was the tetraazadiene complex (**66**) (R = Ph, *p*-tol). The same complex (L = CO) reacts sequentially with CuCl and NaCp to form (**67**) while with L = PPr^i_3, protonation causes migration of the carbene moiety to the cyclopentadienyl ring to give (**68**) (R = Ph, *p*-tol; X = Cl, Br, I, O_2CCF_3). When the anion of the acid is noncoordinating (e.g. using $HBF_4{\cdot}Et_2O$) or methylation is attempted with $[Me_3O]BF_4$, attack occurs on the carbene moiety in $CpRh({=}CPh_2)(L)$ (L = PPr^i_3) and the allyl complex (**69**) (Y = H. Me) is formed.[56,57] The indenyl complex (**70**) (L = $SbPr^i_3$, PPr^i_3) is prepared from $Rh({=}CPh_2)ClL_2$ and indenylpotassium, and like its cyclopentadienyl analog, reacts with CO to transfer the carbene moiety to the indenyl ligand (**71**).[58]



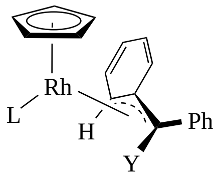
(**66**)



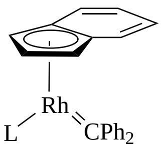
(**67**)



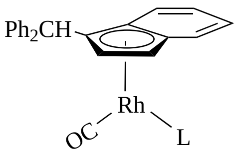
(**68**)



(**69**)



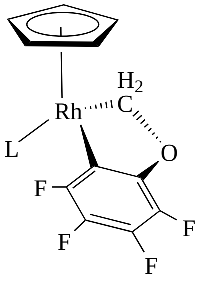
(**70**)



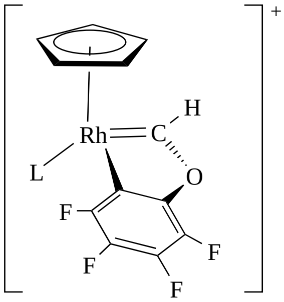
(**71**)

Photolysis (*see* ***Photochemistry of Transition Metal Complexes***) of a solution of $CpRh(PMe_3)(\eta^2\text{-}CH_2{=}CH_2)$ in pentafluoroanisole initially forms $CpRh(PMe_3)(\eta^2\text{-}C_6F_5OMe)$ (two isomers) and then (**72**). Hydride abstraction from (**72**) by trityl tetrafluoroborate generates the carbene complex (**73**).[59] Decarbonylation of $(H_2B(3,5\text{-}Me_2pz)_2)Rh(CO)_2$ with trimethylamine oxide in pyridine forms $(H_2B(3,5\text{-}Me_2pz)_2)Rh(CO)(py)$, which in benzene solution adds methyl iodide to form (**74**). Heating (**74**) at 45 °C yields (**75**) by a rare example of a reverse α-hydrogen migration. It is proposed

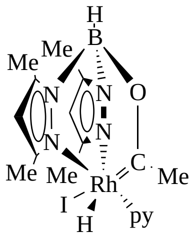
that the formation of (**74**) involves initial oxidative addition of methyl iodide (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation***) to rhodium followed by migratory insertion of the methyl group which is facilitated by the coordination of the oxygen of the carbonyl group to the Lewis acid boron.[60]



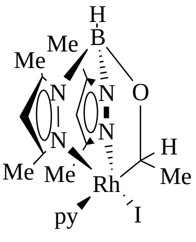
(**72**)



(**73**)

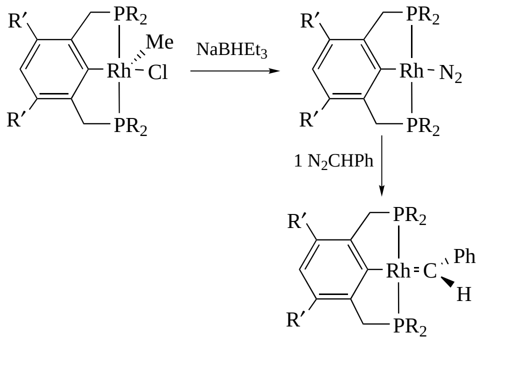


(**74**)

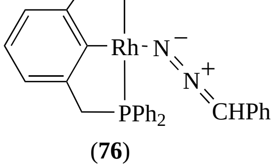


(**75**)

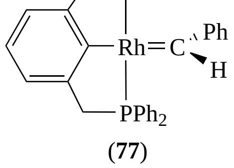
The neutral chloro analog of the ''pincer'' complex (**11**) (Section 2.1) can be reduced to a dinitrogen complex and on addition of phenyldiazomethane, a carbene complex results (equation 41 (R = Bu^t, R′ = Me)). An analogous product (**77**) is obtained at room



(41)

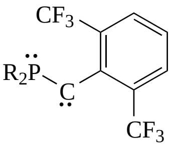


(**76**)



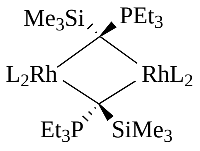
(**77**)

temperature for the complex where R′ = H, but if the diazo compound is added at −70 °C, (**76**) is formed first and on warming converts to (**77**) plus the dinitrogen complex and *trans*-1,2-diphenylethylene. A series of DFT calculations (*see* ***Molecular Orbital Theory***) on the course of the reaction of the diazoalkane to form the carbene complex have been carried out from which it appears that with bulky substituents on phosphorus, conversion of (**76**) into an η^1-C-bound diazo complex is critical.[61] The phosphinocarbene (**78**) (R = NPr$^i{}_2$) forms the carbene complex Rh(=C(PR_2)(2,6-$(CF_3)_2C_6H_3$))Cl$(CO)_2$ when reacted with [Rh(μ-Cl)$(CO)_2]_2$ at −50 °C, but on warming rearranges to the phosphorus-bound isomer Rh(P(R)=C(R)(2,6-$(CF_3)_2C_6H_3$))Cl$(CO)_2$. With [Rh(μ-Cl)(COD)$]_2$, the analogous carbene complex Rh(=C(PR_2)(2,6-$(CF_3)_2C_6H_3$))Cl(COD) is formed which appears to be more stable.[62]

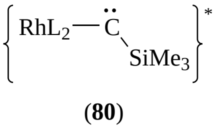


(**78**)

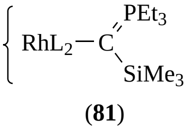
As the reaction of low-valent rhodium complexes with diazoalkanes is frequently used to prepare mono- and dinuclear carbene complexes (*see* ***Carbene Complexes***) (e.g. equation 41), it has been of interest to explore factors controlling the loss of dinitrogen from the initially formed metal complex of the diazoalkane (vide supra). To this end, complexes containing the {Rh(C(N_2)R)} unit have been deliberately synthesized by reaction of RhClL_n (L = PMe_3, $n = 4$; L = PEt_3, $n = 3$) with Li[C(N_2)$SiMe_3$] to form L_nRh(C(=N=N)$SiMe_3$). Photolysis of this product in benzene forms (**79**) (L = PEt_3) through the proposed intermediates (**80**) and (**81**). It is suggested that (**80**) exists in the singlet state because of the stabilizing influence of the neighboring low-spin, electron-rich {RhL_2} unit, and as an electrophilic carbene, readily forms the ylide species (**81**).[63]



(**79**)

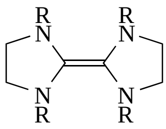


(**80**)

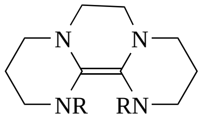


(**81**)

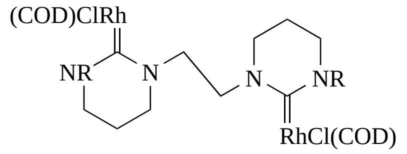
Mentioned in the previous edition[1] as a route to rhodium carbene complexes is the reaction of various low-valent complexes with electron-rich olefins like (**82**) (R = Et, bz). Reaction of $[Rh(\mu\text{-}Cl)(COD)]_2$ with (**82**) forms the tris-carbene complex $Rh(=C(N(R)CH_2CH_2N(R)\text{-})_3Cl)$, while with (**83**) the product is (**84**).[64] In related work, four equivalents of the imidazolium salt (**85**) (X = Br; R = bz) react with $[Rh(\mu\text{-}OEt)(COD)]_2$, prepared in situ from $[Rh(\mu\text{-}Cl)(COD)]_2$ and sodium ethoxide in ethanol to yield (**86**), and using the corresponding triazolium iodide, the same route furnishes (**87**), while with bis(diisopropylformamidinium)chloride the product is $[Rh(=C(NPr^i{}_2)_2)Cl(COD)]$. The last can also be prepared from $[Rh(\mu\text{-}Cl)(COD)]_2$ and bis(diisopropylamino)carbene.[65] An alternate synthesis of (**86**) (X = Cl; R = *p*-tol) involves the reaction of (**85**) with silver oxide to form an intermediate silver imidazolium carbene complex and the reaction of this with $[Rh(\mu\text{-}Cl)(COD)]_2$. The COD ligand can be replaced by two carbonyl ligands. This work has been extended to the chiral oxazoline-substituted imidazolium salts (**88**) (R = Me, Bu^t; R′ = Pr^i, bz), which on treatment with $LiOBu^t$ and $[Rh(\mu\text{-}Cl)(COD)]_2$ in THF form (**89**). Chloride abstraction from (**89**) with $TlPF_6$ then yields (**90**).[66] In related work, the bis(imidazolium) salts (**91**) (R = Bu^n; X = Br; Y = 1,2-C_6H_4. R = Pr^i, Bu^n; X = I; Y = CH_2) can be used to form (**92**) from $Rh_2(OAc)_4$ in acetonitrile (X = I) or from $[Rh(\mu\text{-}Cl(COD))]_2$, potassium iodide, and sodium acetate (X = Br). The complexes function as catalyst precursors for the hydrogenation of C=O and C=N bonds via hydrogen transfer from isopropanol.[67] Treatment of (**91**) (R = Bu^n; X = Br; Y = 2,6-C_6H_3N) with $[Rh(\mu\text{-}Cl(COD))]_2$ and triethylamine forms (**93**) (Z = RhBr(COD)) which is a catalyst precursor for olefin hydroformylation (*see* ***Carbonylation Processes by Homogeneous Catalysis***) and for which NMR studies indicate retention of the dinuclear structure under catalytic conditions.[68] Deprotonation of (**91**) (R = Bu^n; X = Cl; Y = 2,6-(-CH_2)C_6H_3N) with silver oxide forms (**93**) (Z = AgCl) and the {AgCl} units can be replaced by {RhCl(COD)}.[69] In neither example of (**93**) does coordination of the pyridyl nitrogen to rhodium occur, but when (**94**) (R = Pr^i, Bu^n, Bu^t) is reacted successively with $[Rh(\mu\text{-}Cl)(COE)_2]_2$ and carbon tetrachloride, the product is (**95**) (*see* ***Water & O-donor Ligands***) which contains a NCN ''pincer'' ligand (see also **5**–**8**). The water ligand can be replaced by an isocyanide ligand CNR′ (R′ = CO_2Me, SO_2(*p*-tol)) and this derivative in the presence of $KOBu^t$, undergoes an aldol condensation with aldehydes to form the carbene complex (**96**) (R″ = Bu^t, Ph).[70]



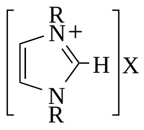
(**82**)



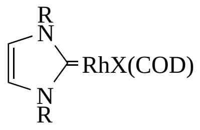
(**83**)



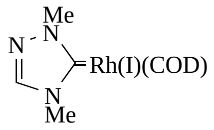
(**84**)



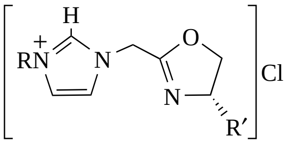
(**85**)



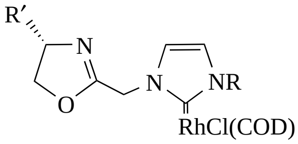
(**86**)



(**87**)



(**88**)



(**89**)

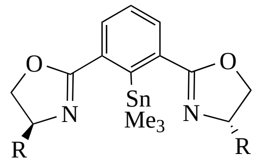
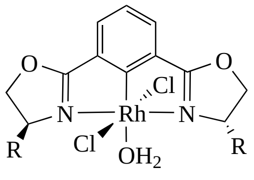
(**93**)

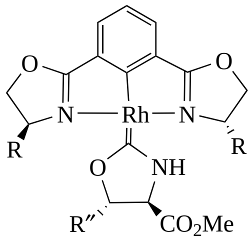


(**94**)



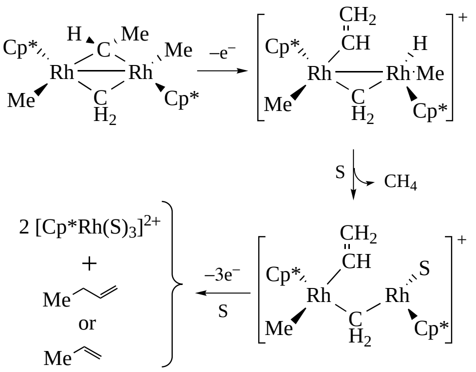
(**95**)

Complexes of the type $[Cp^*Rh(R)(\mu\text{-}CH_2)]_2$ have been studied to probe details of the coupling of alkyl and methylene groups that could be relevant to mechanisms for the Fischer–Tropsch process (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***).[71] Reaction



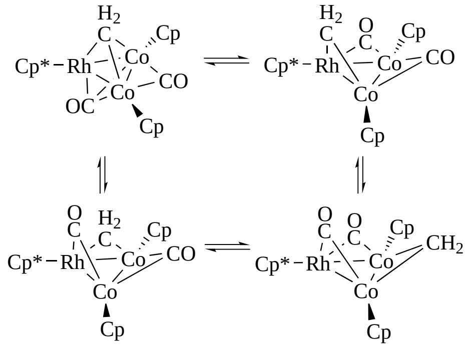
(**96**)

of $[Cp^*Rh(vy)(\mu\text{-}CH_2)]_2$ with HCl forms $Cp^*{}_2Rh_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}CHMe)$ via coupling of one vinyl and one methylene group. Alkylation of this species with Grignard reagents yields $Cp^*{}_2Rh_2(R)_2(\mu\text{-}CH_2)(\mu\text{-}CHMe)$ (R = Me, Et, vy, Bu^n), which proved to be thermally robust. Oxidative decomposition of the dimethyl complex forms methane, propene, and but-1-ene by the process proposed in equation (42) (S = MeCN).[72]



(42)

In the complex $Cp^*Rh(CpCo)_2(CO)_2(\mu\text{-}CH_2)$, NMR studies indicate that the methylene group is quite mobile (*see* ***Stability Constants & their Determination***) (equation 43) with the steps in which it moves



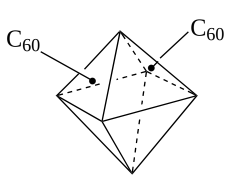
(43)

from a Rh–Co edge to the Co–Co edge thought to have a higher barrier than the other motions.[72]

2.5 Carbonyl Complexes

Carbonyl ligands are very prevalent in organometallic complexes of rhodium and may be either incidental to or necessary for the formation of complexes (*see* ***Carbonyl Complexes of the Transition Metals***) in which they are found. This section focuses primarily on carbonyl cluster complexes (*see* ***Polynuclear Organometallic Cluster Complexes***) in which carbonyl groups are the sole or at least the primary ligands. DFT calculations (*see* ***Molecular Orbital Theory***) on the unstable (in the absence of excess CO) $Rh_2(CO)_8$ molecule predict the lowest energy structure to be $Rh_2(CO)_6(\mu\text{-}CO)_2$ of the C_{2v} symmetry, which is the same as observed for the cobalt analog although unbridged structures are not much higher in energy. The C–O stretching frequencies calculated from this model agree well with experiment.[73]

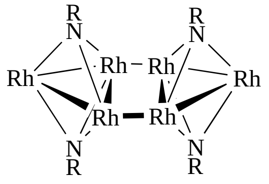
Structures of $Rh_6(CO)_{15}L$ complexes (L = $P(OPh)_3$, $PBu_3{}^n$, $P(4\text{-}XC_6H_4)_3$ (X = CF_3, Cl, F, OMe), DMSO, MeCN, COE) have been determined and the structural effects of substitution are localized primarily in the vicinity of the substitution. In particular, in the triangle of rhodium atoms containing that bearing L, the Rh–Rh distances adjacent to the site of substitution are significantly lengthened and that opposite significantly shortened as compared to those remote from this site. This is attributed to an increase in electron density on the substituted metal as a result of substitution of CO by a ligand of lower π-acid character.[74] Heating of the fullerene (*see* ***Carbon: Fullerenes***) derivative of $Rh_6(CO)_{16}$ formulated as $Rh_6(CO)_9(DPPM)_2(\mu_3\text{-}\eta^2,\eta^2,\eta^2\text{-}C_{60})$ with excess C_{60} in chlorobenzene followed by reaction with benzylisocyanide leads to attachment of a second fullerene to the cluster and the product is $Rh_6(CO)_5(DPPM)_2(\mu_3\text{-}\eta^2,\eta^2,\eta^2\text{-}C_{60})_2$. The skeleton of the complex showing the locations of the fullerene substituents on opposite triangular faces of the metal octahedron is shown in (**97**). Cyclic voltammetric measurements show six well-separated, reversible, 1-electron reduction waves centered on the fullerene cages which are interpreted as the stepwise reduction to $(C_{60}{}^-)$ $Rh(C_{60})$, $(C_{60}{}^-)$ $Rh(C_{60}{}^-)$, and so on, implying an electronic communication between the cages (*see* ***Electrochemistry: Applications in Inorganic Chemistry***). The complex is thus proposed to be a model for carbon nanotubes connected by a heterogeneous inorganic junction of potential future use in electronic materials.[75]



(**97**)

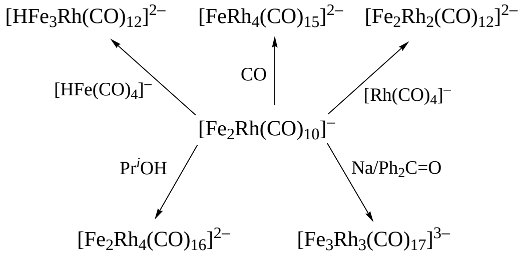
Reaction of $[Rh(\mu\text{-}Cl)(COD)]_2$ with *p*-toluidine and butyl lithium forms the tetrametallic imido cluster $Rh_4(\mu\text{-}NR)_2(COD)_4$ (R = *p*-tol) that is converted to $PPN[Rh_3(\mu_3\text{-}NR)_2(CO)_6]$ on treatment with CO and then [PPN]Cl. Oxidation of the carbonyl cluster with one equivalent of ferricinium hexafluorophosphate yields $[Rh_3(\mu_3\text{-}NR)_2(CO)_6]_2$ whose

skeleton is depicted in (**98**). This is thought to arise from the dimerization of $[Rh_3(\mu_3\text{-}NR)_2(CO)_6]\cdot$ radicals formed by one-electron oxidation of the anionic trimetallic cluster.[76] One and two carbonyl ligands, respectively, in $[Rh_5(CO)_{15}]^-$ can be replaced by amines (bzNH$_2$, Ph(CH$_2$)$_3$ NH$_2$, pip) and diamines (en, pn, tn), while with H$_2$N(CH$_2$)$_4$ NH$_2$ (L$_2$) some $[\{Rh_5(CO)_{14}\}_2(\mu\text{-}L_2)]^{2-}$ is seen in addition to $[Rh_5(CO)_{13}(L_2)]^-$.[77]

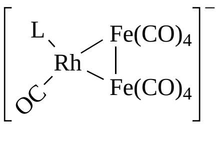


(**98**)

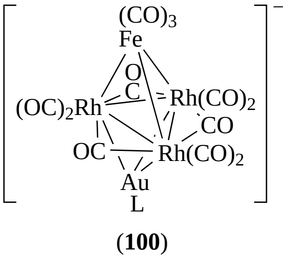
Interest continues in the synthesis of heterobimetallic carbonyl clusters (*see* ***Polynuclear Organometallic Cluster Complexes***) and most are prepared by the addition of carbonyl metallates to small- or medium-sized carbonyl clusters. For example, addition of four equivalents of $[HFe(CO)_4]^-$ to $[Rh(\mu\text{-}Cl)(CO)_2]_2$ forms $[Fe_2Rh(CO)_{10}]^-$, which is converted to (**99**) (L = PPh$_3$) by addition of the phosphine. Similarly, two equivalents of $[Rh(CO)_4]^-$ added to $Fe_2(CO)_9$ followed by refluxing in acetone forms $[Fe_2Rh_2(CO)_{10}]^{2-}$, which on reaction with $[Au(PPh_3)]^+$ gives (**100**) (L = PPh$_3$). Since $[Fe_2Rh(CO)_{10}]^-$ is a 46-electron cluster, it is coordinatively unsaturated which is reflected by its reactivity (equation 44). Combination of 2 mols of



(44)

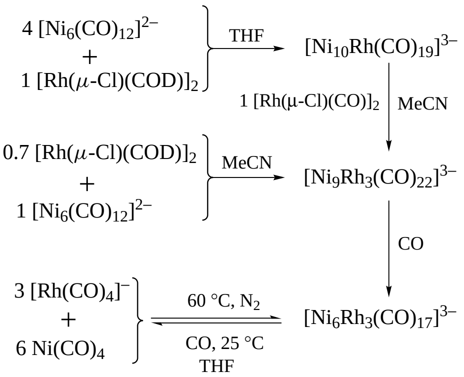


(**99**)

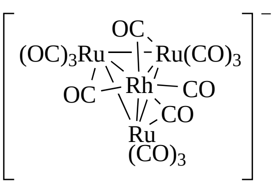


(**100**)

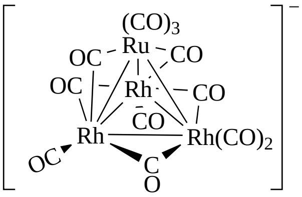
$[Rh(CO)_4]^-$ with 0.67 mol of $Ru_3(CO)_{12}$ gives $[Ru_2Rh_2(CO)_{12}]^{2-}$, which on further reaction with 1.3 mols of $Ru_3(CO)_{12}$ forms (**101**). Oxidation of $[RuRh_4(CO)_{15}]^{2-}$ with iodine yields (**102**) plus $[Rh(\mu\text{-}I)(CO)_2]_2$.[78] Condensation of $Rh_4(CO)_{12}$ with $Pt(PPh_3)_3$ provides a mixture of (**103**) and (**104**) (L = PPh$_3$). Complex (**104**) is an electron-deficient 58-electron cluster. Also, condensation of $[Rh(CO)_4]^-$ with $[PtCl(\mu\text{-}DPPM)]_2$ in methanol in a CO atmosphere forms (**105**) (phenyl groups of DPPM omitted for clarity). The same species can also be obtained, but in lower yield, from the reaction of $Pt_2(CO)_3(DPPM)_2$ and half an equivalent of $Rh_4(CO)_{12}$ under nitrogen in THF solution. Reaction of (**105**) with $Rh_6(CO)_{15}(MeCN)$ forms $\{Rh_6(CO)_{14}\}(\mu\text{-}CO)_2\{Pt_2Rh_2(CO)_5(DPPM)_2\}$via displacement of the weakly bound acetonitrile. The complex is proposed to contain a donor metal–metal bond from the Rh$_6$ unit to the Rh$_2$Pt$_2$ unit. The related reaction of $Pt_2(CO)_3(DPPM)_2$ directly with $Rh_6(CO)_{15}(MeCN)$ at a low temperature followed by warming to room temperature gives $\{Rh_6(CO)_{14}\}(\mu\text{-}CO)_2\{Pt_4(DPPM)_3\}$, where the skeleton is depicted as (**106**). In this instance, there is a dative metal–metal bond from platinum to rhodium.[79] A series of nickel/rhodium clusters have been prepared as indicated (equation 45) but most are



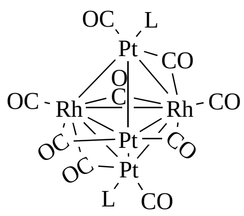
(45)



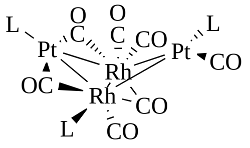
(**101**)



(**102**)



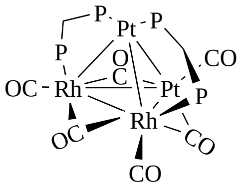
(**103**)



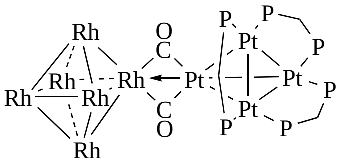
(**104**)

rather unstable, and all attempts to observe Lewis acid/base and redox properties failed because of decomposition.[80]

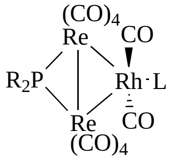
Rhodium/rhenium clusters have been prepared by combination of $RhCl(CO)(PPh_3)_2$ with $[Re_2(\mu\text{-}PR_2)(CO)_8]^-$ (R = Ph, cy) under carbon monoxide and with $TlPF_6$ as a halide abstraction agent. The initially obtained salt, $[Rh(CO)(PPh_3)_2][Re_2(\mu\text{-}PR_2)(CO)_8]$, loses a molecule of triphenylphosphine on standing in solution to give (**107**) (L = PPh_3). If one starts with the preformed cationic rhodium complex $[Rh(COD)(PPh_3)_2]BPh_4$, a redox condensation occurs with $[Re_2(\mu\text{-}PR_2)(CO)_8]^-$ in refluxing THF to form (**108**), which is said to have a rhenium–rhodium double bond.[81]



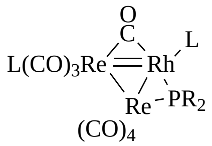
(**105**)



(**106**)



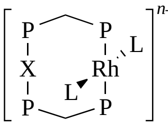
(**107**)



(**108**)

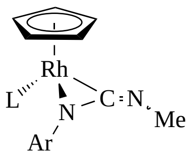
2.6 Isocyanide Complexes

As in the preceding section, the emphasis of this section will be on rhodium complexes containing isocyanide ligands, wherein the isocyanide ligand is the particular focus of the report. For example, there has been an extensive study of the spectroscopic and luminescent properties (*see* ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds*** and ***Electronic Structure of Organometallic Compounds***) of (**109**) (L = $CNBu^t$. X = $Pt(CN)_2$; $n = 1$. X = Ag, Au; $n = 2$). All show an intense singlet $d\sigma^* \rightarrow p\sigma$ absorption and molecular orbital calculations indicate that the $d\sigma^*$ orbital is mainly Rh $4d_{z^2}$ in character while the $p\sigma$ orbital is a combination of isocyanide π^* and Rh $5p_z$ character. The absorption band therefore has significant Rh $\rightarrow \pi^*$ charge transfer character. All complexes are phosphorescent.[82] Thermodynamic parameters for the disproportionation of the mixed-valence dimers $[Rh_2(\mu\text{-}L_2)_{4-n}(\mu\text{-}DPPM)_n]^{3+}$ (L_2 = TM4, $n = 0$; L_2 = dimen; $n = 0$–2; L_2 = bridge; $n = 2$) have been described and it appears that only when no DPPM ligands are present is this a facile process. The large difference in the tendency to disproportionate between this complex and those containing one or more DPPM ligands is attributed to large differences in the energies of the oxidized species within the series relative to those of the mixed-valence starting complexes. These energy differences are largely governed by the different affinities of the oxidized species for axial ligands as a function of the extent of substitution of diisocyanide ligands by DPPM.[83]

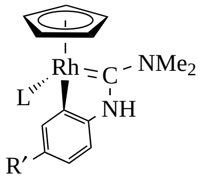


(**109**)

Addition of aryl azides to $CpRh(PMe_3)(CNMe)$ results in coupling of the aryl nitrene with the isocyanide to form (**110**) (Ar = Ph, *p*-tol) which can be converted to (**111**) (R′ = H, Me), another example of a carbene complex (see also **73**, Section 2.4, ***Carbene Complexes***).[84] Replacement of COD in $Rh_2(COD)_2(\mu\text{-}Cl)(\mu\text{-}PBu^t{}_2)$ by *t*-butylisocyanide yields $Rh_2(CNBu^t)_4(\mu\text{-}Cl)(\mu\text{-}PBu^t{}_2)$, which on treatment with one equivalent of lithium di(*t*-butyl)phosphide forms $[Rh(CNBu^t)_2(\mu\text{-}PBu^t{}_2)]_2$, which has a planar Rh_2P_2 core and no Rh–Rh bond. In a chloroform solution, the last complex is slowly converted into a mixture of *cis*- and *trans*-$[RhCl(CNBu^t)(\mu\text{-}PBu^t{}_2)]_2$, while oxidation with ferricinium hexafluorophosphate yields $\{[Rh(CNBu^t)_2(\mu\text{-}PBu^t{}_2)]_2\}^{2+}$. Both of the oxidized dimers contain Rh–Rh bonds.[85]

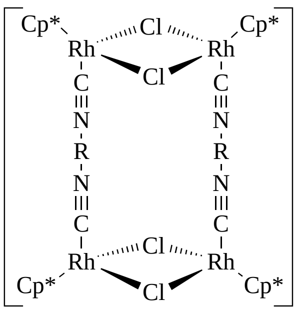


(**110**)

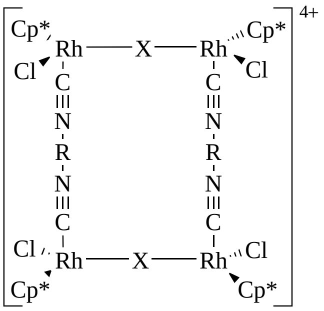


(**111**)

Cleavage of the chloride bridges in $[Cp^*RhCl(\mu\text{-}Cl)]_2$ by 1,4-diisocyanobenzenes yields $\{Cp^*RhCl_2\}_2(\mu\text{-}CN\text{-}R\text{-}NC)$ (R = 2,3,5,6-Me_4C_6; 2,5-$Me_2C_6H_2$). Abstraction of one chloride ligand from each metal by silver triflate is followed by condensation of two of the resulting dications to form the metallamacrocycle (**112**). The larger cavity species (**113**) (X = CN-R-NC, 4,4′-bipyridyl) can be obtained by a second bridge-splitting reaction on (**112**) (see also Section 4.2).[86]



(**112**)

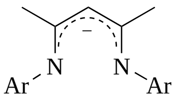


(**113**)

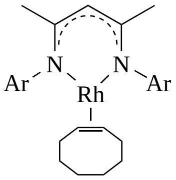
3 COMPOUNDS OF LIGANDS CONTAINING LOCALIZED π-BONDS

3.1 Complexes of Alkenes

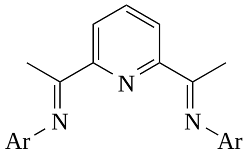
Synthetic routes to alkene complexes remain primarily the same as in the preceding edition, but there has been significant interest shown in forming isolable complexes containing an alkene and either a hydride or an alkyl ligand, in order to study migratory insertions (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis*** and ***Organic Synthesis Using Metal-mediated Coupling Reactions***). An interesting three-coordinate alkene complex, (**115**), results from the treatment of $[Rh(\mu\text{-Cl})(COE)_2]_2$ with (**114**) (Ar = 2,6-$X_2C_6H_3$ (X = Me,Cl)), although when X = Cl, there is an agostic interaction of one chlorine substituent with the metal to relieve the coordinative unsaturation. Complex (**115**) (X = Me) adds dinitrogen and oxidatively adds dihydrogen. A low-temperature NMR study indicates the formation of a dihydrogen adduct (*see* ***Hydrogen Bonding & Dihydrogen Bonding***) prior to the generation of the dihydride species. The same complex is a catalyst for alkene hydrogenation (*see* ***Hydrogenation & Isomerization of Alkenes***) and the rate-determining step is considered to be either the conversion of the dihydrogen adduct to the dihydride or the migratory insertion of the alkene. Presumably, the combined bulk of the diimine and COE ligands permits the isolation of the three-coordinate (**115**), since with $[Rh(\mu\text{-Cl})(COD)]_2$ and $[Rh(\mu\text{-Cl})(C_2H_4)_2]_2$, four-coordinate products are obtained.[87] In related work, (**116**) (Ar = 2,6-$Pr^i{}_2C_6H_3$) reacts with $[Rh(\mu\text{-Cl})(C_2H_4)_2]_2$ followed by treatment with $NaBAr_f$ (*see* ***Boron: Organoboranes***) in the presence of ethylene to form (**117**). This oxidatively adds methyl iodide (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation***) and subsequent abstraction of iodide with $AgBF_4$ in the presence of ethylene forms the cationic alkyl olefin complex (**118**), which was detected spectroscopically but not isolated in pure form. No evidence was found for ethylene polymerization (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***) in this system (presumably migratory insertion of ethylene into the Rh–methyl bond would be the initial step) in contrast to related systems containing the Cn-type ligands (see Section 2.1). The difference in reactivity between the two was attributed to the mer coordination of the supporting ligand here in contrast to the fac coordination of the Cn ligands.[88] Some success in facilitating alkene oligomerization (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***) was realized with $Tp'Rh(C_2H_4)_2$ (see also Reference 18). Heating the solid compound at 60 °C forms a mixture of *exo*- and *endo*-$Tp'Rh(H)(\eta^3\text{-}C_3H_4Me)$, which on photolysis converts to the butadiene complex $Tp'Rh(\eta^2;\ \eta^2\text{-}CH_2{=}CHCH{=}CH_2)$. This last complex can also be generated, together with ethane from the reaction of $Tp'Rh(C_2H_4)_2$ with ethylene at room temperature, but if this is done at −40 °C, the complexes $Tp'Rh(Et)(\eta^3\text{-}C_3H_4Me)$ and $Tp'Rh(\eta^2;\ \eta^2\text{-}CH_2{=}CHCH{=}CHC_2H_5)$ are also seen. The formation of the C–C coupling products is proposed to be initiated by the conversion of an ethylene ligand into a vinyl hydride complex (see also equation 9, section 2.1).[89] Protonation of $(acac)Rh(C_2H_4)_2$ with triflic acid in THF solution forms, predominantly, $(acac)Rh(C_2H_5)$, which was not isolated and is presumably solvated. Some but-2-enes were also detected implicating ethylene insertion into the Rh–Et bond, but no ethylene polymerization was detected. It is proposed that the putative rhodium–butyl complex undergoes β-hydride elimination with subsequent butene displacement by ethylene faster than the ethylene can insert into the rhodium–butyl bond.[90]



(**114**)



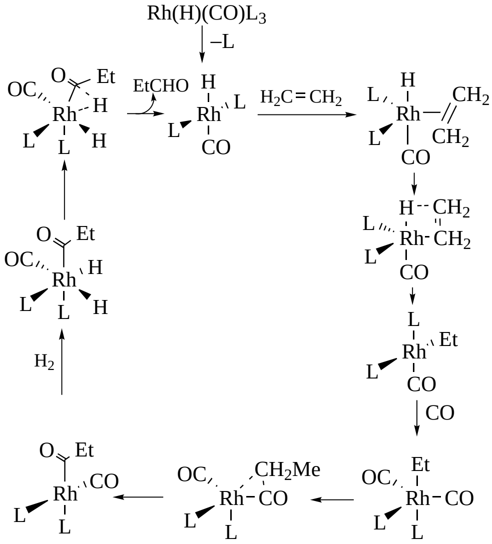
(**115**)



(**116**)

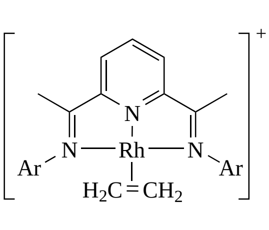
The calix[4]arene-based diphosphine (**119**) (R = Me, Pr^i, Ph; R′ = Pr^i) on reaction with $[Rh(\mu\text{-Cl})(COD)]_2$ and then $TlPF_6$ forms the dinuclear species (**120**). These were tested as catalysts for hex-1-ene hydroformylation (*see* ***Carbonylation Processes by Homogeneous Catalysis***) and that with R = Ph was best, but the performance was not better than extant systems and no special role for the calixarene moieties could be discerned.[91] Several papers have used DFT calculations as part of QM/MM studies (*see* ***Molecular Orbital Theory***) to probe the course of the hydroformylation process (*see* ***Carbonylation Processes***

by Homogeneous Catalysis) catalyzed by $Rh(H)(CO)L_3$ ($L = $ tertiary phosphine) complexes with particular emphasis on the origin of the regioselectivity (straight vs. branched chain aldehyde). There are, however, enough differences between the models used and/or the restrictions on them that comparisons between the results are not easy to make. The first used $Rh(H)(CO)(alkene)(PH_3)_2$ to model the migratory insertion of ethylene and propylene into the Rh bond and the DFT-derived geometries with fixed coordination spheres were used in the MM stage with $L = PPh_3$ to model real systems based on diphosphine ligands. Reasonable predictions for the observed regioselectivities were provided by this model. The use of rigid coordination spheres in the MM stage has been criticized in a second study, which also begins with DFT calculations on $Rh(H)(CO)(alkene)(PH_3)_2$ but uses (**121**) ($X = PPh$, $SiMe_2$, S, CMe, $C{=}CMe_2$, NR, $(CH_2)_2$) as the ligand in the MM stage. It is concluded that here the regioselectivity is governed primarily by nonbonding interactions between the phenyl groups on phosphorus and the alkene. Changes in the ''bite'' angle of the diphosphine seem to have little effect. The most extensive study again used $Rh(H)(CO)(C_2H_4)(PH_3)_2$ for the QM portion and the sequence of equation (46) was proposed as the lowest energy path for the catalytic cycle. The results suggest that the migratory insertion of the carbonyl and ethyl groups is the rate-determining step, although experimentally it is thought that the oxidative addition of dihydrogen is rate-determining. Another peculiarity is the predicted generation of *cis*-$Rh(H)(CO)L_2$ following reductive

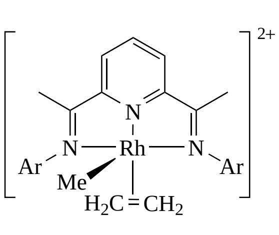


(46)

elimination of aldehyde and the determination that cycles beginning with this isomer are energetically less favorable than those shown above. To explain this, it is suggested that the alkene adduct of *cis*-$Rh(H)(CO)L_2$ could undergo a Berry pseudorotation to generate the isomer shown at the top right of equation (46). These studies were extended to explore the alkene insertion steps for propylene where regiochemical information could be obtained. The possible conformations found for the transition states for propylene insertion are (**122**) and (**123**), with the former on the path to the linear product while the latter is on the path to the branched isomer. Both equatorial–equatorial ($X = CO$; $Y = P$) and axial–equatorial ($X = P$; $Y = CO$) propylene adduct precursors to these transition states were also examined with the conclusion that the axial–equatorial isomer predominated by a factor of 3 but that the equatorial–equatorial isomer was 15 times reactive. There are therefore two channels predicted for the hydroformylation process: linear aldehyde from the less reactive but more abundant alkene adduct through (**122**) ($X = P$; $Y = CO$) and branched product from the more reactive minor adduct through (**123**) ($X = CO$; $Y = P$). The experimentally observed regioselectivities are suggested to arise from ground-state discrimination between the two most stable isomers of the alkene adduct, and therefore, to be particularly sensitive to the steric profile of the phosphine ligands. This question was explored, unfortunately only with ethylene, in MM calculations on $Rh(H)(CO)(C_2H_4)L_2$ ($L = PMe_3$, PPh_3, $P(m\text{-}XC_6H_4)_3$, $P(p\text{-}XC_6H_4)_3$ ($X = SO_3^-$)). For all the aryl phosphine ligands, the presence of the aryl substituents renders the equatorial–equatorial transition state (cf. **122**) ($X = CO$; $Y = P$) more favorable and because of π-stacking interactions, the insertion product *cis*-$Rh(Et)(CO)L_2$ is preferred to the trans isomer.[92] Related DFT calculations on $Rh(H)(CO)_3(CH_2{=}CHMe)$ predict the most stable isomer to be the one having the alkene lying in the equatorial plane of the trigonal bipyramidal coordination sphere. From this, the calculated lowest energy path to aldehyde gives a ratio of linear to branched product comparable to that found experimentally, when $Rh_4(CO)_{12}$ is the catalyst precursor ($Rh(H)(CO)_3(CH_2{=}CHMe)$ is the presumed alkene adduct formed in the catalytic cycle). Polarizable and/or electron-withdrawing substituents on the alkene are predicted to favor branched product while bulky substituents favor the linear isomer.[93]

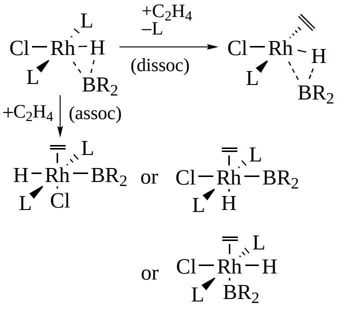


(**117**)

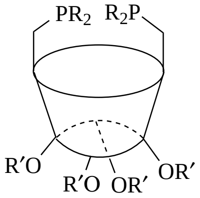


(**118**)

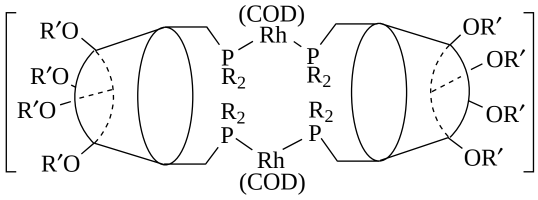
One computational study (*see* ***Molecular Orbital Theory***) has appeared using $\{RhCl(PH_3)_2\}$ to model the rhodium-catalyzed hydroboration of ethylene (*see* ***Hydroboration Catalysis***). Both associative and dissociative pathways were examined (equation 47). In the associative path, three possible



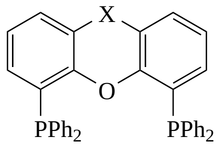
(47)



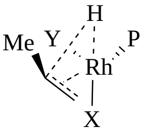
(**119**)



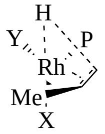
(**120**)



(**121**)



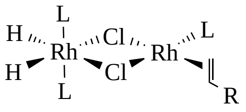
(**122**)



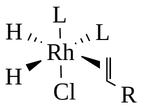
(**123**)

intermediates were considered to be on the reaction coordinate.[94] A related study on the hydrosilylation of alkenes (*see* ***Hydrosilation Catalysis***) using $RhCl(PH_3)_3$ as a catalyst model supports the modified Chalk–Harrod mechanism, namely oxidative addition of the Si–H bond to the metal followed by alkene coordination, insertion of the alkene into the Rh–Si bond, and C–H reductive elimination.[95]

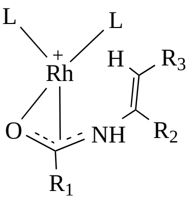
The rhodium-catalyzed hydrogenation of alkenes (*see* ***Hydrogenation & Isomerization of Alkenes***) has also been the subject of several studies, both experimental and computational. The use of para-hydrogen-induced-polarization in the $RhCl(PPh_3)_3$-catalyzed hydrogenation of hex-1-ene and related alkenes demonstrated the presence of several species, heretofore, undetected. Two of these are (**124**) and (**125**). The latter is detected when the alkene is styrene or its derivatives, while the former is determined not to be in the catalytic cycle and so represents a path lowering the catalyst activity. Its formation can be inhibited by the presence of small amounts of free phosphine.[96] The factors responsible for the high enantioselectivity in the hydrogenation of prochiral alkenes (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***), particularly (Z)-α-acetamidocinnamate esters catalyzed by cationic rhodium complexes of diphosphines have been explored by NMR and computational methods. There appears, from these results, to be considerable conformational mobility of the metal-complexed alkene so that a rigid chiral template is not established by the metal diphosphine framework. Instead, the primary enantiodiscriminating interaction is that between the plane of the enamide ester functionality and the proximal arene ring of the ligand. Molecular mechanics calculations were able to account for the diastereoselectivity of alkene binding but not the relative reactivities of the oxidative adducts of the alkene complexes with dihydrogen. This latter feature has been previously shown to be critical in determining the enantiomeric excess produced in the product. Some of the computational work suggested the possible importance of species such as (**126**) in the catalytic cycle.[97]



(**124**)



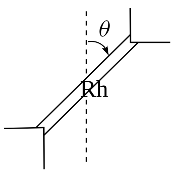
(**125**)



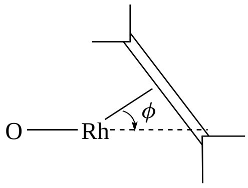
(**126**)

The classical Dewar-Chatt-Duncanson model for metal–alkene bonding has been revisited with a combination of X-ray structural data (*see* ***Diffraction Methods in Inorganic Chemistry***) and DFT calculations (*see* ***Molecular Orbital Theory***), particularly on complexes of the type $(acac)Rh(alkene)_2$. These indicate the existence of distortions from idealized geometry involving a ‘‘twist’’ (**127**), where the axis of the double bond is no longer perpendicular to the molecular plane and a ‘‘roll’’ (**128**), where the line

joining the midpoint of the double bond to the metal is no longer in the molecular plane. The latter distortion is seen for unsymmetrically substituted alkenes and occurs so as to place the more nucleophilic carbon atom closer to the molecular plane.[98] The coordination geometries of (acac)Rh(C_2H_4)$_2$ and its hfac analog determined by X-ray structure analysis (*see* ***Diffraction Methods in Inorganic Chemistry***) are reproduced satisfactorily by DFT calculations. Similar calculations to determine ^{103}Rh chemical shifts in (acac)Rh(alkene)$_2$ complexes also agree well with experiment and with a correlation found previously between these chemical shifts and stability constants for these monoalkene complexes. Chelating and fluorinated alkenes do not follow this correlation presumably because of the chelate effect in the former and bonding more akin to a metallacyclopropane in the latter.[99]

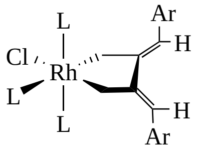


(**127**)

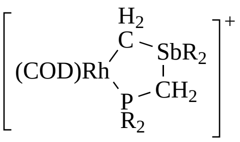


(**128**)

The complex [Cp*Rh(CH_3)(μ-CH_2)$_2$Rh(L)Cp*]PF_6 (L = η^2-C_2H_4) has been synthesized from the analog with L = MeCN by ligand exchange and obtained as a 2:1 mixture of trans and cis isomers. Decomposition above room temperature formed mainly methane and ethylene and small to trace amounts of ethane and propylene.[100] As another example that water is not necessarily incompatible with organotransition metal compounds (*see* ***Water & O-donor Ligands***), the complexes [Rh(L_2)(H_2O)$_2$]OTs (L_2 = COD, NBD, CH_2=C(Me)CH=CH_2, CH_2=C(Me)C(Me)=CH_2, (C_2H_4)$_2$) have been prepared from [Rh(μ-Cl)(L_2)]$_2$ and silver tosylate in water.[101] The unsubstituted double bond in mono-aryl allenes coordinates to rhodium in four-coordinate *trans*-RhClL_2(H_2C=C=CHAr) and five-coordinate RhClL_3(H_2C=C=CHAr) (L = PMe_3; Ar = Ph, *p*-FC_6H_4) (cf. **39, 45**) which are prepared, respectively, from [Rh(μ-Cl)L_2]$_2$ or RhClL_3 and approximately stoichiometric quantities of the allene. Particularly in the four-coordinate complex, there is an agostic interaction of an ortho hydrogen on the aryl group with a metal. If three equivalents of the allene are reacted with RhClL_3, coupling of two allene molecules occurs to form (**129**).[102] The unsymmetrical ligand $R_2PCH_2SbR_2$ (R = Pr^i) cleaves the chloride bridge in [Rh(μ-Cl(COD))]$_2$ to form RhCl(COD) ($R_2PCH_2SbR_2$) where the ligand coordinates only via phosphorus. Chelation can be achieved by abstraction of the chloride by $AgPF_6$, and addition of diazomethane to the resulting cationic complex forms (**130**) instead of the desired carbene complex.[103]



(**129**)

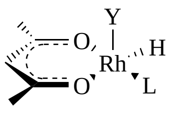


(**130**)

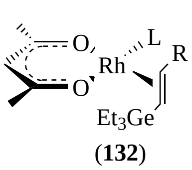
3.2 Complexes of Alkynes

Simple alkyne complexes continue to be reported, but the primary interest is in systems where the alkyne is transformed either by rearrangements (see Section 2.4 for conversion to vinylidenes and allenylidenes) or by coupling reactions between alkynes and/or other coordinated ligands (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***). Terminal alkynes cleave a Co–Co bond in $Rh_nCo_{3-n}(CO)_{12}$ (n = 1, 2) to form the butterfly clusters $Rh_nCo_{3-n}(CO)_6(\mu\text{-}CO)_4(\mu_4,\eta^2\text{-}HC{\equiv}CR)$ (R = CpFe(η^5-C_5H_4), CH_2OH, $MeOC_{10}H_6C(HMe)C(O)OCH_2$) (*see* ***Polynuclear Organometallic Cluster Complexes***).[104]

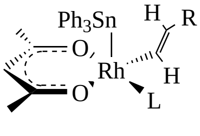
The final product of the reaction of alkynes (PhC≡CH, PhC≡CPh, DMAD, HFB, HC≡CCO_2Me) with Cp*Rh(PMe_3)H_2 is the corresponding alkene complex Cp*Rh(PMe_3)(η^2-alkene) formed by hydrogenation of the C≡C bond. In the cases of HFB and methyl propiolate, intermediate vinyl hydride complexes could be detected.[105] Triethylgermane undergoes oxidative addition to (acac)Rh(COE)(Pcy$_3$) to form (**131**) (Y = GeEt_3; L = Pcy$_3$), which effects hydrogermylation (*see* ***Germanium: Organometallic Chemistry***) of terminal alkynes to yield (**132**) (R = CO_2Me, Ph). Complex (**131**) (Y = SnPh_3) is similarly obtained from triphenylstannane but only the hydride ligand can be transferred to an alkyne and (**133**) (R = CO_2Me, Ph) results. The difference is attributed to the greater strength of a C–Ge bond over a C–Sn bond coupled with the Rh–Sn bond being stronger than a Rh–Ge bond.[106] Aryl phosphines containing *o*-methoxy groups are often *O*-demethylated on reaction with transition metal complexes and this occurs in the reaction of [Cp*Rh(μ-Cl)Cl]$_2$ with $PPh_n(2,6\text{-}(MeO)_2C_6H_3)_{3-n}$ (n = 1, 2) to form (**134**) (R′ = Ph, 2,6-(MeO)$_2C_6H_3$). Alkyne coupling occurs with terminal alkynes (PhC≡CH, *p*-tolC≡CH) to give (**135**) (R′ = Ph; R_1 = R_4 = Ph, *p*-tol; R_2 = R_3 = H), while with R″C≡CCO_2R, the product is (**136**) (R′ = Ph, R = Me, Et; R″ = H, R = Me, R″ = CO_2Me).[107] Cou-



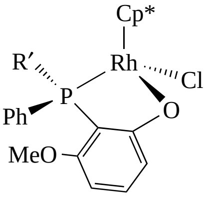
(**131**)



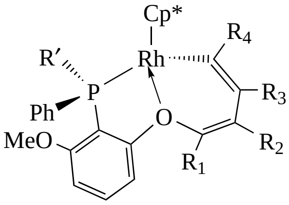
(**132**)



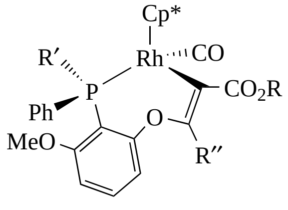
(**133**)



(**134**)

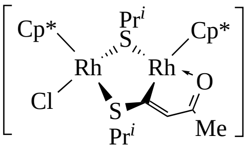


(**135**)

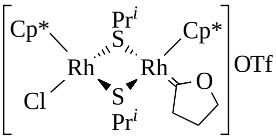


(**136**)

pling of methyl propiolate with one of the bridging thiolate ligands (*see* ***Tellurium: Organotellurium Chemistry***) in [Cp*Rh(μ-Cl)(μ-SPr^i)$_2$]OTf yields (**137**) (R = CO$_2$Me), while HC≡C(CH$_2$)$_2$OH forms the cyclic carbene (**138**).[108]

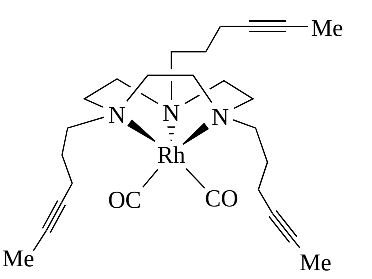


(**137**)

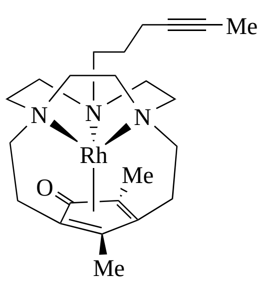


(**138**)

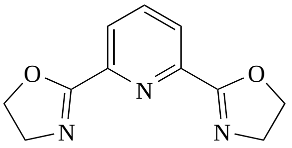
Complex (**139**) is prepared from [Rh(μ-Cl)(CO)$_2$]$_2$ and a Cn derivative (**1** (R = −(CH$_2$)$_3$C≡CMe; Section 2.1)) by standard methods. Either thermal or photochemical conditions cause coupling of two alkynyl arms with a carbonyl group (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***) to yield (**140**).[109] Cyclization with metallacycle formation (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***) occurs when the diyne O(CH$_2$C≡CCO$_2$Me)$_2$ is reacted with the Rh(I) chloro complex of the bis(oxazoline) ligand (**141**) to yield (**142**),[110] while acidification of the dinuclear acetylide complex [Cp*Rh(C≡CR)(μ-CH$_2$)]$_2$ (R = Ph, *p*-tol) with HBF$_4$ initiates coupling of both acetylide ligands with the methylidene groups (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***) to give (**143**) (X = H, Me) together with its anti isomer. Since HCl merely cleaves the acetylide ligand from [Cp*Rh(C≡CR)(μ-CH$_2$)]$_2$, the formation of (**143**) appears to require the presence of a noncoordinating anion and it is proposed that the reaction may proceed through (**144**) and (**145**) as intermediates although no vinylidene species could be detected even at a low temperature. In this instance, one alkynyl unit couples with one methylene unit but when phenyl acetylene reacts with {[Cp*Rh(MeCN)(μ-CH$_2$)]$_2$}$^{2+}$, both methylene units couple with two alkyne molecules (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***) to form (**146**).[111]



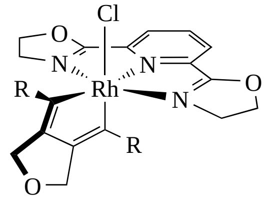
(**139**)



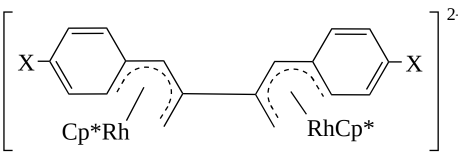
(**140**)



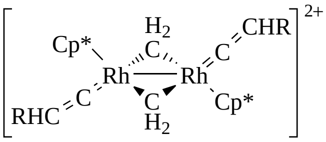
(**141**)



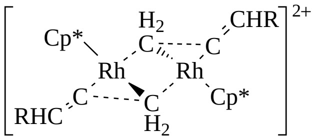
(**142**)



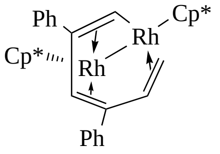
(**143**)



(**144**)



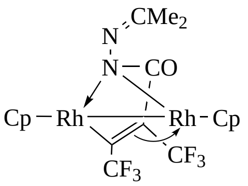
(**145**)



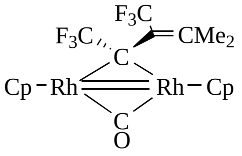
(**146**)

A considerable number of reactions of CpRh(μ-CO)(μ-η^2:η^2-F$_3$CC≡CCF$_3$)RhCp have been reported which illustrates the diversity of products that can be obtained in transition metal alkyne chemistry (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***). Reaction of this complex with dimethyldiazomethane forms a mixture of (**147**) and (**148**), and on recrystallization (**148**) converts to (**149**) by

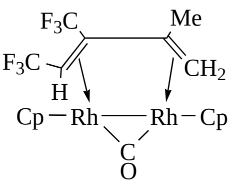
a 1,4 hydrogen shift. By contrast, $CpRh(\mu\text{-}CO)(\mu\text{-}\eta^2{:}\eta^2\text{-}F_3CC{\equiv}CCF_3)RhCp$ with $N_2C(CO_2Me)_2$ forms (**150**) ($R = CO_2Et$) where the alkylidene unit couples with the alkyne to form (**151**). The formation of (**147**), one of a number of examples of the complexation of intact diazoalkanes, is taken to indicate that the first step of both reactions is coordination of the diazoalkane to the metal via nitrogen, with the subsequent course of the reaction being determined by both steric and electronic factors. Attempts to couple $(CpMe)Mn(CO)_2(THF)$ (*see* ***Manganese: Organometallic Chemistry***) with $CpRh(\mu\text{-}CO)(\mu\text{-}\eta^2{:}\eta^2\text{-}F_3CC{\equiv}CCF_3)RhCp$ in a photolytic reaction led instead to cleavage of the methylcyclopentadienyl ligand from manganese and the formation of (**152**).[112] The alkynyl phosphines $Ph_2PC{\equiv}CR$ ($R = Me, Ph$) act as simple phosphine ligands (L) toward $CpRh(\mu\text{-}CO)(\mu\text{-}\eta^2{:}\eta^2\text{-}F_3CC{\equiv}CCF_3)RhCp$ to form $CpRh(CO)(\mu\text{-}\eta^1{:}\eta^1\text{-}F_3CC{\equiv}CCF_3)Rh(L)Cp$, but on treatment of the initial product with alumina in the presence of oxygen, alkyne coupling occurs to form (**153**).[113] In a similar fashion, $CpRh(CO)(\mu\text{-}\eta^1{:}\eta^1\text{-}F_3CC{\equiv}CCF_3)Rh(L)Cp$ ($L = SRR'$ ($R = R' = Me, Et, Pr^n$, bz. $R = Me$; $R' = Et$) is formed with the addition of one equivalent of the disulfide, but when these products ($R = R' = Me, Et$) are reacted with more of the same disulfide, (**154**) ($R'' = Et, Bu^s$) is formed in a metal-mediated Stevens rearrangement.[114] Complex (**155**) is formed from $CpRh(CO)(\mu\text{-}\eta^1{:}\eta^1\text{-}F_3CC{\equiv}CCF_3)Rh(L)Cp$ ($L = \eta^1$-DPPE) and $CpPd(\eta^3\text{-}C_3H_5)$.[115]



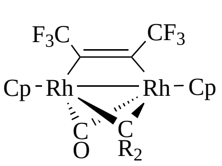
(**147**)



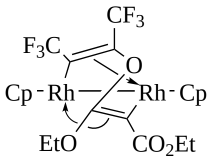
(**148**)



(**149**)

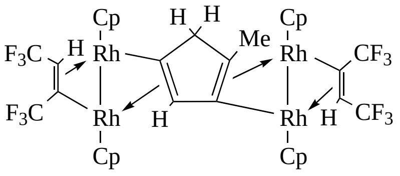


(**150**)

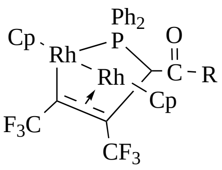


(**151**)

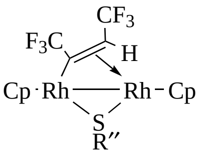
The reaction of $RhCl(PMe_3)_3$ with $Li(THF)_3[Si(SiMe_3)_3]$ in the presence of alkynes leads to Si–C coupling and



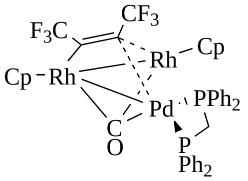
(**152**)



(**153**)

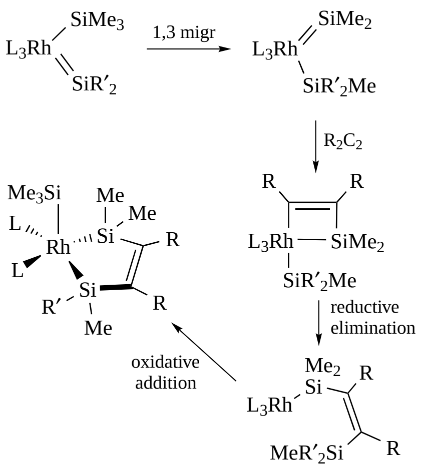


(**154**)



(**155**)

metallacycle formation (equation 48 ($L = PMe_3$; $R = Me, Ph$)). It is proposed that $L_3Rh(Si(SiMe_3)_3)$ is formed initially and is converted to the

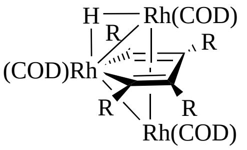


(48)

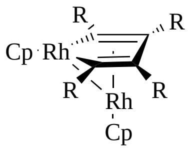
silylene complex shown at the top left of equation (48) by a 1,2 migration of a trimethylsilyl group.[116]

As has been demonstrated repeatedly in the past, the reaction of alkynes with coordinatively unsaturated metal complexes frequently leads to a plethora of products resulting from the coupling of two or more alkyne molecules, sometimes also with inclusion of molecules present as ligands on the starting complex (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***). Treatment of $[Rh(\mu\text{-}Cl)(COD)]_2$ with Pr^nLi and but-2-yne forms (**156**) ($R = Me$), but photolysis of $CpRh(\eta^2\text{-}C_2H_4)_2$ with $RC{\equiv}CR$ ($R = Me, Et$) yields $CpRh(\eta^2\text{-}RC{\equiv}CR)(\eta^2\text{-}C_2H_4)$, $CpRh(\eta^4\text{-}C_6R_6)$, and (**157–160**) among other species. The oxygen atom in (**159**) is considered to result from hydrolysis during chromatographic workup of the crude reaction mixture while the formation of (**160**) suggests the intermediacy of a vinyl hydride species as has been found in the related Tp′ and Cn systems (see Section 2.1).[117] Coupling of a

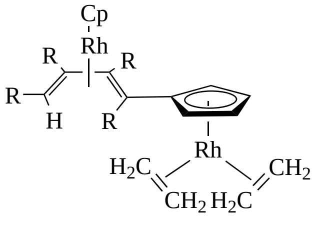
coordinated alkyne with an isocyanide occurs when CpRh(η^2-PhC≡CPh)(SbPr$^i_3$) with one equivalent of methyl isocyanide and (**161**) is formed. This reacts with a further two equivalents of an isocyanide to give the double insertion product (**162**) (R = Me, Bu^t).



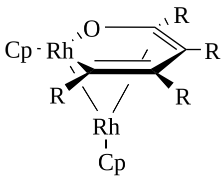
(**156**)



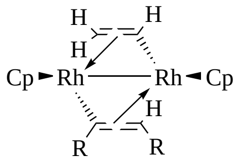
(**157**)



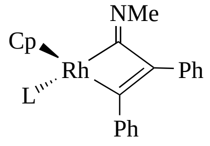
(**158**)



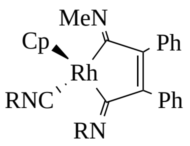
(**159**)



(**160**)



(**161**)



(**162**)

Complex (**162**) (R = Me) can be obtained directly from CpRh(η^2-PhC≡CPh)(SbPr$^i_3$) and three equivalents of methyl isocyanide.[118]

Considerable use has been made of $[Pt(C{\equiv}CR)_4]^{2-}$ (R = Bu^t, $SiMe_3$) and *cis*-$[(C_5F_5)_2Pt(C{\equiv}CR)_2]^{2-}$ (R = Bu^t, Ph, $SiMe_3$) for the construction of multimetallic complexes via coordination of other metals to the C–C triple bonds. Thus, $[Pt(C{\equiv}CR)_4]^{2-}$ with $[Rh(COD)(acetone)_2]^+$ forms (**163**) (R = Bu^t, $SiMe_3$), while *cis*-$M(C_6F_5)_2(THF)_2$ (M = Pd, Pt) reacts with Cp*Rh(X)(C≡CR)(PEt_3) to give (**164**) (X = Cl, C≡CR; R = Bu^t, Ph; R′ = C_6F_5; M = Pd, Pt). Further reaction of (**164**) with an excess of $[M'(C{\equiv}CPh)]_n$ (M′ = Cu, Ag) forms (**165**). Similarly, *cis*-$[(C_5F_5)_2Pt(C{\equiv}CR)_2]^{2-}$ and $[Rh(\mu\text{-}Cl)(COD)]_2$ give (**166**) while with $[Rh(COD)(Et_2O)_x]^+$ the bimetallic complex (**167**) is formed. Finally, acetylide ligand transfer from $[Pt(C{\equiv}CR)_4]^{2-}$ (R = Bu^t, $SiMe_3$) to rhodium occurs in its reaction with $[Cp^*Rh(PEt_3)(acetone)_x]^{2+}$ and the product is (**168**) (L = PEt_3). Reaction of (**168**) with one equivalent of *cis*-$Pt(C_6F_5)_2(THF)_2$ attaches a {*cis*-$Pt(C_6F_5)_2$} fragment to the two acetylide ligands attached to Pt.[119]

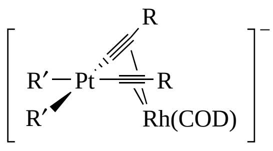
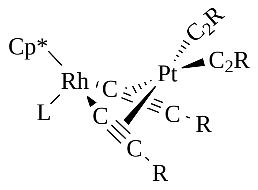
(**166**)



(**167**)



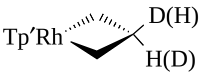
(**168**)

4 COMPOUNDS OF LIGANDS CONTAINING DELOCALIZED π-BONDS

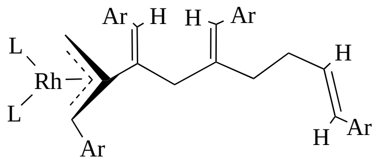
4.1 Allyl Complexes

Oxidative addition of allyl bromide (*see* ***Carbon–Carbon & Carbon–Heteroatom Activation***) to Tp′Rh(COE)(MeCN) initially yields Tp′Rh(η^1-$CH_2CH{=}CH_2$)(Br)(MeCN) but on heating in benzene solution it converts into Tp′Rh(η^3-C_3H_5)Br. This is an example of a typical procedure for the formation of η^3-allyl complexes, where the η^1-allyl complex is formed via oxidative addition of an allyl halide to a low-valent metal center or by metathesis of a metal halogen

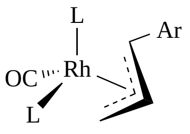
bond with an allyl Grignard or lithium reagent. Loss of a relatively labile two-electron donor ligand via thermolysis or photolysis converts the one-electron donor η^1-allyl ligand to a three-electron donor η^3-allyl ligand. Despite NMR evidence for significant electron deficiency in the allyl group in Tp′Rh(η^3-C_3H_5)Br, its reaction with MeMgBr replaces the bromide by a methyl group suggesting attack at the metal rather than at the allyl ligand as had been expected. Similarly, reaction with $LiBHEt_3$ forms Tp′Rh(η^3-C_3H_5)(H), but when $LiBDEt_3$ is used, incorporation of deuterium into the allyl ligand occurs to give Tp′Rh(η^3-CH_2CDCH_2)(H) in 92% isotopic purity. Also, reaction of Tp′Rh(η^3-CH_2CDCH_2)Br with $LiBHEt_3$ forms Tp′Rh(η^3-C_3H_5)(D) in 85% isotopic purity indicating that at least in this system, initial attack of hydride (or deuteride) occurs at the allyl ligand to form (**169**), which then undergoes β-hydride (or deuteride) elimination.[120] Multiple insertions of mono(aryl)allenes into the initially formed allyl complex occurs when an excess of the allene is reacted with Rh(H)$(PPh_3)_4$ and (**170**) (Ar = p-XC_6H_4 (X = H, Me, OMe, Bu^t, Cl, F); L = PPh_3) is the product but with Rh(H)(CO)$(PPh_3)_3$, only the initial allyl complex (**171**) results.[121] The majority of the phosphine-complexed rhodium in the solution resulting from the addition of DPPB to [Rh(μ-H)(COD)]$_4$ is (η^3-C_8H_{13})Rh(DPPB) resulting from partial hydrogenation of the COD ligand. Hydrogenolysis of this complex in the presence of DPPB forms Rh(H)$(DPPB)_2$ via the postulated intermediate Rh(H)(DPPB). This last species is considered to be the active catalytic species when a DPPB/[Rh(μ-H)(COD)]$_4$ mixture is used to catalyze the hydrogenation of carbon dioxide to formic acid (*see* ***Organic Synthesis using Transition Metal Carbonyl Complexes***).[122]



(**169**)

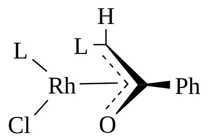


(**170**)

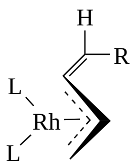


(**171**)

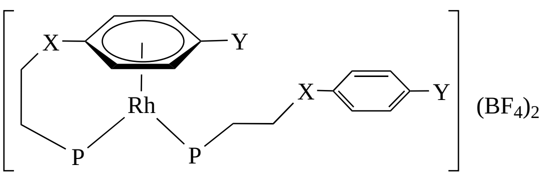
Two equivalents of the potassium enolate K[PhC(O)CH_2] react with [Rh(μ-Cl)L_2]$_2$ to form the oxaallyl complex (η^3-CH_2C(Ph)O)RhL_2 (L = PPh_3), a rare example of a complex containing an unsupported oxaallyl ligand. Addition of an extra ligand causes an isomerization to the enolate complex Rh(OC(Ph)=CH_2)(L′)L_2 (L′ = CO, Bu^{t}NC). The reactivity of the (η^3-CH_2C(Bu^t)O)RhL_2 analog differs markedly in that with CO the products are pinacolone and [Rh(μ-CO)(CO)L_2]$_2$, while with the isocyanide the oxaallyl ligand rearranges to the carbon-bound form in Rh(CH_2C(O)Bu^t)L_2(CNBu^t)$_2$. The differences in reactivity as compared with analogous allyl complexes are attributed to the greater stability of the η^1-enolate form as compared with an η^1-allyl.[123] Following the standard procedure, (η^3-allyl)Rh(COD) (allyl = C_3H_5, 2-Me-C_3H_4) is generated from reaction of (allyl)MgBr with [Rh(μ-Cl)(COD)]$_2$ and the COD can be replaced by various bis(phosphino)methane ligands giving (η^3-allyl)Rh($R_2CH_2PPr^i{}_2$) (R = Pr^i, cy, Ph). These initially add one carbonyl ligand to the metal but in the presence of excess CO undergo a reversible migratory insertion of CO into the allyl group to give the acyl complexes Rh(C(=O)CH_2C(R′)=CH_2)$(CO)_2$($R_2CH_2PPr^i{}_2$) R′ = H, Me).[124] An attempt to generate an acyl carbene complex from the reaction of [Rh(μ-Cl)(PPr^i_3)$_2$]$_2$ and PhC(=O)CHN_2 led instead to the acyl ylide complex (**172**)[125] while action of vinylmagnesium bromide on the vinylidene complex *trans*-Rh(=C=CHR)Cl(PPr^i_3)$_2$ initially formed (**46**) (R = H, Bu^t, Ph; L = $PPr^i{}_3$), but on standing in benzene solution this underwent coupling of the vinyl and vinylidene ligands to yield (**173**) (see also Section 2.3). Similarly, *trans*-Rh(=C=CHR)(Me)(PPr^i_3)$_2$, prepared in an analogous fashion at low temperature undergoes C–C coupling (*see* ***Organic Synthesis Using Metal-mediated Coupling Reactions***) at room temperature to form (η^3-1-R-C_3H_4)Rh(PPr^i_3)$_2$ (R = H, Ph, Bu^t). For R = H, Ph the syn isomer forms, while R = Bu^t gives the anti.[126]



(**172**)



(**173**)

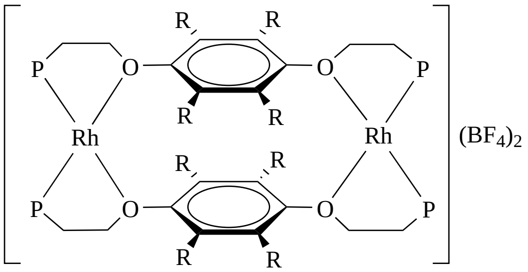


(**174**)

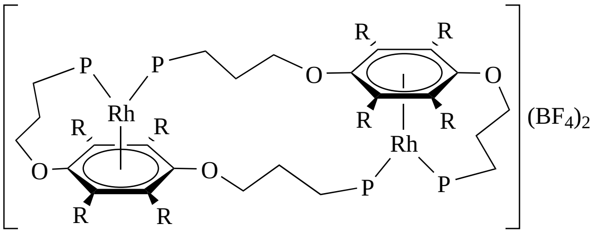
A series of DFT calculations (*see* ***Molecular Orbital Theory***) on Rh(η^3-C_3H_5)$_3$ indicate that the ground-state structure has no symmetry. Calculated ionization energies agree well with values obtained from photoelectron spectra. The calculated potential-energy surface indicates the presence of three transition states, one of which involves an η^1-allyl ligand between the several minima that are found, and variable-temperature NMR measurements appear consistent with there being three distinct fluxional processes (*see* ***Stability Constants & their Determination***).[127]

4.2 Arene Complexes

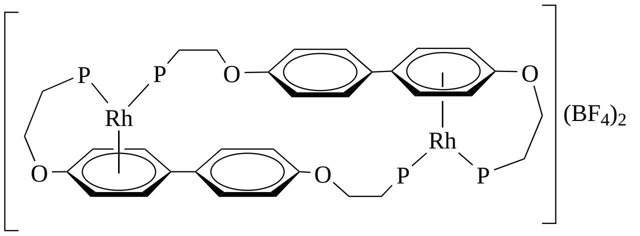
Arene complexes figure prominently in a series of investigations into the synthesis of metallamacrocyclic complexes. The first report is on (**174**) (X = CH_2; Y = H, F. X = O; Y = H) that are obtained from $Ph_2PCH_2CH_2XC_6H_4Y$ and $[Rh(COE)(THF)_2]BF_4$, while an analogous route with 1,4-$(Ph_2PCH_2CH_2O)_2C_6R_4$ (R = Me) forms the dinuclear species (**175**). Using the more flexible ligand 1,4-$(Ph_2PCH_2CH_2CH_2O)_2C_6R_4$ (R = Me) allows for arene coordination and (**176**) is formed instead. Interestingly, with the ligand 4,4′-$(Ph_2PCH_2CH_2)_2C_6H_4C_6H_4$ arene coordination also occurs and (**177**) is formed. The coordination of the oxygen atoms in (**175**) and the arene groups in (**176**) and (**177**) serve to initially satisfy the coordination requirements of the metal and constitute a ''weak link'' approach to directing the synthesis in an efficient manner toward the final metallamacrocycle. Thus, successive reaction of (**176**) with acetonitrile and then carbon monoxide displaces the arene from the metal and forms (**178**) (R = Me). Similarly, the ''weak links'' in (**175**) and (**177**) are disrupted by carbon monoxide to form (**179**) ($n = 1$; R = Me. $n = 2$; R = H), while reaction of (**175**) with 1,4-diisocyanobenzene in acetonitrile forms the ''occupied'' metallamacrocycle (**180**).[128] The calix-shaped metallacyclophane (**181**) is formed from 9,10-bis(2-diphenylphosphinoethyl)anthracene and $[Rh(\mu\text{-Cl})(CO)_2]_2$ at a low temperature.[129]



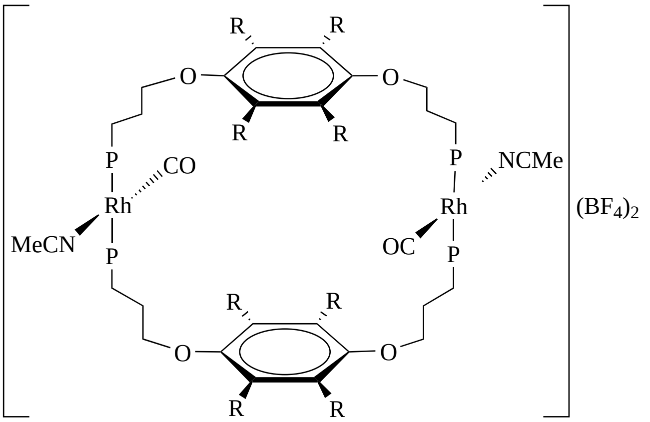
(**175**)



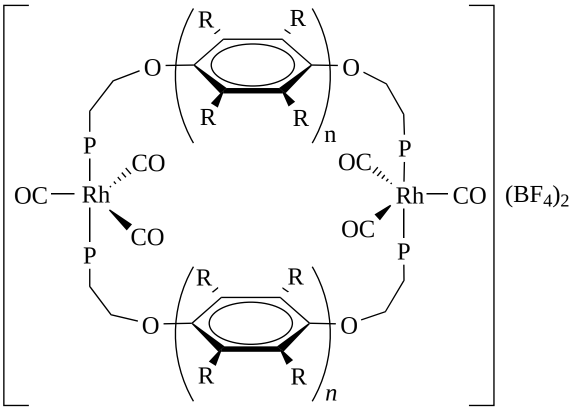
(**176**)



(**177**)



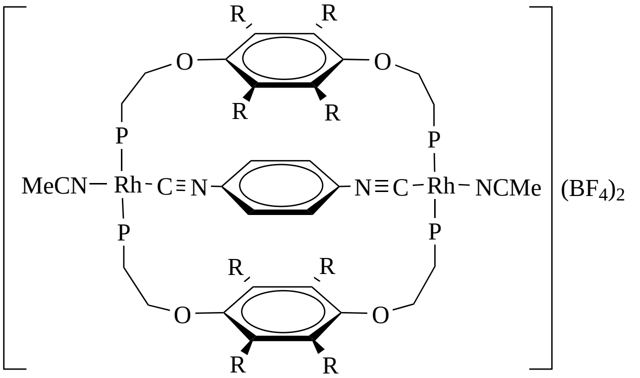
(**178**)



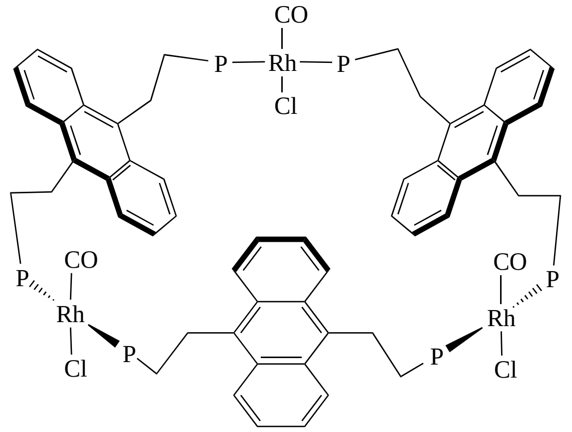
(**179**)

Complexes of formula $[(\eta^6\text{-arene})Rh(CO)L]PF_6$ (arene = C_6H_6, $C_6H_5CF_3$, C_6H_5OMe, mesitylene, 1,3,5-$(MeO)_3C_6H_3$; L = $PPr^i{}_3$) are readily formed by displacement of the weakly bound solvent from $[Rh(COE)(L)(acetone)_2]PF_6$ by the arene, and the COE ligand can be then replaced by the more strongly bonding alkene ethylene. Treatment of $[Rh(COE)(PPr^i_3)(acetone)_2]PF_6$ with $Pr^i{}_2P(CH_2)_nPh$ ($n = 2$, 3) forms (**182**) (L = COE) and analogs with L = C_2H_4, maleic anhydride, $EtO_2CC{\equiv}CH$, $SbPr^i_3$, and $Pr^i{}_2P(CH_2)_nPh$ can be prepared by substitution reactions.[130]

Photolysis (*see* ***Photochemistry of Transition Metal Complexes***) of a mixture of $CpRh(C_2H_4)_2$ and hexamethylbenzene in hexane solution forms a mixture of (**183**) and (**184**). Analogs are similarly formed with biphenyl under the same conditions.[131] The tetrameric borole complex $[Rh(\mu_3\text{-I})(\eta^5\text{-}C_4H_4BPh)]_4$ is converted to $[(\eta^5\text{-}C_4H_4BPh)Rh(MeCN)_3]BF_4$ by halide abstraction with $AgBF_4$. The acetonitrile can be

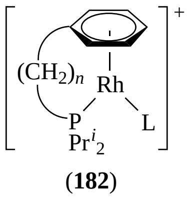


(**180**)

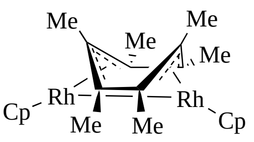


(**181**)

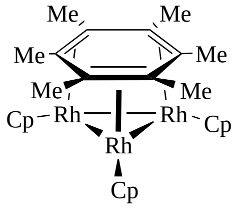
replaced by hexamethylbenzene to give $[(\eta^5\text{-}C_4H_4BPh)Rh(\eta^6\text{-}C_6Me_6)]BF_4$, but if the acetonitrile complex is taken to dryness it polymerizes to (**185**).[132] A final report on arene complexes concerns the chemistry of rhodium complexes containing η^6-coordinated tetraphenylborate ions (*see* ***Boron: Organoboranes***). For example, $(C_2H_4)_2Rh(\eta^6\text{-}C_6H_5BPh_3)$ plus $n-1$ equivalents of $(C_2H_4)_2Rh(OTf)$ forms $\{[(C_2H_4)_2Rh(\eta^6\text{-}C_6H_5)]_nBPh_{4-n}\}(OTf)_{n-1}$ ($n = 2$, 3). The complexes in THF or dichloromethane solution under dinitrogen decompose to form biphenyl, benzene, ethylbenzene, and styrene. The formation of the last two products indicates a process transferring a phenyl group to an ethylene ligand and the formation of a species such as $\{(C_2H_4)_2Rh(C_6H_5)\}$ is proposed.[133]



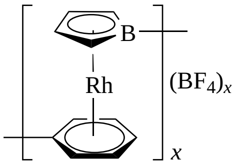
(**182**)



(**183**)



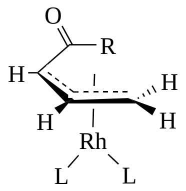
(**184**)



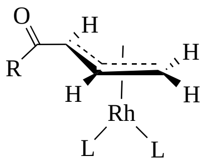
(**185**)

5 MISCELLANEOUS COMPLEXES

A new report on oxapentadienyl complexes includes the reaction of $[Rh(\mu\text{-}Cl)L_2]_2$ with several potassium oxapentadienides to form a mixture of the isomers (**186**) and (**187**) ($L = PMe_3$, PEt_3; R = Me, H). When $L = PEt_3$ and R = Me, reaction of (**186**) with methyl triflate forms (**188**), while with HBF_4 a mixture of (**189**) and (**190**) is obtained.[134] Reaction of diphenyl ketene with $[Rh(\mu\text{-}Cl)(COE)_2]_2$ and four equivalents of a phosphine forms *trans*-$RhCl(\eta^2\text{-}O{=}C{=}CPh_2)L_2$ ($L = PPr^i{}_3$, Pcy_3, $PBu^t{}_2Me$) where it is the C=O bond which is coordinated with the metal. In comparison to the iridium analog, there is less π-backbonding. The isotopically labeled complexes with $Ph_2C{=}^{13}C{=}O$ and $Ph_2C{=}C{=}^{18}O$ were also prepared and used to analyze the infrared spectrum leading to an identification of the C=O stretching vibration of the coordinated ketene.[135] Condensation of $[Cp^{tt}{}_2ZrS_2]^{2-}$ (Cp^{tt} = 1,3-$Bu^t{}_2C_5H_3$) with $[Rh(\mu\text{-}Cl)(L_2)]_2$ forms (**191**) (L_2 = COD, NBD, TFB). The same complex can also be synthesized from $Cp^{tt}{}_2Zr(SH)_2$ and $Rh(acac)(L_2)$. Replacement of the diolefin ligands in (**191**) with carbon monoxide occurs readily and one carbonyl ligand on each rhodium can then be replaced by a phosphine or a phosphite.[136] Hydrolysis of Cp^*TaMe_4 with two equivalents of $[Rh(\mu\text{-}OH)(COD)]_2$ forms (**192**) and this is further hydrolyzed by 4,6-dimethyl-2-hydroxy-3-cyanopyridine to yield (**193**).[137]

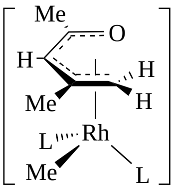


(**186**)

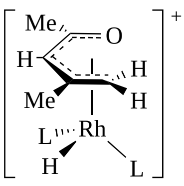


(**187**)

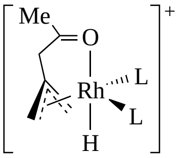
The uncoordinated phosphorus atoms in $[Pt_2(\mu\text{-}dpmp)_2L_2](PF_6)_2$ (L = xylylisocyanide) can bind a rhodium atom in



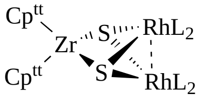
(188)



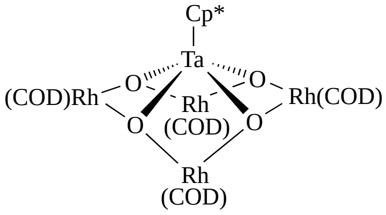
(189)



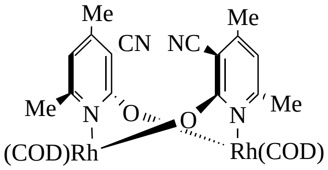
(190)



(191)

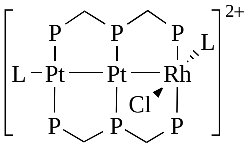


(192)

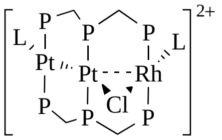


(193)

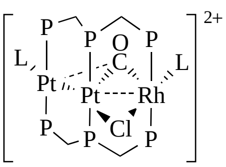
the reaction with $[Rh(\mu\text{-}Cl)(COD)]_2$ to form a mixture of (**194**) and (**195**). Reaction of (**195**) with carbon monoxide forms (**196**) while with methyl propiolate (**197**) (R = Me) is the product.[138]



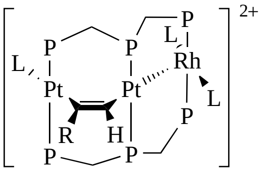
(194)



(195)



(196)



(197)

DFT calculations (*see* ***Molecular Orbital Theory***) on $CpRh(CO)_2$ and $[RhCl_2(CO)_2]^-$ have been used to determine the ground-state molecular structures, and these structures with symmetry-adapted cluster-configuration interaction calculations have been used to explore the nature of excited states (*see* ***Electronic Structure of Organometallic Compounds***). The ground state is predicted to be a singlet with the triplet state lying significantly above it. The activation process for the anion is predicted to be thermal dissociation of a carbonyl ligand but this process requires much more energy in the neutral complex. In the excited state of the anion, all strong absorptions are Rh → CO MLCT in nature while for $CpRh(CO)_2$ the Rh → CO MLCT and the Cp → {Rh + CO} absorptions are strongly mixed in the higher excited states with the latter having the greater oscillator strength. The results suggest that the low quantum efficiency for $CpRh(CO)_2$ to activate C–H and Si–H bonds can be attributed to a low proportion of MLCT excitation in the higher excited states (*see* ***Photochemistry of Transition Metal Complexes*** and ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds***).[139] Enthalpies of addition of CO, H_2, and Bu^tNC to $[Rh(\mu\text{-}Cl)(PPr^i_3)_2]_2$ (which has been conclusively determined to be dimeric in solution) have been measured[140] (*see* ***Bonding Energetics of Organometallic Compounds***) and the analog $[Rh(\mu\text{-}Cl)(Bu^t_2PCH_2PBu^t_2)]_2$ has been prepared. In solution, this latter species is thought to convert to the solvated monomer $RhCl(Bu^t_2PCH_2PBu^t_2)(S)$ and is a catalyst precursor for the hydrosilylation of but-2-yne by $HSi(OEt)_3$ (*see* ***Hydrosilation Catalysis***). A much better system uses $Rh(Me)(Bu^t_2PCH_2PBu^t_2)(PMe_3)$ which is prepared by addition of PMe_3 to $RhCl(Bu^t_2PCH_2PBu^t_2)(S)$ followed by reaction with methyllithium. This system shows a high selectivity for the cis hydrosilylation product and the resting state of the catalyst is thought to be $Rh(PMe_3)(Si(OEt)_3)(Bu^t_2PCH_2PBu^t_2)$, which could be isolated from reaction of $Rh(Me)(Bu^t_2PCH_2PBu^t_2)(PMe_3)$ and the silane at low temperature.[141]

1 INTRODUCTION

Ruthenium was first recognized as a distinct metal in 1844 in Estonia by Clauss and was named after Ruthenia (Russia). However, its blue chloride solution had been previously observed by Vauquelin in Paris in 1804. Ruthenium is the least abundant platinum metal (10^{-3} to 10^{-4} ppm) after rhodium. In 2002, the demand for ruthenium was 11.6 tons, an increase of 1.8 tons compared to 2001, mainly because of increased sales of ruthenium paste to the electronics industry, for the manufacture of chip resistors and hybrid integrated circuits (HIC). Its atomic number is 44, its atomic weight 101.07, and its electronic configuration $[Kr]4d^75s^1$. Seven stable isotopes are known. Some physical data are reported in Table 1 (*see* ***Coordination Chemistry: History*** and ***Coordination Numbers & Geometries***).

Among the platinum metals, ruthenium shows the largest range of oxidation states, from −II to +VIII, with most of the inorganic chemistry taking place in the +II and +III states. The chemistry of ruthenium has been comprehensively reviewed in a monograph in 1984 and in '*Comprehensive Coordination Chemistry'* in 1987 and 2003.[1–4] In the most recent review, the results (including osmium chemistry) have been divided into two chapters referring to low- and high-oxidation states.[3,4]

This article represents an updated version of the one published in EIC-1. It is organize in the same way, with a survey of the coordination and inorganic chemistry of ruthenium, classified by the nature of the ligand, together with recent highlights in this field. Some old references will not be quoted and can be found in EIC-1. It is worth noting that the border with organometallic chemistry remains tenuous (see, for example, the use of classical coordination compounds for catalyzing organic reactions; *see* ***Ruthenium: Organometallic Chemistry***).

2 RUTHENIUM–HALIDE COMPLEXES

Compounds of the formulation RuX_3 are known for all four halides (X = F, Cl, Br, I). $RuCl_3$ exists as two well-characterized phases (α-$RuCl_3$ and β-$RuCl_3$), which

Table 1 Selected physical properties of ruthenium

Lattice structure	Close-packed hexagonal
Metallic radius for 12-coordination	0.134 nm
Density (20 °C)	12 450 kg m^{-3}
Melting point	2310 °C
Boiling point	3900 °C
Resistivity (0 °C)	6.80 μΩ cm
Ionization potential:	
1st	7.364 eV
2nd	16.76 eV

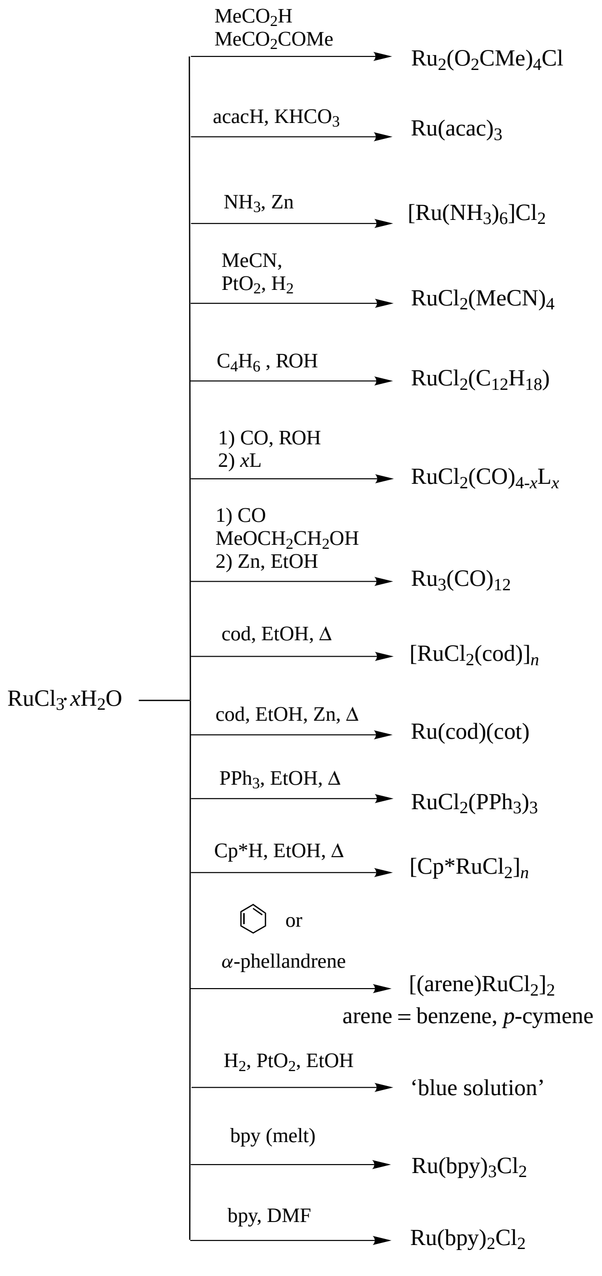
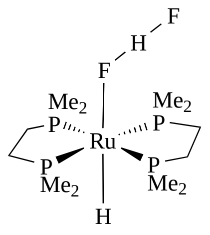


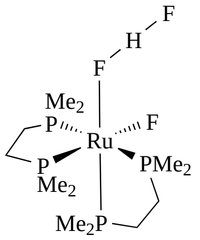
Scheme 1

are prepared by heating ruthenium metal in a stream of CO/Cl_2 at 600 to 700 °C and 330 to 340 °C, respectively. In contrast, the complex commonly known as 'hydrated ruthenium trichloride', or '$RuCl_3 \cdot xH_2O$', is readily soluble in various polar solvents and is commercially available. It is by far the most common starting material in ruthenium chemistry, whether inorganic or organometallic (see Scheme 1 for selected examples of important compounds). However, it was demonstrated that this species actually corresponds to a mixture of different ruthenium compounds, mostly in the +IV oxidation state. Species such as $H_3[Cl_3Ru(\mu\text{-}OH)_3RuCl_3]$ and $H_3[Cl_3Ru(\mu\text{-}OH)_2(\mu\text{-}O)RuCl_3]$ have been shown to exist in the mixture. We will, nevertheless, refer to the common commercial name throughout this article.

A large number of mixed-ligand ruthenium(III) halides are known. One of the simplest is $K_2[RuCl_5(H_2O)]$, which is a valuable well-defined Ru^{III} starting material. A series of dinuclear complexes $Ru_2Cl_4(dppb)_2L$ can be obtained by electrolysis from the corresponding $RuCl_3(dppb)L$ complexes.[5] There is no strong evidence for the existence of any RuX_2 complexes. However, reduction of $RuCl_3 \cdot 3H_2O$ by various reagents (Zn, H_2/PtO_2, Na/Hg, Zn/Hg, etc.) in alcoholic or aqueous solutions affords a deep-blue solution (first observed by Vauquelin). The nature of such solutions is still controversial. Investigations by Rose and Wilkinson in the late 1960s have concluded in favor of the presence of the anionic cluster $[Ru_5Cl_{12}]^-$, although no X-ray evidence is as yet available on this compound. It was, nevertheless, found to be a valuable precursor for the synthesis of a large variety of ruthenium (II) derivatives. Bino and Cotton have shown that addition of tetraethylammonium chloride to the deep-blue solution obtained upon dissolving $Ru_2(OAc)_2Cl$ in 12 M HCl led to a green crystalline material, shown to be the homoleptic trimer $[Ru_3Cl_{12}]^{6-}$ containing Ru(III), Ru(II), and Ru(III) with short Ru–Ru distances (2.805(1) Å) in agreement with single Ru–Ru bonds.



(**1**)



(**2**)

Some homoleptic fluorides of ruthenium are well characterized up to the oxidation state +VI: RuF_6 is a volatile dark-brown solid. Mixed-ligand complexes such as $RuOF_4$ are also known. RuF_4 has been isolated by treatment of AsF_5 with $[RuF_6]^{2-}$ in a HF solution.[6] With the other halides, the chemistry starts at the oxidation state IV. $RuCl_4$ can be observed in the gas phase between 400 and 800 °C, whereas the dianions $MX_6{}^{2-}$ (X = F, Cl, Br) are stable. During the last decade, considerable progress has been made in the field of transition metal–fluoride complexes. Several fluoride(carbonyl) complexes have been characterized (*see* ***Carbonyl Complexes of the Transition Metals***). A series of bifluoride HF_2 complexes incorporating mono- or diphosphines are now available.[7] In particular, two bifluoride complexes can be isolated from *cis*-$RuH_2(dmpe)_2$. The hydride complex *trans*-$RuH(HF_2)(dmpe)_2$ (**1**) was obtained by addition of $Et_3N \cdot 3HF$ or by reaction with fluoroarenes as a result of C–F activation, whereas reaction with fluoroalkenes produced the fluoride complex *cis*-$RuF(HF_2)(dmpe)_2$ (**2**). The coordination mode of

the fluoro ligand, terminal versus bridging, plays an important role in the stabilization of d^6 and d^8 complexes.[8]

3 RUTHENIUM COMPLEXES OF OXYGEN-DONOR LIGANDS (*See* ***Water & O-donor Ligands***)

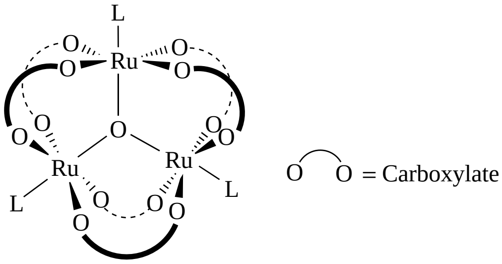
3.1 Ruthenium Homoleptic Oxo Species

The ruthenium(VIII) complex RuO_4 and salts such as $K_n[RuO_4]$, derived by reduction ($n = 1-3$), have been reported in the literature. However, the compound originally thought to be the ruthenium(VI) oxide $[RuO_4]^{2-}$ has been identified by X-ray crystallography as $[RuO_3(OH)_2]^{2-}$. RuO_4 is a yellow, crystalline, low-melting (25.4 °C), and highly volatile solid. Care must be taken when using it since it is a highly toxic and powerful oxidizing agent. It reacts explosively with a variety of organic solvents. It is, nevertheless, a useful oxidizing reagent for organic substrates such as alcohol, amine, sulfide, and so on. The perruthenate (^{n}Pr$_4$N)RuO_4 salt is a useful, mild, and selective oxidant of alcohols to aldehydes or ketones, even in allylic systems. O_2 or NMO is used as co-oxidant.[9] Interestingly, the salt can be recovered when using ionic liquids (*see* ***Oxidation Catalysis by Transition Metal Complexes***).[10] The ruthenium(IV) oxide, RuO_2, is a stable metallic oxide displaying a low chemical reactivity but interesting physical properties. Under high pressure, the rutile form of RuO_2 can be converted to a new cubic phase, which presents a very low compressibility (comparable to that of diamond).[11]

3.2 Mixed-ligand Oxo Derivatives

The study of mixed-ligand oxo derivatives is closely related to the use of these species in catalytic oxidation systems (including the epoxidation of alkenes and the oxidation of alkanes. *See* ***Oxidation Catalysis by Transition Metal Complexes***). In such complexes, the oxo group can be terminal, doubly bridging, or triply bridging.

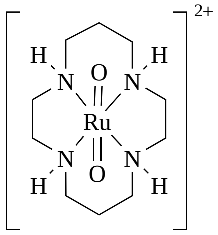
The chemistry of triply bridging oxo(carboxylate) ruthenium clusters of general formula $[Ru_3(\mu_3\text{-}O)(\mu_2\text{-}O_2CR)_6(L)_3]^n$ (**3**) has been extensively developed. A rich chemistry is associated with the strong electronic and magnetic interactions involving Ru(II), Ru(III), and Ru(IV) centers. They are relevant to biomimetic systems, redox catalysis, and molecular devices.[12] A number of dinuclear ruthenium complexes incorporating a bridging oxygen have been isolated and used as a water oxidation catalyst. The μ-oxo(bipyridyl) dimer $[\{Ru(bpy)_2(OH_2)\}_2O]^{4+}$ (known as 'blue ruthenium dimer') is one of the most effective electrocatalytic reagents. The mechanism by which it oxidizes water to dioxygen is very complex (loss of $4e^-$ and $4H^+$) and has been extensively investigated by Meyer *et al.*[13]



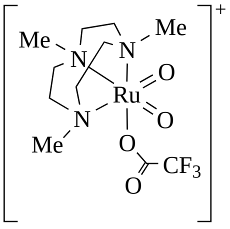
(**3**)

Monooxo and dioxo ruthenium (IV), (V), and (VI) complexes have been extensively studied. Che's group has been very active in this area, and a very detailed analysis of this field can be found in the chapter written by Che and Lau and published in '*Comprehensive Coordination Chemistry*'.[4] The chapter covers the various aspects of the chemistry (synthesis; characterization, including the Pourbaix diagrams for many representative species; reactivity; and catalysis). The most important classes of ligands for such $Ru(O)_n$ centers are (1) the porphyrins; (2) the macrocyclic tertiary amine ligands (*see* ***Macrocyclic Ligands***); and (3) the pyridine, polypyridyl, and related ligands. Most of the compounds are very active oxidants for a variety of organic and inorganic substrates.

Groves *et al.* isolated the first dioxoruthenium(VI) porphyrin complex $Ru(O)_2$TMP, able to efficiently catalyze the aerobic epoxidation of alkenes at ambient temperature and pressure.[14] A number of dioxo $[Ru(O)_2(por)]$ and oxo(imido) [Ru(O)(por)(NR)] complexes of Ru (VI) with porphyrinato (por) ligands are now available. All these Ru(VI) complexes are diamagnetic. Complexes incorporating chiral porphyrins have also been isolated, and for example, enantioselective aerobic epoxidation of alkenes is achieved by complex (**4**). Recent developments involve the design of dendritic ruthenium porphyrins.[15] Similar high-oxidation oxo complexes can be prepared using various macrocyclic amine ligands such as [14]ane-N4 (**5**) or 14-tetramethylcyclam (TMC) and their 15- and 16-member analogs. A cis configuration, as in complex (**6**), can be obtained using a triazacyclononane ligand. (**6**) oxidizes disubstituted alkynes to 1,2 diketones in good yields.[16]

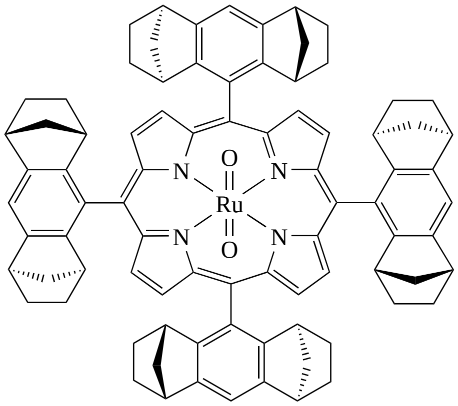


(**5**)



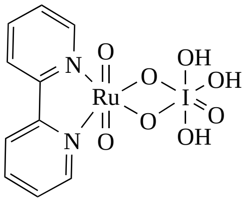
(**6**)

Bis-oxo-Ru(VI) complexes containing nonlabile oxidation-resistant nitrogen-donor ligands such as pyridine, bipyridine,



(**4**)

terpyridine, and related ligands are another important class of compounds that behave as four-electron oxidants and convert alcohols to aldehydes or ketones. The remarkable reactivity of high-oxidation-state ruthenium and osmium polypyridyl complexes has been recently reviewed by Meyer and Huynh.[17] The polypyridyl species are stronger oxidants than the macrocyclic family. The chemistry of periodato-derived species has been developed, and for example, the complex, $[Ru(O)_2(bpy)\{IO_3(OH)_3\}]$ (**7**), containing the triply protonated periodate ligand $[I(O)_3(OH)_3]^{2-}$ has been isolated. (**7**) behaves as a six-electron oxidant for the stoichiometric oxidation of alkenes.[18] Chloro and carboxylato dioxo complexes of Ru(VI) have been prepared and are also used as oxidants of halides, alcohols, sulfides, and even alkanes (*see* ***Oxidation Catalysis by Transition Metal Complexes***).

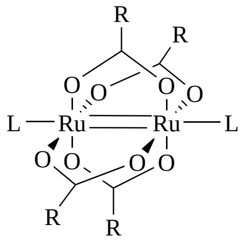


(**7**)

3.3 Carboxylate Ligands

The carboxylate group can act as a three-electron bridging or chelating ligand, as well as a one-electron monodentate ligand. This gives rise to a rich chemistry in which interconversion between the modes of coordination of the ligand and nuclearity of the complexes is facile. Examples of chelation are found in the phosphine adducts $Ru(OAc)_2(PPh_3)_2$ and $RuH(OAc)(PPh_3)_3$, which are prepared by metathetical exchange with chloride groups or by protonation of polyhydrides with acetic acid. The dicarboxylate complexes $Ru(OAc)_2(BINAP)$ are at the origin of all the chemistry developed by Noyori in asymmetric catalytic hydrogenation reactions (see Section 6.2). Similar complexes of the formula $Ru(O_2CCF_3)_2(ROH)_2(PP)$, incorporating various chiral phosphines (PP (diphosphines)), have also been characterized. The two carboxylates act as monodentate ligands, and two solvent molecules remain in the coordination sphere of the metal, in cis positions.[19]

Bridging carboxylates are mainly found in three types of structures: μ_3-oxo-bridged trimers, μ_2-oxo- or hydroxo-bridged dimers (see Section 3.2), and metal–metal multiply bonded dimers. Diruthenium tetracarboxylates exist as homovalent Ru_2(II,II) and mixed-valent Ru_2(II,III) species (*see* ***Mixed Valence Compounds***). They all adopt the familiar 'lantern' type motif (see structure (**8**)). The first dimers $[Ru_2(OCOR)_4Cl]$ were prepared by reaction of $RuCl_3\cdot 3H_2O$ with a mixture of carboxylic acid/anhydride acid. The crystal structure of $[Ru_2(OCOMe)_4Cl]$ revealed the presence of infinite chains of Ru_2 units linked by Cl. Analogous complexes can be prepared using a variety of acids. Diadducts of the type $[Ru_2(OCOR)_4L_2]X$ incorporate L ligands such as H_2O, $OPPh_3$, THF, py, MeOH, and DMSO. The diruthenium carboxylate complexes display interesting magnetic and electronic properties as potential molecular materials and liquid crystals. They are now being tested as antitumor drugs.[20]



(**8**)

3.4 Other Oxygen-donor Ligands

Water reacts as a ligand in numerous inorganic and organometallic compounds. It normally behaves as a two-electron ligand on one ruthenium center, although some rare cases of water bridging two ruthenium centers are known. The homoleptic ruthenium(III) and ruthenium(II) complexes $[Ru(H_2O)_6]^{n+}$ have been known for nearly 40 years. In the course of their studies on Ring Opening Metathesis Polymerization (ROMP) reactions, Grubbs *et al.* explored the reactivity of $[Ru(H_2O)_6](tosyl)_2$ with acyclic- and monocyclic-functionalized alkenes (L), generating monoalkene adducts $[Ru(H_2O)_5L]^{2+}$ (*see* ***Water & O-donor Ligands***).[21]

Hydroxy ligands generally result from the protonation of oxo or deprotonation of aqua species and are thus found in systems similar to those described above. They occupy terminal or doubly or triply bridging positions. Alternative routes involve the metathetical exchange of Cl^- by OH^- or oxidative addition of H_2O. These routes have been used by Wilkinson *et al.* to prepare unsaturated trans hydroxo

hydrido derivatives such as $RuH(OH)(PPh_3)_2(H_2O)$.[1,2] A series of alkoxide and hydroxide complexes have now been designed by Bergman *et al.*, and their properties and reactivities have been reviewed. The complexes, with a strongly polarized Ru–O bond, typically display nucleophilic reactivity (*see* ***Water & O-donor Ligands***).[22] The formation of an (alkoxy)ruthenium hydride and a piperidinyloxy species are postulated in the $RuCl_2(PPh_3)_3$/TEMPO-catalyzed aerobic oxidation of alcohols.[23]

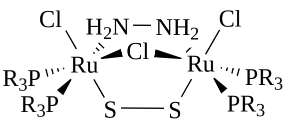
$Ru(acac)_3$ is readily prepared from $RuCl_3{\cdot}3H_2O$, 2,4-pentanedione, and potassium hydrogencarbonate in hot water. Its structure has been determined by X-ray and neutron diffraction measurements at various temperatures.[24] This compound can be reduced to $[Ru(acac)_3]^-$. Protonation leads to liberation of acacH, thus making this compound a suitable starting material for ruthenium(III) chemistry. $Ru(acac)_3$-mediated oxidative di- and trimerization of 1,3-diamino benzene produce new diimine $Ru(acac)_2$ complexes.[25] Ruthenium complexes with the bulky $N(SPR_2)_2$ ligand, a sulfur analogue of acac, have been synthesized.[26]

4 RUTHENIUM COMPLEXES OF SULFUR-DONOR LIGANDS (*See S-donor Ligands*)

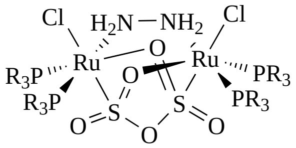
Ruthenium–sulfur systems have attracted attention, primarily owing to their relevance to biology and catalysis, in particular, for the hydrodesulfurization process. (*see* ***Hydrodesulfurization & Hydrodenitrogenation***). Soft sulfur ligands alone cannot stabilize Ru(VI) centers, and no Ru(V) complexes seem to have been reported with any sulfur ligands. Sulfide, thiolate, and thioether ligands are unique as they display versatile electronic properties: they can act as pure σ-donors, σ-donor π-acceptors, or even as σ- π-donors because of their lone pairs (*see* ***Subvalent Compounds***). The coordination chemistry of new mixed-donor ligands is now being investigated to benefit from the properties of the different atoms N, P, O, and S (*see* ***Sulfur: Inorganic Chemistry***).

4.1 Sulfides and Thiolato Ligands

Ruthenium sulfide (RuS_2) as well as other chalcogenides RuX_2 (X = Se, Te) adopt a cubic pyrite structure and should be regarded as Ru^{2+} $(S_2)^{2-}$. They are very stable compounds that are readily prepared by several routes, including direct combination of the elements. The chemistry of ruthenium complexes with bridging sulfide groups has been particularly examined by Matsumoto *et al.* The synthesis and properties of a family of complexes with a strong μ-donor ligand $(S_2)^{2-}$ bridging two Ru centers have been described. Of particular interest is the reaction of (**9**) with O_2. Amongst other products, oxidation of the sulfide ligand results in the formation of (**10**) with a unique bridging $S_2O_5{}^{2-}$ ligand.[27]

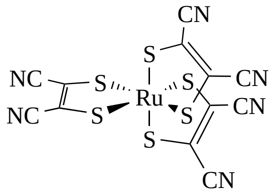


(**9**)

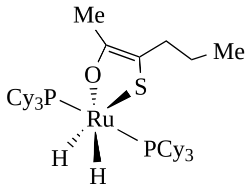


(**10**)

Numerous examples of complexes containing terminal or bridging thiolato ligands are known. For example, fluorinated thiolates Ru(II) and (III) species have been prepared in which $C_6F_5S^-$ acts either as a terminal ligand or as a bridging ligand between two ruthenium centers.[28] Trigonal-bipyramidal Ru(IV) thiolate complexes display a characteristic trigonal-planar $Ru(SR)_3$ core, and the organometallic reactivity of these species is now being explored.[29] The homoleptic complex $[Ru(mnt)_3]^{2-}$ (**11**) with only sulfur atoms in the coordination sphere of ruthenium has been isolated. (**11**) decomposes in the presence of light, leading to the formation of a compound $[Ru(mnts)_2]^{2-}$ containing a novel tridentate (mnts) ligand.[30] Various examples of hydrido(thiolate) complexes have been reported. Interestingly, protonation can occur at the metal, or at the hydride to form a dihydrogen complex, or at the sulfur site to give a thiol complex (see Section 8). The reactivity of the bis(dihydrogen) complex $RuH_2(H_2)_2(PCy_3)_2$ with sulfur heteroaromatic compounds leads to new compounds presenting different coordination modes of the S-substrates. As an example, C–S splitting in 2-acetylthiophene results in the formation of a dihydride metallocycle (**12**) with a new thiolato ligand η^2-(O,S) coordinated to ruthenium.[31]



(**11**)



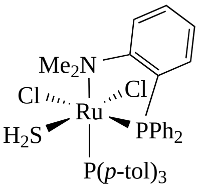
(**12**)

4.2 Thioethers and Analogous Derivatives

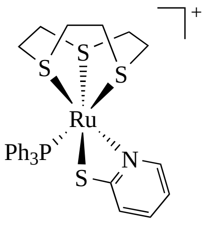
Numerous examples of complexes containing thioethers have been reported, including the first example by Sellmann *et al.* of a transition metal compound containing H_2S, namely, $Ru(SH_2)(PPh_3)(S_4)$ (S_4 = 2,2′-(ethylenedithio)bis(thiophenolate)). There is now an example of a room-temperature stable complex with a P–N ligand (see structure (**13**)).[32]

The remarkable complexing properties of cyclic thioethers, in particular, those exploited by Schröder's and Yoshida's groups, have stimulated a great interest in metal–thioether chemistry. These cyclic ligands bind preferentially to soft metal ions and have allowed the preparation of complexes displaying unusual stereochemistry and/or oxidation states. The most common thioethers involved are [9]ane-S_3,

[12]ane-S_3, [12]ane-S_4, [14]ane-S_4, [16]ane-S_4, and [18]ane-S_6. The affinity of ruthenium for these thioethers (see structure (**14**)) is evidenced by the loss of arene upon reaction of $[RuCl_2(arene)]_2$ with [9]ane-S_3, yielding the homoleptic derivative $[Ru([9]ane\text{-}S_3)]^{2+}$. Neutral (such as $[RuCl_2(PR_3)[9]ane\text{-}S_3]$), cationic ($[RuCl(L^1)(L^2)([9]ane\text{-}S_3)]^+$), or dicationic complexes ($[Ru(L^1)_2(L^2)([9]ane\text{-}S_3)]^{2+}$) can be prepared as well as dinuclear species.[33]

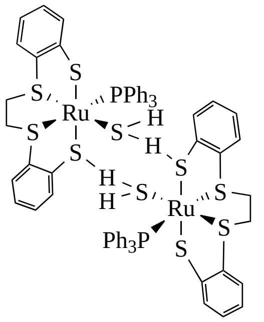


(**13**)

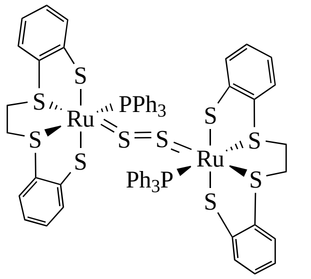


(**14**)

Sellmann *et al.* have extensively surveyed the coordination properties of tetra- and pentadentate ligands in the search for reduction of N_2 by metal–sulfur complexes under mild conditions (see structures (**15**) and (**16**)).[34] The Ru‘S4’ core is not always preserved and partial cleavage of S–C bonds can occur. To circumvent this problem, the ethylene bridge in ‘S4’ has been replaced by an *o*-phenylene bridge.[35]



(**15**)



(**16**)

Pentaammine Ru(III) polarizes thiourea by complexing sulfur, and the complex $[Ru(NH_3)_5SC(NH_2)_2](S_2O_6)_{3/2}\cdot H_2O$ is isolated. The data are consistent with LMCT from a filled $p\pi$ sulfur orbital to the vacant $d_{xy}\pi$-orbital on Ru(III).[36]

4.3 Sulfoxides

Sulfoxide ruthenium complexes have received attention in part from the fact that they are useful starting materials for new organometallic and coordination compounds and in part from their role in biology and catalytic processes (*see* ***Metal-related Diseases of Genetic Origin***). Potential applications are found in medicinal chemistry, in particular as antitumor agents and as radiosensitizers. The complex Na{-*trans*[$RuCl_4$(DMSO)(Im)]} known as (NAMI), is the first ruthenium compound to enter clinical trials.[37–39]

$RuCl_2(DMSO)_4$ can be conveniently prepared by refluxing $RuCl_3\cdot 3H_2O$ in DMSO for a few minutes. This complex has found wide interest as a starting material, although DMSO is often difficult to eliminate. The sulfoxide ligand has two possible sites of coordination, sulfur and oxygen. Coordination to sulfur is generally observed in the case of ruthenium, and the $d\pi$-S back-bonding plays a major role. S to O linkage isomerization was first shown, by Taube *et al.*, to occur upon oxidation of $[Ru(NH_3)_5(DMSO)]^{2+}$. More recent studies demonstrate that DMSO can also be S-bonded to Ru(III) and Ru(IV) and suggest that the κS-(DMSO) σ-donation to Ru is extensive in Ru(II) and Ru(IV) states.[40] The complex $[Ru(bpy)_2(DMSO)_2]^{2+}$ is yellow and has two S-bound DMSO ligands. Upon irradiation, a color change to red is observed, which is attributed to linkage isomerization from S- to O-bound DMSO. The yellow color is slowly recovered in the dark.[41]

5 RUTHENIUM COMPLEXES OF NITROGEN-DONOR LIGANDS (*See Ammonia & N-donor Ligands*)

Supramolecular chemistry involving transition metal complexes has received increasing interest over the last decade. Photo-redox processes for solar energy conversion, information storage systems, biosensors, and complexes with antitumor activity are currently under investigation. In this area, the inorganic chemistry of ruthenium, largely dominated by the chemistry of nitrogen-donor ligands, plays a major role. Several important achievements in inorganic chemistry have involved nitrogen-donor ruthenium derivatives. These include (1) the first dinitrogen complexes, (2) the Creutz–Taube complex for the study of electron transfer and for the study of electron transfer in ruthenium-modified proteins, (3) the photochemistry of $[Ru(bpy)_3]^{2+}$ and all the applications of this and related complexes (from photovoltaic cells to DNA intercalation), and (4) the aerobic oxidation of alkenes in the presence of ruthenium–porphyrin derivatives using both oxygen atoms.

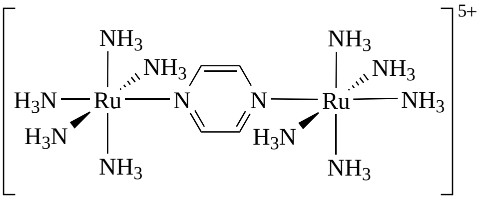
The chemistry of the higher oxidation states is dominated by metal–ligand multiple bonds, with the oxo ligand being the ligand of choice. There are no complexes of Ru(VIII) and Ru(VII) incorporating an imido or a nitrido ligand and almost no Ru(V) compounds. A number of nitrido Ru(VI) complexes exist with a variety of ligands, but the chemistry is much less matured than the analogous osmium chemistry (*see* ***Nitrides: Transition Metal Solid-state Chemistry***). There are no nitrido mononuclear Ru(IV) complexes, but a number of μ-nitrido species are known.

The simple amido complex $[Ru(NH_3)_5(NH_2)]^{2+}$ can be easily prepared by deprotonation of $[Ru(NH_3)_6]^{3+}$, and a series of hydrido(amido) ruthenium complexes have been recently reported.[22] The chemistry of Ru(VI) imido complexes is largely concentrated on oxo(porphyrins) compounds of general formula Ru(O)(NR)(por). Extensive work on oxo ruthenium(VI) complexes incorporating N-ligands has been performed, as already mentioned in Section 3.2. Three main classes of ligands can be distinguished: (1) the porphyrins, (2) the macrocyclic tertiary amine ligands, and (3) the pyridine, polypyridyl, and related ligands. The results show a rich electrochemistry, and numerous studies are connected to the use of these compounds as oxidants for a variety of substrates (*see* ***Oxidation Catalysis by Transition Metal Complexes***). Ruthenium porphyrins are efficient catalysts for a collection of organic reactions such as epoxidation and cyclopropanation of alkenes and hydroxylation and amidation of alkanes. For example, a dendritic ruthenium porphyrin efficiently catalyzes the EDA cyclopropanation of styrene.[15]

5.1 Ammine Salts

The hexaammine ruthenium(II) salt $[Ru(NH_3)_6]Cl_2$ is conveniently prepared by zinc reduction of $RuCl_3{\cdot}3H_2O$ in aqueous ammonia. It is readily oxidized in several ways to the corresponding ruthenium(III) derivative, $[Ru(NH_3)_6]^{3+}$. The ruthenium(II) complex is substitutionally very labile, unlike the ruthenium(III) analogue, and complexes of the general formula $[Ru(NH_3)_5(L)]^{2+}$ display a very rich photochemistry. $[Ru(NH_3)_5N_2]^{2+}$ was the first transition metal–dinitrogen complex, the discovery of which in 1965 stimulated the rapid development of nitrogen fixation chemistry (*see* ***Nitrogenase Catalysis & Assembly***). The first compound containing a bridging dinitrogen group, $[(NH_3)_5Ru(N_2)Ru(NH_3)_5]^{4+}$, was then obtained by mixing $[Ru(NH_3)_5N_2]^{2+}$ and $[Ru(NH_3)_5(H_2O)]^{2+}$.[1,2] Studies on the photochemistry of Ru(II) ammine complexes really started in 1969 with molecular nitrogen complexes. The photochemical reactions are dominated by substitution processes. The studies provide a better knowledge into the excited states reactivity of d^6 centers. The properties of the MLCT states in Ru(II)–ammine complexes depend on the nature of the L ligand. They can be varied by controlling the acidity of the medium and are solvent dependent. Several investigations have been focused on the prediction of electronic spectra and on identifying the extent of ruthenium–ligand electronic coupling in mononuclear and dinuclear species. The electronic spectra calculations are performed using modified INDO/s method (*see* ***Photochemistry of Transition Metal Complexes***; ***Photochemistry of Transition Metal Complexes: Theory***).[42–44]

Mixed-valence complexes exhibit interesting properties when significant electron coupling occurs between the donor and acceptor sites. Most of the systems are Ru(II)/Ru(III) species, but if electronic coupling is sufficient, there is a complete blending of oxidation states and the odd electron is delocalized over both sites. The μ-pyrazine-bridged dimer (**17**), also named the Creutz–Taube ion, was the first designed mixed-valence complex. The Nobel prize for chemistry was awarded to Taube in 1983 for his work on the mechanisms of electron transfer reactions (*see* ***Electron Transfer in Coordination Compounds*** and ***Electron Transfer Reactions: Theory***).[1–3] The electronic structure of (**17**) has been the subject of numerous studies. The complex is considered 'delocalized' but appears to have properties of both class II and class III in the Robin and Day classification. In particular, its spectroscopic properties show some residual localization. It should now be considered as the prototype of a new class of mixed-valence species, Class II–III, as evidenced by Meyer *et al.*[45] Medium effects on charge transfer in metal complexes have also been reviewed by Meyer *et al.*[46] Inventing new analogues of the Creutz–Taube ion remains a very active area of research.[47]

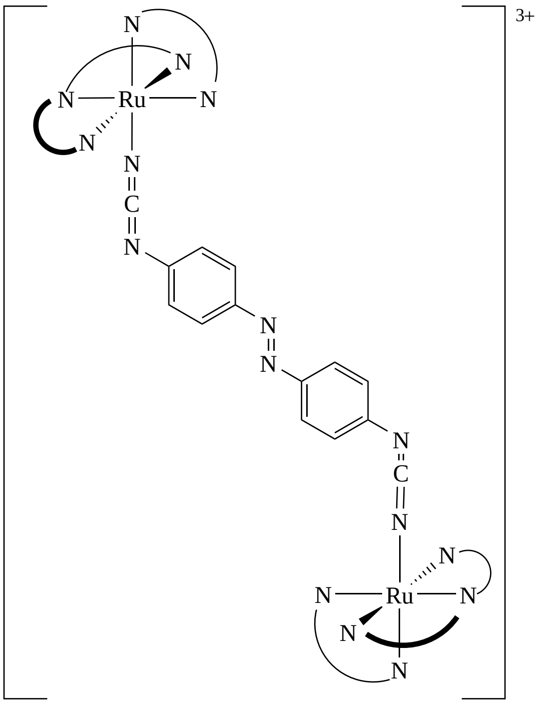


(**17**)

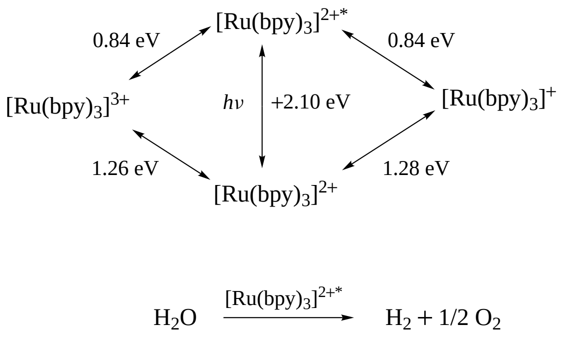
Long-distance intervalence electron transfer is now demonstrated with metal–metal distances up to 25 Å. Distance dependence of electron transfer has strong implications for the search of, for example, molecular switch devices or biosensors. The bridging ligand dicyanamidobenzene has been extensively studied, and for example, complex (**18**) exhibits a very strong coupling (0.32 eV) for a metal–metal distance of 19.5 Å.[48]

5.2 $[Ru(bpy)_3]^{2+}$ and Related Complexes. Some Selected Applications

A huge growth has been observed in $[Ru(bpy)_3]^{2+}$ chemistry over the last two decades as the complex displays a unique combination of air and thermal stability and redox and photophysical properties (*see* ***Electron Transfer in Coordination Compounds*** and ***Electron Transfer Reactions: Theory***). More generally, ruthenium complexes incorporating pyridine or multidentate ligands based on aromatic imines have attracted more attention than all the other classes of inorganic ruthenium derivatives (*see* ***Photochemistry of Transition Metal Complexes*** and ***Photochemistry of Transition Metal Complexes: Theory***).[3] An exhaustive database of bipyridine-containing molecules has now been reported.[49] Complexes of the general formula $[RuL_6]^{2+}$ (L = py; L_2 = bpy, phen, and derivatives; L_3 = terpy, etc.) can be prepared by a variety of



(**18**)



Scheme 2

methods.[1–3] In the case of $[Ru(bpy)_3]^{2+}$, a convenient method involves the reduction of $RuCl_3$ with H_2 over Pt black, followed by treatment with bpy in MeOH. The red crystals are obtained with 80% yield. It is out of the scope of this article to extensively review the photochemistry and photophysics studies on $[Ru(bpy)_3]^{2+}$ and related species, but we will give a few principles and highlight a few outstanding applications. Many investigations have benefited from the tremendous progress seen in various techniques (such as, for example, time-resolved femtosecond absorption spectroscopy).

$[Ru(bpy)_3]^{2+}$ possesses a luminescent excited state, $[Ru(bpy)_3]^{2+*}$, which can act as a reducing agent to give $[Ru(bpy)_3]^{3+}$ or as an oxidizing agent to give $[Ru(bpy)_3]^{+}$. Therefore, the energy-transfer process may be coupled to either an oxidizing or a reducing agent. The redox potentials for couples involving $[Ru(bpy)_3]^{2+}$ and the excited state $[Ru(bpy)_3]^{2+*}$ are shown in Scheme 2. Its redox potentials are in favor of water splitting.

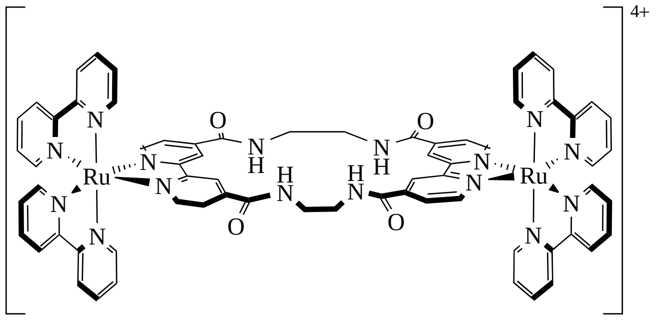
The design of new molecules, aimed at controlling the transfer of energy and of electrons from the excited state, is still an active area of research. The current understanding of electron flow through proteins has been achieved mainly through the use of photoprobes, with photoactive Ru(II)-diimine complexes being in widespread use.[50]

A rich chemistry has flourished in the search for new luminescent systems (*see* ***Luminescence*** and ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds***). A great variety of inorganic architectures have been obtained, including helicates and large multicomponent arrays. As an example, rack-type polynuclear ruthenium complexes have been assembled by Lehn *et al.* These rack-type structures are based on tridentate ligands with pyrimidine and pyridine moieties. A fine tuning of the absorption and luminescence properties of these complexes can be performed by introducing substituents on the pyrimidine ring. These systems represent key structures for the development of photonic and electronic devices.[51] The control of the direction of the energy-transfer process in a multicomponent species offers new perspectives for artificial functions operating at the molecular level. The synthesis of multicomponent systems incorporating Ru(II) polypyridine and anthracene chromophores has been performed. The direction of the intercomponent energy-transfer process is reversed on passing from room temperature to 77 K.[52] Dentritic luminescent structures are now rather common as illustrated by the report in '*Inorganic Synthesis*', of a decanuclear ruthenium(II) polypyridine complex.[53,54]

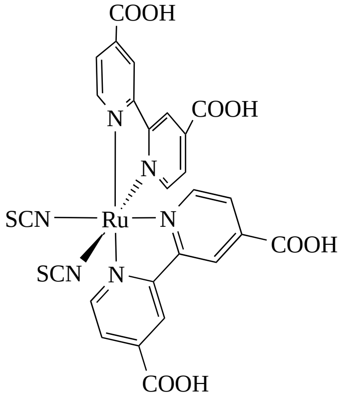
Incorporation of the $Ru(bpy)_3$ moiety into acyclic, macrocyclic, and calixarene frameworks leads to a new class of anion receptors capable of optical and electrochemical sensing (see (**19**)).[55] The remarkable reactivity of high-oxidation-state ruthenium and osmium polypyridyl complexes has been recently reviewed by Meyer and Huynh,[17] whereas the significance of polypyridyl complexes as biomimetic models for the photosynthetic reaction center was analyzed by Dürr and Bossmann.[56] The viologen-linked $[Ru(bpy)_3]^{2+}$ system has been widely investigated, and a soluble polymer based on a polypyrrole–bisviologen-linked $[Ru(bpy)_3]^{2+}$ dyad is now available. The photostability of the dyad network in the presence of oxygen offers new possibilities in photoinduced redox processes (*see* ***Electrochemistry: Applications in Inorganic Chemistry***).[57]

5.2.1 Molecular Photovoltaics

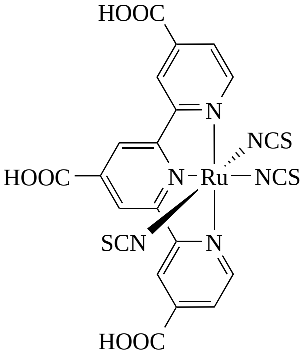
The photochemical properties of bipyridine ruthenium compounds are at the origin of impressive results in the field of molecular photovoltaics. In 1991, Grätzel *et al.* prepared a molecular photovoltaic system by coating TiO_2 with a bipyridine complex linked to the surface



(**19**)



(**20**)



(**21**)

by carboxylate groups (*see* ***Semiconductor Interfaces*** and ***Superconductivity***). This system is able to inject one electron into the semiconductor conduction band extremely rapidly after photoexcitation. It is now admitted that the process occurs in the femtosecond time regime. By contrast, the back reaction of the electrons with the oxidized ruthenium complex is slow (microsecond to millisecond timescale). This first dye-sensitized nanocrystalline solar cell gave a conversion yield of 7%. Following this result, hundreds of other complexes have been synthesized and tested, but the polypyridyl–ruthenium complexes remain the precursors of choice for achieving the best photovoltaic performances. The best results are now obtained by complexes (**20**) and (**21**), known as N3 and black dye, respectively. The efficiency obtained with the black dye (**21**) is 10.4% under standard air mass 1.5 reporting conditions. The interaction between the carboxylic group and TiO_2 is of fundamental importance as the dye is attached via two carboxylates. Projects concerning molecular engineering with judicious substitutions of the carboxylic groups are under investigation. The ultimate goal is the splitting of water into dihydrogen and dioxygen by sunlight.[58,59] In photosynthesis, water oxidation is accomplished by photosystem II (PSII), which is a large membrane-bound protein. Several studies, aimed at mimicking the light-driven oxidation of water accomplished by PSII, involve the use of a photosensitizer, a ruthenium(II) complex incorporating bpy units, linked to manganese complexes (*see* ***Photosynthesis***).[60]

5.2.2 Molecular Machines

A special issue devoted to molecular machines appeared in ‘Accounts of Chemical Research’ in 2001. It reflects the current interest for this field in which ruthenium complexes act as important tools. Molecular machines are characterized by a mobile part and a stationary part. Photochemical and electrochemical inputs can make a machine work, offering the advantage of being switched on and off easily and rapidly. Mechanically interlocked molecules, such as rotaxanes and catenanes, are suitable candidates. Crown ethers, cyclophanes, and calixarenes are representative families of the cyclic component. The design of even more sophisticated molecular-level machines should open the way to a variety of applications. We have selected three examples to illustrate this fascinating field.

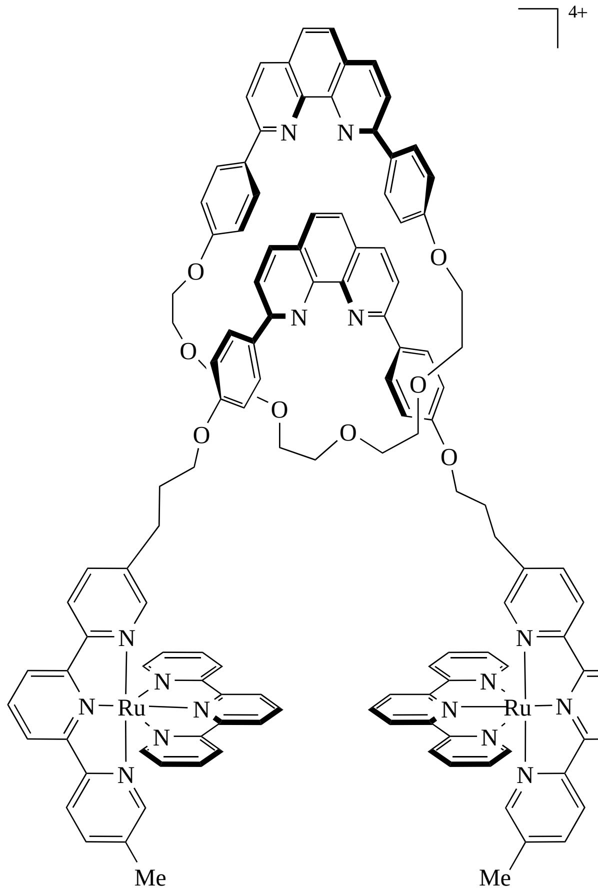
The design of a rotaxane is a synthetic challenge. One strategy is to combine a bifunctional ligand and two different metals, as demonstrated by Sauvage *et al.* The bifunctional ligand containing one dpp and two terpy units is treated with a preformed Cu(I)(dpp) macrocyclic complex to afford a prerotaxane complex with pendent terpyridines. The $[Ru(terpy)]^{2+}$ is then anchored to the pendent ligands. Selective removal of the cage Cu(I) template produces the rotaxane shown as structure (**22**).[61]

Another recent example also comes from Strasbourg’s group that prepared the first rotaxane with a $[Ru(diimine)_3]^{2+}$ core. The synthetic scheme consists of a ‘threading’ step followed by a stopping reaction: a ruthenium bisphenanthroline complex, acting as an axis, is threaded through a 35-membered ring macrocycle incorporating a bpy unit. The pseudorotaxane is shown in structure (**23**). The length of the threaded ring is too short and an isomer in which the axial ruthenium complex is attached in an exo fashion is also obtained (see structure (**24**)). A modified strategy has allowed the synthesis of a real rotaxane deriving from (**23**).[62]

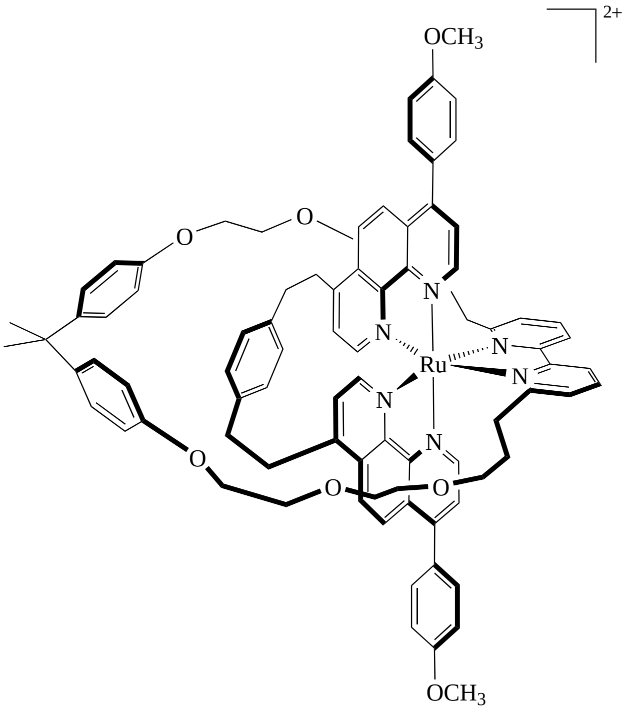
The third example comes from Stoddart’s and Balzani’s groups. They prepared a photochemically driven molecular-level abacus by a four-step process. The system is made up of a photoactive unit P (a $[Ru(bpy)_3]^{2+}$-type complex serving as a stopper), two different π-electron acceptors A_1 and A_2 playing the role of stations for a π-electron-donor ring R (the BPP34C10 macrocycle), a rigid spacer S, and a tetraarylmethane group as second stopper T. The [2]rotaxane is shown as structure (**25**). The photochemically driven switching of the ring R between stations A_1 and A_2 is achieved by a mechanism involving a sacrificial electron donor.[63,64]

5.2.3 Interaction with DNA

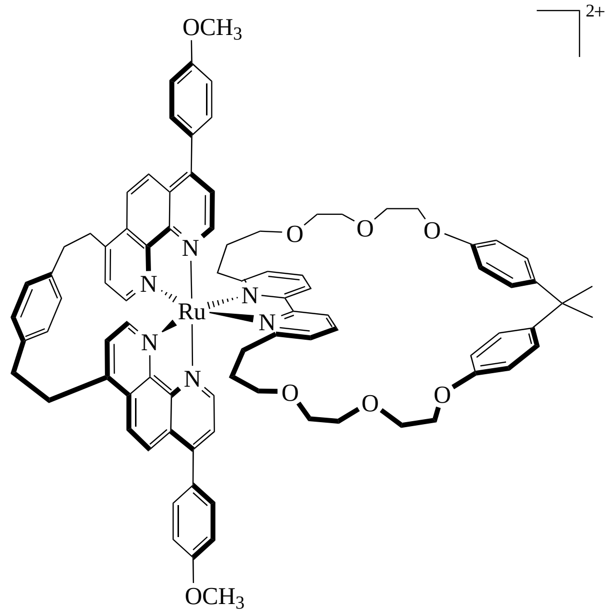
Transition metal complexes can help target DNA sites with specificity, probe DNA, and furnish highly



(**22**)



(**23**)

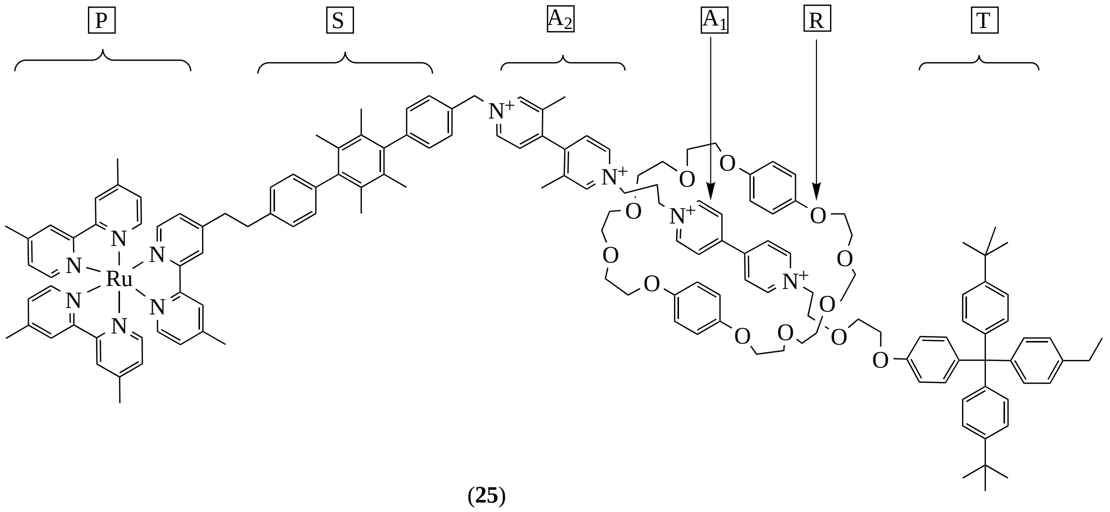


(**24**)

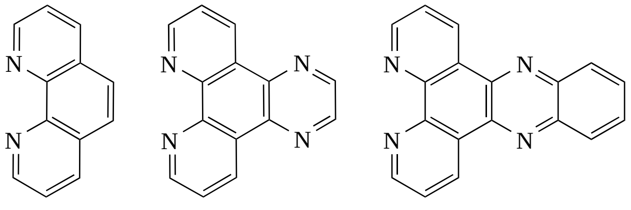
sensitive diagnostic agents. Metallointercalators contain planar aromatic heterocyclic groups able to insert and stack between the base pairs of double helical DNA (*see* ***Intercalation Chemistry*** and ***Nucleic Acid–Metal Ion Interactions***). Extensive work was performed by Barton *et al.*, and key features on recognition and reaction of metallointercalators with DNA have been reviewed in 1999.[65] One of the earliest examples concerned $[Ru(phen)_3]^{2+}$ existing, like any tris(diimine) ruthenium complex, as a mixture of enantiomers. In order to improve the complex binding affinities for DNA, the search for new ligands favoring intercalation was undertaken. Structures (**26–28**) are some typical examples. Minor changes in the ligand architecture and electronic structure can lead to profound influences on binding geometries.

The data concerning $[Ru(phen)_2(dppz)]^{2+}$ nicely illustrate the concept of 'molecular light switch' (dppz for **28**). When the complex is bound to DNA, the excited-state lifetime is approximately 200 ns, whereas without bounding, it is only 200 ps. This light-switch effect provides the basis for a valuable photophysical probe of nucleic acids. Luminescent characteristics of the complexes bound to DNA can also be used to illustrate the chiral discrimination associated with binding to the right-handed helix. Direct oxidation of DNA bases is also obtained by electrochemical activation of $[Ru(bpy)_3]^{2+}$. Recent developments concern the damage to DNA sites from a distance: site damage up to 200 Å away from the site of intercalation of the metal oxidant has been reported (*see* ***Long-range Electron Transfer in Biology***). One of the main challenges now is to use these molecules in vivo.[65,66]

The synthesis and properties of Ru(II) nucleosides and oligonucleotides have been recently reported using solid-phase



(**25**)



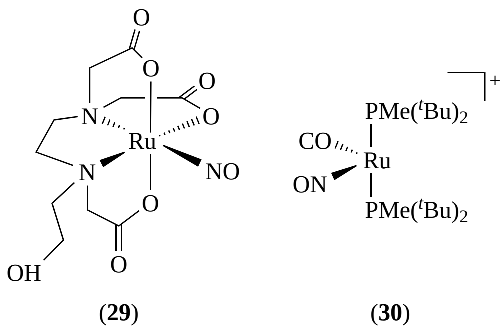
(**26**) (**27**) (**28**)

phosphoramidite chemistry. The first results offer interesting perspectives.[67]

5.3 Nitrosyl Ligands

The nitrosyl ligand can be combined with any other ligand (X, OH, H_2O, CO, PR_3, acac, NH_3, cyclam, *N*-aromatic heterocycles, NO_2, SO_2, DMSO, etc.) to form a wide range of nitrosyl ruthenium compounds (neutral, cationic, and anionic) with linear or bent NO ligands. This has been recently reviewed by Legzdins *et al.* and Housecroft.[3,68] The organometallic chemistry of nitrosyl ruthenium complexes is very rich, and various alkyl, acyl, alkene, carbene, and allyl complexes are known (*see* ***Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry*** and ***Ruthenium: Organometallic Chemistry***). The last decade has seen a renewed interest in understanding the chemistry of metal nitrosyl complexes, owing to the participation of NO in a wide range of physiological processes. The coordination and the release of NO by ruthenium dimethylsulfoxide[39] and ruthenium amine[69] complexes have been extensively investigated. Techniques such as X Ray, ^{15}N NMR, IR, EPR are very useful for determining the mode of bonding (i.e. N is deshielded by up to 450 ppm in bent form as compared to linear NO ligands). Spectroscopic methods associated with electrochemical techniques lead to a better understanding of the NO release mechanism. Studies of the reactivity of nitrosyl complexes are oriented toward reactions involving oxygen transfer to or from nitrosyl ligands and reduction of coordinated nitric oxide. For example, Shepherd *et al.* have studied, for the first time, a series of NO^+, $NO^{\cdot}$, and NO^- $[Ru(hedta)]^{n-}$ complexes by keeping a constant ligand–metal environment (see structure (**29**)). They found that the metal remained in the same oxidation state (II).[68]

The most common geometry displayed by ruthenium nitrosyl complexes is octahedral. However, some square-pyramidal and sawhorse geometries have been characterized. Chloride abstraction from $Ru(NO)Cl(CO)(PR_3)_2$ presenting a square-pyramidal geometry leads to $[Ru(NO)(CO)(PR_3)_2]^+$ (**30**) with a sawhorse structure, as a result of an intramolecular redox process. NO bending modification, from bent to linear, is concomitant with a formal decrease in the ruthenium oxidation state from +II to 0.[68] $[Ru(NO)_2Cl(PPh_3)_2]PF_6$ was the first complex containing the two modes of binding, that is, linear and bent (Ru–N–O axial, 138° Ru–N–O equat, 178° ν_{NO} linear, 1845 cm^{-1}; ν_{NO} bent, 1687 cm^{-1}).

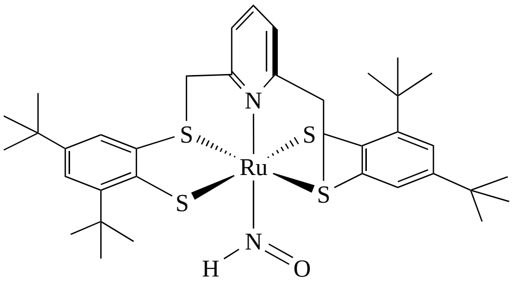


(**29**) (**30**)

5.4 Miscellaneous Nitrogen Ligands

Although they have not yet attracted as much attention as the nitrosyl complexes, a large number of the isoelectronic thionitrosyl ones have been prepared. The most representative family is $Ru(NS)Cl_3L_2$, where L is phosphines, arsines, or stilbines. A linear bonding mode is observed.

We have previously mentioned in Section 4.2 the chemistry developed by Sellmann *et al.*, by using tetradentate or pentadentate ‘S4’ ligands. The use of such a ligand in nitrosyl ruthenium chemistry allowed the first conversion of a nitrosyl complex into a ruthenium HNO complex (**31**) by addition of $NaBH_4$ to [Ru(NO)(py^{bu}S4)]Br. The formation and decomposition of HNO complexes is often invoked in many processes such as combustion of fuels, oxidation of N_2, reduction of HNO_2, and so on.[70]

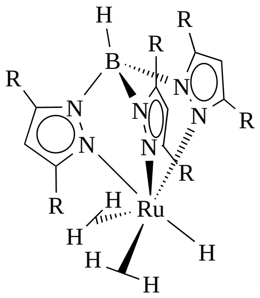


(**31**)

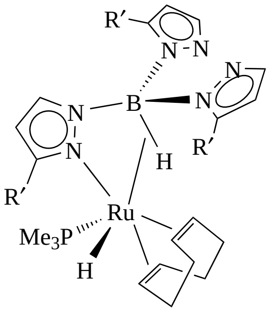
A large number of compounds with N-donor heterocyclic ligands have been prepared. Ruthenium complexes incorporating phthalocyanine or aza-macrocyclic ligands are known (*see* ***Macrocyclic Ligands***). In comparison to porphyrin chemistry, metallosalens and metallosalophens have received little attention, despite an easier synthetic access. A series of mononuclear and binuclear ruthenium derivatives with N_2O_2 Schiff base ligands are available. Some of them can act as supramolecular synthons.[71] α-Amino acids stabilize Ru(bpy)$_2$ moieties to produce the corresponding cations. The amino acid acts as a bidentate N,O-donor, leading to a five-membered metallocycle. A six-membered imine Ru(III) metallocycle was obtained by reduction of an oxime with $RuCl_2(PPh_3)_3$.[72]

The chemistry of ruthenium complexes incorporating edta, or related ligands such as pac, is generally based on substitution reactions of the water ligand present in the coordination sphere of the metal. The catalytic properties of these complexes in various organic transformations have been exploited, including electrocatalytic studies.[73]

The trispyrazolyl borate chemistry (*see* ***Boron–Nitrogen Compounds***) of ruthenium has prospered mainly during the last decade and is mostly restricted to ruthenium (II). The most common coordination mode of the tripyrazolylborates (Tp) ligand is the $\kappa^3(N,N',N'')$ mode (see structure (**32**)), but there are also some examples of the $\kappa^3(N,N',H)$ and κ^2(N,H) (see structure (**33**)) modes.[74,75] Two principal areas have been explored: the search for new polyhydrides and the organometallic reactivity of TpRu precursors. A rare example of a stable bis(dihydrogen) complex Tp*RuH(H_2)$_2$ (**32**) could be isolated. Its chemistry is dominated by the electrophilic character of the hydride and dihydrogen ligands, as illustrated by the rapid exchange in deuterated solvents or by the absence of protonation by acids. A series of substituted complexes [Tp*RuH(H_2)L] could be obtained (L = PCy_3, tetrahydrothiophene (THT), py, $NHEt_2$). (**32**) catalyzes the reduction of ketones in mild conditions either by H_2 or by H_2 transfer from alcohols.[74] Cationic Tp complexes of the general formula $[TpRu(H_2)LL']^+$ were obtained by protonation of the corresponding hydrides.[76] TpRuCl(cod) is a precursor of choice for inducing a rich organometallic reactivity, which has been reviewed. Tp complexes accommodating carbon single or double bonds have been obtained and various catalytic coupling reactions were performed.[77] Another precursor of choice is TpRuCl(PPh_3)$_2$, whose synthesis has been described in ‘Inorganic Synthesis’.[78] BpRuH(cod) is a valuable precursor for a series of bispyrazolyl BpRu complexes in which the Bp ligand is able to coordinate with the ruthenium using three different modes: $\kappa^3(N,N',$H), κ^2(N,H), or $\kappa^2(N,N')$.[79]



(**32**)

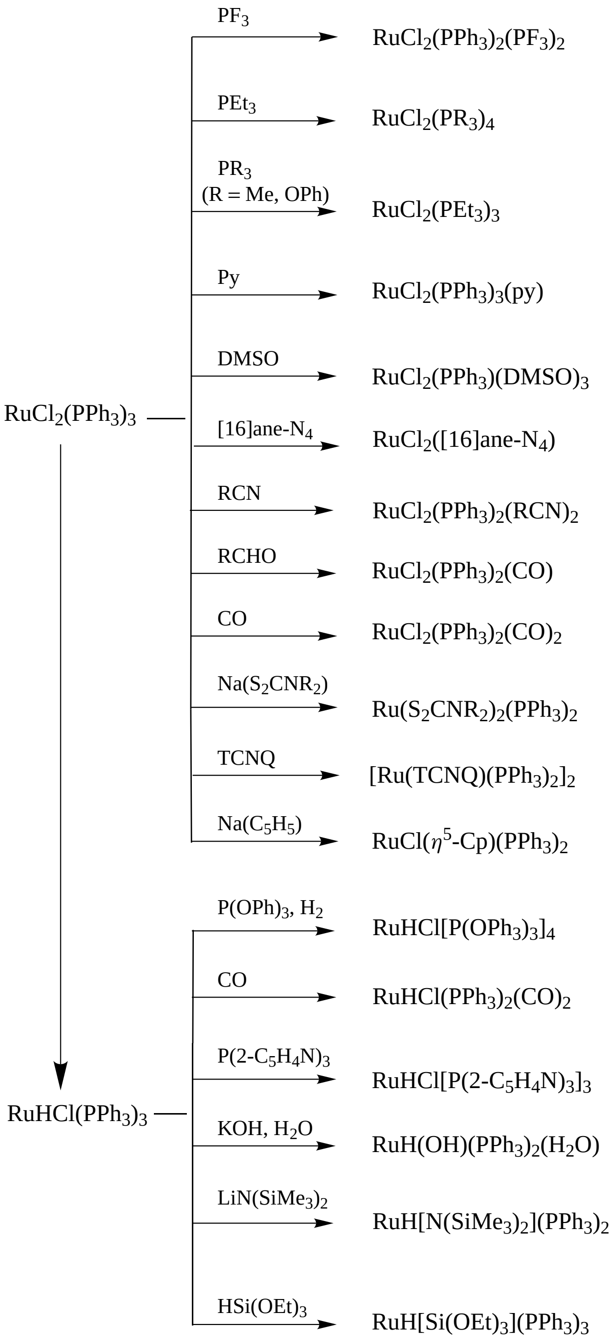


(**33**)

Nitriles, specifically acetonitrile, play an important role as solvents in inorganic chemistry. Nitriles are therefore found as co-ligands in various ruthenium complexes. [$RuCl_2(MeCN)_4$] is readily prepared by reduction of $RuCl_3 \cdot 3H_2O$ in acetonitrile using different methods, a convenient one being the use of dihydrogen and Adam’s catalyst (PtO_2). This complex is an excellent well-defined ruthenium(II) starting material.

6 RUTHENIUM COMPLEXES OF PHOSPHORUS-DONOR LIGANDS (*See P-donor Ligands*)

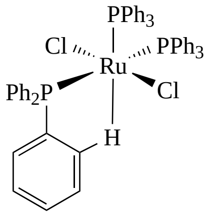
The chemistry of ruthenium (II) complexes incorporating P-donor ligands, particularly phosphines and diphosphines, is flourishing. This class of compounds has given rise to a versatile organometallic reactivity. They are also found in many catalytic cycles, but decoordination of the phosphine from the coordination sphere of the metal is often required for the catalysis to proceed.



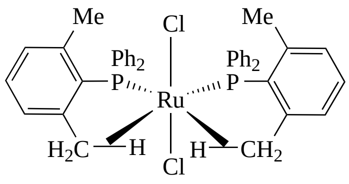
Scheme 3

6.1 Triphenylphosphine Derivatives

The most important phosphine derivative of ruthenium is $RuCl_2(PPh_3)_3$ (**34**), which is readily prepared from $RuCl_3 \cdot 3H_2O$ and PPh_3 in methanol. This procedure is, however, not generally used since large basic phosphines (P^iPr_3, PCy_3) lead to alcohol decarbonylation, whereas trichloro-bridged ruthenium(III) dimers are obtained by using small basic phosphines such as PMe_2Ph. $RuCl_2(PPh_3)_3$ (**34**) has found wide use as a precursor for other ruthenium(II) complexes and as a catalyst precursor for various reactions, essentially associated with hydrogenation or hydrogen transfer (*see* ***Hydrogenation & Isomerization of Alkenes***). $RuCl_2(PPh_3)_3$ can undergo three types of elementary reactions: (1) nucleophilic substitution of chloride groups, (2) addition of two-electron donor ligands, and (3) substitution of triphenylphosphine ligands and, usually, a combination of the three of them. Selected examples are shown in Scheme 3. The structure of (**34**) can be considered as octahedral, one hydrogen atom of a phenyl ring of a phosphine occupying the vacant coordination site. However, the Ru–H distance is long (2.59 Å), indicating a very weak agostic interaction. Additional structural information can be gained on (**34**) and related complexes by ^{31}P CP/MAS NMR spectroscopy.[80] It is remarkable that the use of ortho-methyl substituents has allowed the isolation of the first complex with two Ru···H–C agostic interactions $RuCl_2\{PPh_2(2,6\text{-}Me_2C_6H_3)\}_2$ (**35**), as demonstrated by NMR and X ray.[81] $RuCl_2(PPh_3)_3$ was one of the first transition metal complexes shown to activate dihydrogen heterolytically. The mechanism involves deprotonation from a transient unstable dihydrogen complex (*see* ***Dihydrogen Complexes & Related Sigma Complexes***). As shown in Scheme 3, some or all of the phosphine ligands can be substituted by various ligands. This includes diop, which leads to $[\{RuCl_2(diop)\}_2(\mu\text{-}diop)]$, and various bidentate phosphines (L_2), leading to complexes of the general formula $RuCl_2L_2(PPh_3)_2$ or $RuCl_2(L_2)_2$.



(**34**)



(**35**)

Phosphine substitution by water-soluble ligands has been used for the design of new catalysts that could be recovered from the aqueous phase. Extensive intra- and intermolecular hydrogen bonding are responsible of the high water solubility of a secondary–tertiary hydroxymethylphosphine complex, $[Ru\{P(CH_2OH)_3\}_2\{P(CH_2OH)_2H\}_2Cl_2]$.[82] The most important class of water-soluble ligands incorporates sodium sulfonate groups, with tppts being the preferred ligand. The complexes $RuCl_2(tppts)_3$, $[RuCl_2(tppts)_2]_2$, $RuHX(tppts)_3$ (X = Cl, I, OAc), and $RuH_2(tppts)_4$ can be prepared, and these display a reactivity in water similar to that of triphenylphosphine complexes in organic solvents, with, in some cases, an increase in activity and enhanced regioselectivity.[83]

The reaction of $RuCl_2(PPh_3)_3$ with diphenylcyclopropene led to the isolation of the alkylidene complex, whereas

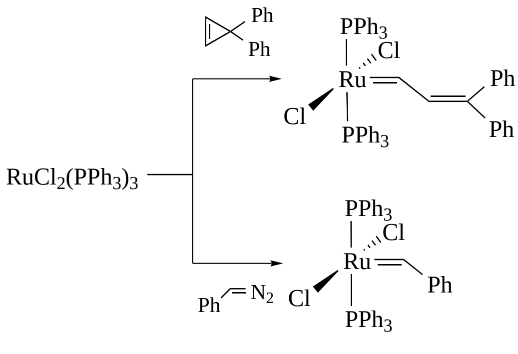
addition of an aryldiazoalkane allowed the formation of the benzylidene catalyst (see Scheme 4). These complexes are the first members of the $L_2X_2Ru{=}CHR$ family that has led to impressive developments, mainly by R. Grubbs' group, in the field of olefin metathesis (*see* ***Carbene Complexes***; ***Metathesis Polymerization Processes by Homogeneous Catalysis***; ***Organic Synthesis Using Metal-mediated Metathesis Reactions***, and ***Ruthenium: Organometallic Chemistry***).[84]

$RuCl_2(PPh_3)_3$ and $RuHCl(PPh_3)_3$ display a large catalytic activity. $RuHCl(PPh_3)_3$ is one of the most active alkene hydrogenation catalysts, while $RuCl_2(PPh_3)_3$ is of special use for hydrogen transfer reactions, in particular, the hydrogenation of bulky or functional compounds (equation 1) (*see* ***Hydrogenation & Isomerization of Alkenes***). $RuCl_2(PPh_3)_3$ is also a catalyst for hydrosilation (*see* ***Hydrosilation Catalysis***), although it is slow; chlorocarbon addition to alkenes; and even oxidation.

$$\mathrm{RR'CHOH + MeCH{=}CMeCO_2H} \xrightarrow{\mathrm{RuCl_2(PPh_3)_3}} \mathrm{RR'CO + MeCH_2CHMeCO_2H} \qquad (1)$$

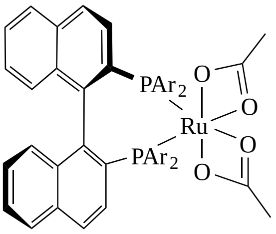
6.2 Diphosphine Complexes

A large number of bidentate phosphine ligands accommodate ruthenium in various oxidation states and in mono- or dinuclear structures. Some can be found in the same complex as both a monodentate and a bidentate ligand. The number of Ru(III) complexes is rather limited, but a series of $RuCl_3(P{-}P)L$ complexes have been prepared with P–P = dppb or diop. In the case of L = H_2O, the X-ray structure shows that the aqua ligand forms hydrogen bonds with two chloro ligands of a neighboring molecule (*see* ***Hydrogen Bonding & Dihydrogen Bonding***). The exchange coupling between the two Ru III centers is evidenced by ESR data.[85] The most important family is represented by complexes of the general formulation $RuX_2(L{-}L)_2$. Since the earlier work by Chatt *et al.*, a wide range of cis and trans $RuX_2(L{-}L)_2$ complexes have been synthesized by the reaction of $RuCl_3{\cdot}3H_2O$, $RuCl_2(PPh_3)_3$, $RuCl_3(py)_4$, or $K_2RuCl_5(OH_2)$ with L–L in alcoholic solution (L–L = dppm, dppe, dppp, dmpe, etc.). Elegant studies involving laser flash photolysis and matrix isolation show the importance of $RuH_2(L{-}L)_2$ complexes in C–H bond activation. Dihydrogen loss and formation of square-planar $Ru(L{-}L)_2$ intermediates are induced by photolysis (*see* ***Photochemistry of Transition Metal Complexes*** and ***Alkane Carbon–Hydrogen Bond Activation***).[86] A few ruthenium complexes incorporating trans-spanning diphosphine ligands have been synthesized. However, the advantages of using such peculiar ligands remain to be demonstrated.[87]

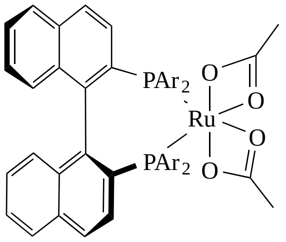


Scheme 4

The most significant industrial applications come from Noyori *et al.*, who have described ruthenium complexes bearing chiral BINAP ligands (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***).[88,89] Noyori shared the Nobel Prize for chemistry in 2001 with Knowles and Sharpless for his achievements in asymmetric catalysis. BINAP–Ru dihalide catalysts have a very wide scope in industrial applications. The first key complexes, (**36**) and (**37**), were obtained in good yield by the reaction of $[RuCl_2(cod)]_n$ with (*S*)-or (*R*)-BINAP and triethylamine at 110 °C, followed by final treatment with sodium acetate in *t*-butyl alcohol at 80 °C. The crystal structure of $[Ru(OCO\text{-}^t Bu)_2\{(S)\text{-BINAP}\}]$ indicates a C2 chirality. They are very effective catalysts in the hydrogenation of alkenes or ketones (*see* ***Hydrogenation & Isomerization of Alkenes***). For example, the synthesis of the anti-inflammatory drug Naproxen is achieved quantitatively in 97% optical yield.

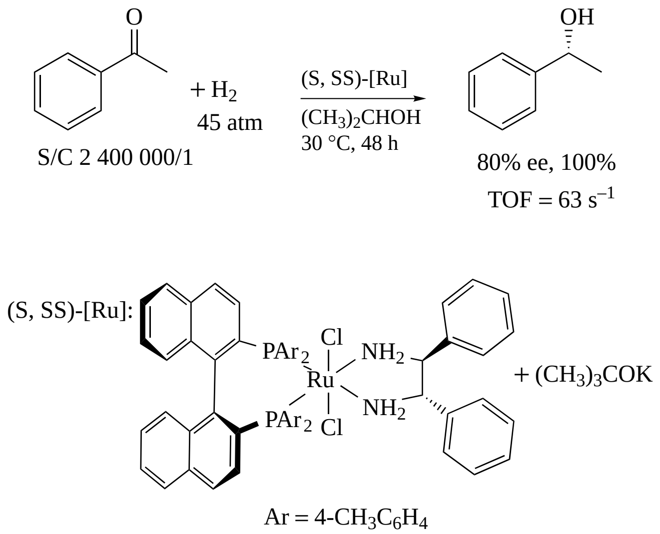


(**36**) (*R*)-BINAP Ru^{II} complex

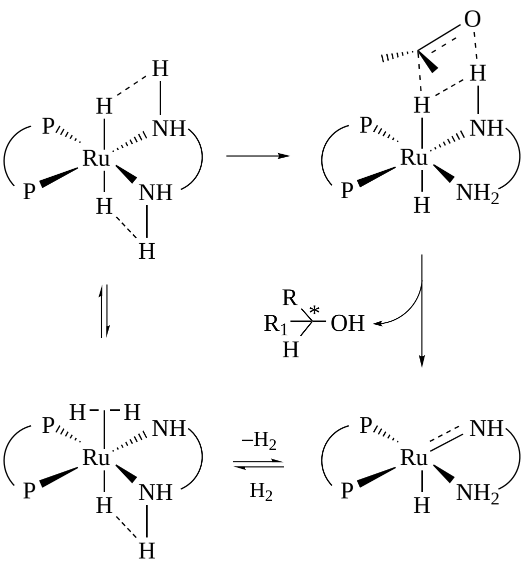


(**37**) (*S*)-BINAP Ru^{II} complex

These Ru-catalysts provide a practical way to prepare an intermediate for prostaglandin synthesis. Antibacterials and carbapenem antibiotics are now produced industrially. New achievements have been obtained with the introduction of diamine ligands, leading to the asymmetric synthesis of various pharmaceutical compounds. The catalyst mixture, as shown in Scheme 5, consists of a complex of the form $RuCl_2$(diamine)(diphosphine) with an alkoxide base, dihydrogen, and ketone in 2-propanol (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***).[88,89] An in-depth mechanistic study was performed by Morris' group, leading to a better understanding of the catalytic cycle as depicted



Scheme 5



Scheme 6

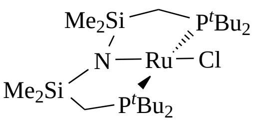
in Scheme 6.[90] The use of the water-soluble dibenzofuran-based diphosphine ligands (BIFAPS) leads to high ee's in Ru-catalyzed hydrogenations (similar to BINAP).[91]

6.3 Polydentate Phosphines, Pincer Ligands, Phosphorus Heterocycles, and Phosphorus-based Hemilabile Ligands

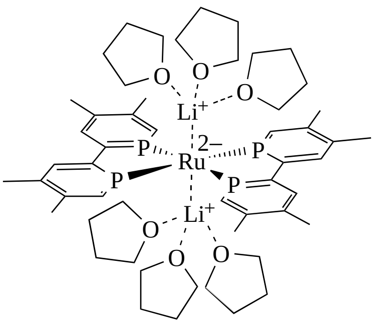
The use of polydentate phosphines has received a renewed interest, with the search for new families of polyhydrides or molecular dihydrogen complexes (*see* ***Dihydrogen Complexes & Related Sigma Complexes***). For example, PP_3RuCl_2 ($PP_3 = P(CH_2CH_2PPh_2)_3$) was used as an entry to mono- and polyhydride ruthenium(II) complexes. The Ru (II) complex [(triphos)$RuH(BH_4)$] with the tripodal ligand triphos reacts with KO^tBu to form the ruthenate complex [K(triphos)RuH_3]. The compound catalyzes benzothiophene hydrogenolysis into 2-ethylthiophenol.[92] Various ruthenium complexes containing a triphosphine ligand deriving from $PPh(CH_2CH_2PR_2)_2$ and $PPh(CH_2CH_2CH_2PR_2)_2$ have been prepared, including chiral ligands. The ability of the polydentate phosphine to control the stereochemistry and coordination number of the resulting complexes, and the presence of hydride and/or dihydrogen ligands provide access to unusual chemical (homogeneous catalysis) and structural properties.[93] A series of complexes incorporating a rigid allene-bridged polyphosphine exhibit room-temperature luminescence.[94]

During the past decade, the chemistry of complexes incorporating phosphine-based pincer ligands has rapidly developed. Most of these ligands are cyclometalated and thus will not be reviewed in this chapter. However, various complexes incorporating PNP ligands have been prepared and show interesting spectroscopic and catalytic properties (*see* ***Phosphorus–Nitrogen Compounds***).[3,95,96] The reactivity of the ligand $(R_2PCH_2SiMe_2)_2N$– on ruthenium has now appeared. The most striking result is the characterization of a four-coordinate, planar Ru(II) displaying a triplet state as a consequence of the low-coordination number and the lack of agostic interactions (see structure (**38**)).[97]

2,2′-Biphosphinines (tmbp) are analogous to bipyridines, albeit containing two phosphorus atoms (*see* ***Phosphorus: Organophosphorus Chemistry***). These ligands behave as excellent π acceptors, and chloro ruthenium complexes incorporating one or two tmbp could be isolated. The most significant result was obtained using the reduced ligand, and stabilization of a dianionic Ru complex was achieved. The complex $[Ru(tmbp)_2][Li(THF)_3]_2$ (**39**) presents a square-planar geometry with electrostatic interaction between Ru and Li centers.[98]



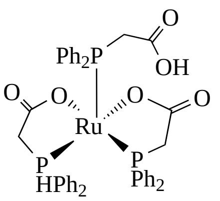
(**38**)



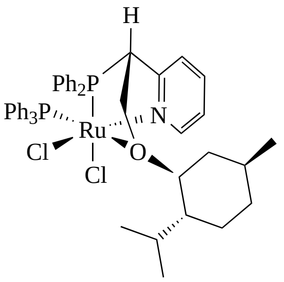
(**39**)

The synthesis of hemilabile ligands for the design of new catalysts is a very active area of research. Hemilabile ligands act as chelating ligands with one strongly and one weakly bonding group (see Structures (**40**) and (**41**)). The

weakly bonding group can be easily displaced, offering new opportunities for catalytic applications. In this context, the chemistry of mixed phosphorus chelating ligands has been particularly examined (*see* ***Mixed Donor Ligands***). The most common type concerns the phosphorus–oxygen association, while systems with phosphorus–sulfur or phosphorus–nitrogen ligands are more limited. A common reaction involves PPh_3 substitution by the hemilabile ligand L from $RuCl_2(PPh_3)_3$ or from $RuHCl(PPh_3)_3$.[99]



(**40**)

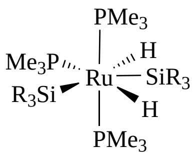


(**41**)

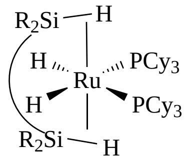
7 RUTHENIUM COMPLEXES OF GROUP-14 LIGANDS

Carbonyl complexes and complexes incorporating isocyanides are generally considered to be organometallic and are not reviewed in this article (*see* ***Ruthenium: Organometallic Chemistry*** and ***Carbonyl Complexes of the Transition Metals***). In contrast, cyanides are regarded as inorganic complexes (*see* ***Cyanide Complexes of the Transition Metals***). $K_4[Ru(CN)_6]$ was first prepared in 1896 through the action of KCN on $K_2[RuO_4]$ or $RuCl_3 \cdot xH_2O$. Hexacyanide is found as a tetraanion with various cations or even as the tetracid. This complex undergoes a variety of substitution reactions and gives rise to cyano-bridged polynuclear compounds, either homo- or heteronuclear. Among the substitution reactions, a lot of interest has been devoted to the photophysical properties of mixed cyanide/diimine complexes.[100]

Silane activation by ruthenium complexes has been a field of intense activity over the past decade. This was made possible thanks, in particular, to the fantastic progress achieved in NMR and X-ray techniques, as well as in DFT calculations. A number of ruthenium complexes incorporating a silicon-attached ligand (*see* ***Silicon: Inorganic Chemistry***) are now available, with several variations of interactions between the silane and the metal.[101] Full oxidative addition can be observed leading to Si–H bond breaking and formation of the corresponding silyl or bis(silyl) complexes (**42**).[102] Arrested addition leads to the isolation of σ-silane complexes, analogous to the σ-dihydrogen complexes (*see* ***Dihydrogen Complexes & Related Sigma Complexes***).[103,104] Bridging and terminal SiR_2 groups (silylene complexes with Ru=Si bonds) can also be isolated.[101] The factors that promote the formation of the different structures are multiple, and the substituents on silicon and the electron density on ruthenium play a crucial role. Ruthenium complexes incorporating one, and even two, σ-Si–H bonds are now available, as shown by the general structure $[RuH_2\{(\eta^2\text{-}HSiR_2)_2X\}(PCy_3)_2]$ (**43**).[104] It is important to note that in these bis(silane) complexes, the establishment of secondary interactions between the silicon atoms and the classical hydrides stabilize the complexes and promote the unusual cis position of the bulky phosphines.[105]



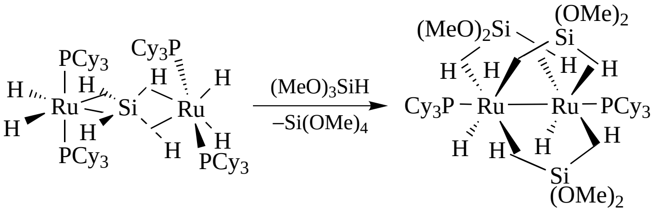
(**42**)



(**43**)

Unusual redistribution at silicon is observed by adding secondary silanes to the bis(dihydrogen) complex $RuH_2(H_2)_2(PCy_3)_2$ (see Section 8).[106] The complex $[RuH_2(PR_3)_2]_2(\mu\text{-}\eta^2:\eta^2:\eta^2:\eta^2\text{-}SiH_4)$ (**44**) (R = Cy, ^{i}Pr) is isolated with the SiH_4 ligand trapped in between the two metals. The silane is coordinated to the metals via four σ-Si–H bonds. Each interaction involves σ-donation to a ruthenium and back-bonding from the other ruthenium. A second redistribution process is observed after addition of an excess of $HSi(OMe)_3$ to (**44**). The dinuclear complex (**45**) is isolated, and the data show that the frontiers between true σ-Ru–H–Si interactions and more delocalized systems are not clear-cut (see Scheme 7).[106] Silyl and σ-silane complexes find important applications as catalyst precursors for Si–C coupling in hydrosilylation, dehydrogenative silylation, and dehydrocoupling for the formation of vinyl silanes and oligomeric carbosilanes, respectively (*see* ***Hydrosilation Catalysis***; ***Carbon–Carbon & Carbon–Heteroatom Activation***, and ***Polysiloxanes & Polysilanes***).

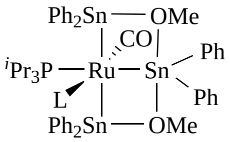
In comparison to Si, much less work has been published concerning Ge or Sn (*see* ***Germanium: Organometallic Chemistry*** and ***Tin: Organometallic Chemistry***). The complex $Ru(GeMe_3)_2(PMe_3)_4$ is an effective catalyst for the production



(**44**) (**45**)

Scheme 7

of high molecular weight polygermanes from $HGeMe_3$.[107] A number of complexes incorporating the $RuSnR_3$ moiety have been prepared. A rare example of a complex (**46**) containing a four-electron tridentate tin donor ligand was isolated,[108] and more recently, the complex $Ru(SnPh_3)_2(P_2C_2Ph_2)_2$ with two $SnPh_3$ units and a bis(diphosphabutadiene) ligand was reported.[109]



(**46**)

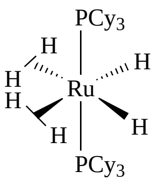
8 RUTHENIUM HYDRIDE COMPLEXES (*See Hydride Complexes of the Transition Metals* and *Dihydrogen Complexes & Related Sigma Complexes*)

The rich chemistry of ruthenium hydride developed rapidly after the preparation of $RuHCl(PPh_3)_3$.[1] The polyhydrides $RuH_2(PPh_3)_4$ and $RuH_4(PPh_3)_3$ were synthesized by reduction of $RuCl_2(PPh_3)_3$ with hydride donor reagents such as $NaBH_4$. The dihydride $RuH_2(PPh_3)_4$ can be used as an interesting alternative to conventional Lewis acid and base catalysts, as proven by its specific activity for nitrile activation.[110] Numerous hydrido derivatives containing other anionic functional ligands were prepared, either by anionic substitution of chloride on $RuHCl(PPh_3)_3$ or by reaction of the polyhydrides with acidic compounds (equation 2). The synthesis of hydride complexes, using $(BH_4)^-$ or $(AlH_4)^-$, may involve the formation of $Ru{-}BH_4$ or $Ru{-}AlH_4$ derivatives with one or two bridging hydrides. The method of preparation by reduction of chloride precursors has allowed the synthesis of derivatives of alkyl phosphines with a small cone angle, for example, $RuH_2(PBu_3)_4$. However, for bulky alkylphosphine derivatives, the preparation involves hydrogenation of the ruthenium(0) precursor $Ru(C_8H_{10})(C_8H_{12})$ (see equation 3).

$$RuH_2(L)(PPh_3)_3 + HX \longrightarrow RuHX(PPh_3)_3 + L + H_2 \qquad (2)$$

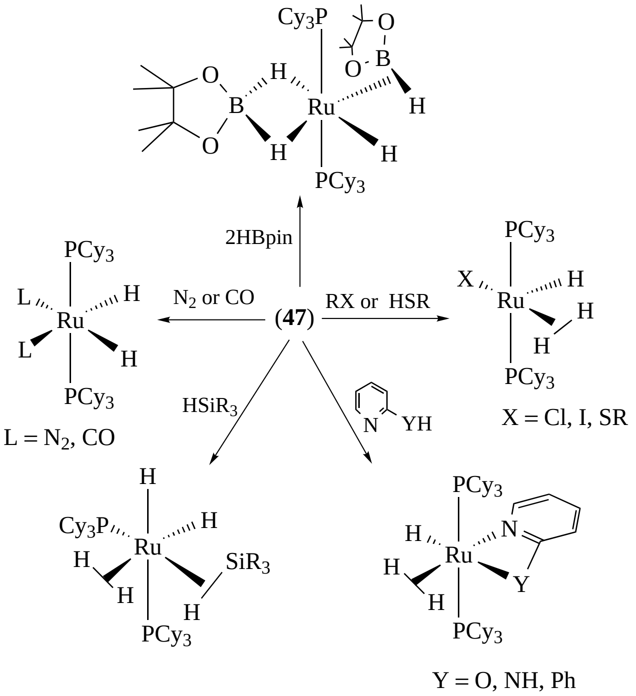
$$X = OCOR, SH, SR, Cl, etc;\ L = H_2, N_2, PPh_3$$

The discovery by Kubas of the coordination of dihydrogen without dissociation gave a new impetus to ruthenium hydride chemistry (*see* ***Dihydrogen Complexes & Related Sigma Complexes***).[111] As mentioned already in Section 7, considerable progress in NMR and X-ray techniques have allowed better characterization of many compounds and, in particular, better discrimination between a dihydride or a dihydrogen formulation. In addition, many more theoretical studies are now performed on polyhydrides and σ-complexes. Key information is thus gained, not only on the structures and energetics but also on the dynamic processes that are common in these systems.[105,112] $RuH_4(PPh_3)_3$ was mentioned as early as 1976 by Ashworth and Singleton as possibly containing undissociated dihydrogen. This was confirmed 10 years later by Crabtree and Hamilton who reformulated it as $RuH_2(H_2)(PPh_3)_3$. Similarly, $RuH_6(PCy_3)_2$ was reformulated as $RuH_2(H_2)_2(PCy_3)_2$ (**47**), a rare example of a thermally stable bis-dihydrogen complex (see equation 3). This complex displays a versatile reactivity, in some cases, similar to $RuH_2(H_2)(PPh_3)_3$ and $RuH_2(N_2)(PPh_3)_3$ (see Scheme 8). In particular, it reacts with halocarbons and thiols to give the corresponding 16-electron dihydrogen complexes, $RuH(H_2)X(PCy_3)_2$ (X = Cl, I, SR). The chemistry of (**47**) was reviewed in 1998 before the report of its X-ray crystal structure in 2000.[74,113] The reactivity of (**47**) with silanes leading to the formation of new σ-silane complexes and to interesting catalytic applications has been briefly described in Section 7.[103–106] It was also possible to activate various boranes, both stoichiometrically and catalytically (*see* ***Boron Hydrides***; ***Boron: Organoboranes***, and ***Hydroboration Catalysis***).[114,115] Remarkably, a complex incorporating two boron-attached ligands coordinated with two different bonding modes, $[RuH\{(\mu\text{-}H)_2Bpin\}(\sigma\text{-}HBpin)(PCy_3)_2]$, was isolated and proved to be an active species for catalytic formation of vinyl boranes or for selective hydroboration of olefins.[114] (**47**) is also a catalyst precursor for the hydrogenation of S- and N-heteroaromatic substrates (*see* ***Hydrodesulfurization & Hydrodenitrogenation***).[31,116] The presence of labile dihydrogen ligands is the key factor in the ability of (**47**) to catalyze, at room temperature, the Murai reaction (C–C bond coupling of an olefin with a functionalized aromatic compound. *See* ***Carbon–Carbon & Carbon–Heteroatom Activation*** and ***Ruthenium: Organometallic Chemistry***). In the case of acetophenone, the resulting orthometalated complex $RuH(H_2)(o\text{-}C_6H_4C(O)Me)(PCy_3)_2$ displays remarkable spectroscopic properties as exchange couplings between the hydride and the coordinated dihydrogen molecule can be detected by NMR.[117]



(**47**)

Ruthenium polyhydride complexes containing monophosphaferrocenes are now available.[118] In contrast to Cp ruthenium chemistry, the use of a trispyrazolyborate ligand favors the formation of dihydrogen structures: the chemistry of Tp

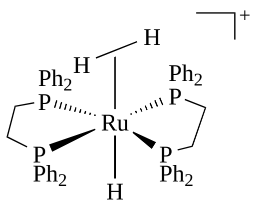


Scheme 8

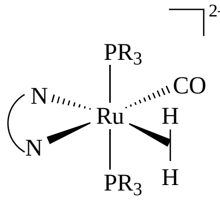
and Bp ruthenium complexes has been briefly described in Section 5.4.[74–79]

Anionic polyhydride derivatives were obtained by reaction of potassium naphthalenide with $RuHCl(PPh_3)_3$ in THF. Addition of H_2 yields the trihydride $[RuH_3(PPh_3)_3]^-$, whereas the intermediacy of a diphenylbutadiene derivative is necessary to reach the pentahydride $[RuH_5(PPh_3)_2]^-$ after elimination of one phosphine ligand. A one-pot reaction was obtained by using a mixture of $RuCl_3$/2.5 P^iPr_3, KH, and a crown ether under a dihydrogen atmosphere. Interion proton hydride NH···HRu interactions exist in the salts $[K(Q)][RuH_5(P^iPr_3)_2]$ when Q is 1-aza-18-crown-6 or 1,10-diaza-18-crown-6.[119]

Cationic derivatives are prepared by protonation (which can lead to dihydrogen evolution) or by halide abstraction in the presence of dihydrogen. The cations $[RuH_3L_4]^+$ and $[RuH_5L_3]^+$ can be prepared by one of these methods. Most of the $[RuH_3L_4]^+$ complexes have now been reformulated as $[RuH(H_2)L_4]^+$. An important class of hydride derivatives contains chelating phosphorus-donor groups. Thus, the neutral $RuHX(L_2)_2$ (X = H, Cl; L_2 = dppm, dppe, dcype, etc.) can adopt a cis or a trans configuration, but the corresponding cationic dihydrogen species ($[RuX(H_2)(L_2)_2]^+$) all display a trans configuration. These compounds were extensively studied, and $[RuH(H_2)(dppe)_2]^+$ (**48**) is one of the few complexes characterized by a neutron diffraction structure.[120] Dicationic complexes, as shown in structure (**49**), can also be prepared, and they display even more acidic properties than many cationic complexes.[121] The use of an acidic dihydrogen ruthenium complex as catalyst results in heterolytic cleavage of H_2 and, for example, in catalytic hydrogenolysis of trimethylsilyl enol ethers.[122] A review was published in 1998 on the properties of dihydrogen complexes as homogeneous reduction catalysts (*see* ***Hydrogenation & Isomerization of Alkenes***).[123] NMR methods play a major role in the characterization of polyhydrides (J_{H-D}, T_1; rate of intramolecular exchange; rate of exchange with other incoming ligands). The parahydrogen-induced polarization (PHIP) method is a relatively new NMR technique that can also bring valuable information on the detection of intermediates. It can be used as a mechanistic probe in highly fluxional systems, as was illustrated in ruthenium hydride carbonyl systems.[124]



(**48**)



(**49**)

Unusual ruthenium porphyrin dihydrogen complexes were also obtained.[111] Dinuclear hydride or dihydrogen complexes generally result from the dimerization of hydride and/or chloride precursors. A number of bioctahedral complexes of central core $Ru(\mu\text{-}X)_3Ru$ have thus been prepared. The properties of the dinuclear complex $[RuHCl(P^iPr_3)_2]_2$ have been extensively studied by Caulton's group, and a rich organometallic chemistry has been reported.[125] Ruthenium hydride complexes have been used to prepare heterobimetallic complexes. Three strategies have been employed: (1) use of a ruthenium anion and reaction with transition metal chloride derivative or vice versa, (2) addition of Lewis acidic cations to ruthenium hydrides, and (3) use of bridging ligands. The mixture of *cis*- and *trans*-$RuH_2(dppm)_2$ is, for example, able to react with a variety of metallic fragments to yield mono- or bis-dppm-bridged hydrido species. An unusual example of a ruthenium–iridium complex, a mixed hydrido-alkoxide bridge, was reported.[126]

Hydrogen bonding is a well-known phenomenon that has led to major developments during the last decade in the field of polyhydrides. The formation of the so-called dihydrogen bond (M–H···H–X) can occur intermolecularly between a hydride and a weak acid (see equation 4) or intramolecularly between a hydride and a pendant ligand with an NH or OH group. This type of interaction is very important as it may control reactivity and selectivity in solution. A few examples have appeared in ruthenium chemistry.[127,128]

$$\text{Ru–H} + \text{H–X} \longrightarrow \text{Ru–H}\cdots\text{H–X} \longrightarrow \left[\text{Ru}(\text{H–H})\right]^+ X^- \qquad (4)$$

9 POLYNUCLEAR COMPLEXES OF RUTHENIUM

The chemistry of ruthenium carbonyl clusters is presented in ***Ruthenium: Organometallic Chemistry*** and ***Polynuclear Organometallic Cluster Complexes***, so the subject of metal particles deposited on supports will not be described in this article (*see* ***Ruthenium: Organometallic Chemistry*** and ***Polynuclear Organometallic Cluster Complexes***). The field concerning giant clusters and the molecular chemistry of metal particles in organic solutions has grown rapidly during the last decade. The ruthenium complex $Ru(C_8H_{10})(C_8H_{12})$, as shown by Chaudret *et al*., has been found to be a useful precursor for the controlled synthesis of well-dispersed nanoparticles stabilized by polymers or various ligands. Recent developments have shown that some of these compounds may be viewed as large inorganic clusters composed of a core of a few nanometers adopting the hcp structure of bulk ruthenium and a surface accommodating both ancillary ligands such as amines and thiols as well as active ligands such as hydrides. These species are active catalysts, in particular, for arene hydrogenation.[129,130] It is, in general, still difficult to distinguish between homogeneous and colloidal catalysis in such systems, although significant progress has recently been made, in particular, by Finke.[131]

acac = Acetylacetonate; allyl = η^3-C_3H_5, η^3-C_3R_5; arene = η^6-C_6R_6; bpy = 2,2′-bipyridine; cod = 1,5-cyclooctadiene; cot = Cyclooctatetraene; Cp = Cyclopentadiene (C_5H_5); Cp* = Pentamethylcyclopentadiene (C_5Me_5); dmbpy = 4,4′-dimethyl-2,2′-bipyridine; dppm = (diphenylphospino) methane; *p*-cymene = 1-isopropyl-4-methyl-C_6H_4; dad = Diazadienes, RN=CR′–CR′=NR; quin = 8-quinolate; nbd = Norbornadiene; OTf = Trifluoromethanesulfonate OTs = Tosylate; PPN = $(Ph_3P)_2N$; $RuCl_3$ = $RuCl_3{\cdot}3H_2O$ (approximate); tmbpy = 4,4′,5,5′-tetramethyl-2,2′-bipyridine.

1 INTRODUCTION

Unlike iron, whose organometallic chemistry dates from the end of the nineteenth century (*see* ***Iron: Organometallic Chemistry***), that of its second-row transition metal congener ruthenium had to wait for the discovery of the sandwich compound ferrocene in 1951 (*see Ferrocene*). The impetus from that breakthrough stimulated all areas of organometallic research, and ruthenocene was reported the very next year.[1] More so than in its coordination chemistry (*see* ***Ruthenium: Inorganic & Coordination Chemistry***), it has become apparent that the organometallic chemistry of ruthenium has many features in common both with iron and with its heavier analog osmium (*see* ***Osmium: Organometallic Chemistry***). Thus, many complex types and reactions that are discussed below have counterparts with either iron or osmium or both. As is the case in all transition element groups, there is a tendency for substitution or addition (*see Oxidative Addition*) and elimination (*see Reductive Elimination*) reactions to be slower when proceeding down a group in the periodic table. The middle elements, in particular ruthenium and rhodium, profit from this trend, for example, hydride (*see Hydrides*) and alkyl bonds (*see Alkyl Complexes*) are generally more stable and consequently more abundant in ruthenium species than in analogous structures of iron. Conversely, rigid structures have been found in osmium complexes in cases where the ruthenium analogs are either unstable or highly fluxional (*see Fluxional Molecule*). Thus, ruthenium complexes in many instances are more stable than those of iron, yet are more mobile than the osmium equivalents.

Whereas the chemistry of the metallocenes (*see Metallocene Complexes*) is rather similar for the three elements, differences are obvious in their carbonyl chemistries (*see Carbonyl Compound*), which for ruthenium and osmium are based principally on the dodecacarbonyl $M_3(CO)_{12}$. The pentacarbonyl, a basic material for the carbonyl chemistry of iron, is readily available from daylight photolysis of $Ru_3(CO)_{12}$ (**1**) under CO in solution, but is far less common. Furthermore, carbonyl halides have played a role in the carbonyl chemistry of ruthenium, but analogous compounds of iron or even osmium are less frequently used. Among the iron group metals, cluster carbonyls that incorporate additional main group atoms, mostly hydrogen, carbon, and nitrogen, are broadly similar, although osmium shows the greatest diversity of compounds.

Owing to its higher position in the spectrochemical series (*see Spectrochemical Series*), ruthenium responds more strongly to changes in ligand field (*see Ligand Field Theory*) than iron. Consequently, the higher oxidation states Ru^{III} and Ru^{IV}, which are abundant in the coordination chemistry of the element, become strongly oxidizing in the presence of acceptor ligands, and are transformed into Ru^{II} (or even Ru^{I} or Ru^{0}) by mild reducing agents, such as alcohols. This property has been exploited in the synthesis of carbocyclic and alkenic π-complexes (*see Alkene Complexes*) of ruthenium where the halide $RuCl_3$ is treated with ligand or ligand precursors in alcohols with or without additional reducing agents. Hydrogenation/dehydrogenation reactions (*see Hydrogenation*) of poly- and cycloalkenic ligands are frequently observed in these reactions under mild conditions; a stable 18 valence electron coordination environment (*see Eighteen Electron Compounds*) is thereby produced.

The common starting material for nearly all preparations of ruthenium is a hydrated chloride ($RuCl_3$) of approximate composition $RuCl_3{\cdot}3H_2O$, containing 36–42% Ru. Although the material from most sources is not very pure, for example, containing nitrosyls from prior contact with nitric acid, the presence of impurities in most cases is not a serious problem and the yields of conversion of '$RuCl_3{\cdot}3H_2O$' can be nearly quantitative based on metal content.

The following article is organized according to basic complex types, where the preparation, structures, and properties of these complexes are described in some detail. Examples of other types of complexes derived from these most basic examples are discussed. Early reviews of the organometallic chemistry of ruthenium can be found in the comprehensive treatise by Seddon and Seddon,[2] and in the articles by Bruce, Bennett, and Matheson in *Comprehensive Organometallic Chemistry I*;[3] the latter have been updated.[4] A review of the 'Tentacular Chemistry of $[Cp^*Ru(OMe)]_2$' has also been published.[5]

2 CARBONYLS

2.1 General Characteristics

For a metal with eight valence electrons, 'electron precise' carbonyl structures (*see Electron Precise Compound*) are $M(CO)_5$ and $[M(CO)_4]_3$, which are known for all three metals of the iron group, albeit with quite different properties for the different metals. The next member, $[M(CO)_3]_6$, is not formed since a four-connected vertex requires more metal–metal bonding orbitals than can be arranged on the surface of a sphere. Bonding orbitals directed towards the inside of the cluster, however, form MOs that will accommodate more electrons than would be predicted by an 18 valence electron count for each metal (*see Eighteen Electron Compounds*), that is, 86 instead of 84 for a six-vertex *closo* cluster (*see Closo Cluster*). This situation is realized in the iron group by the anions $[M_6(CO)_{18}]^{2-}$, M = Fe, Ru, Os (isolectronic to $M_6(CO)_{16}$, M = Co, Rh, Ir).

An even-electron fragment, such as $M(CO)_n$ (M = Fe, Ru, Os), can form a three-connected vertex by incorporation of a one-electron ligand, such as hydrogen. Thus, the analog to the tetracarbonyls of the cobalt group $[M(CO)_3]_4$ in the iron group is represented by the $MH(CO)_3$ moiety, as in $[HRu(CO)_3]_4$, or as in the equivalence of two H or one H^- for one CO, giving $H_2Ru_4(CO)_{13}$ or $[HRu_3(CO)_{11}]^-$. The equivalence of one CO to two electrons generates species such as $M(CO)_4{}^{2-}$ or $[M_6(CO)_{18-n}]^{2(n+1)-}$ with $n = 0$, 1, and 2.
